Preface

Welcome to the fifth edition of *Language Intervention Strategies in Aphasia and Related Neurogenic Communication Disorders*. The first edition of this book was published in 1981, the second in 1986, the third in 1994, and the fourth in 2001. All four editions grew out of the realization that the discussion of aphasia therapy had become a major theme in clinical aphasiology literature but that the specification of numerous types or strategies of intervention was of fairly recent origin.

All five texts grew out of the belief that there continues to be a substantial number of approaches applicable to the remediation of language-disordered adults that should be brought together and shared. The five texts are also grounded in the realization that a variety of different therapeutic principles and approaches need to be articulated, assembled, applied, and critiqued in order to strengthen the quality of future work in our field.

The major purpose of the fifth edition is to bring together significant thoughts on intervention and to stimulate further developments in the remediation of adults with aphasia. It should be noted that some of the models presented in this text still need to be supported by controlled studies and long-term clinical application.

Each edition of this text is increasingly informed by the view that language is cognitively based (Chapey, 2008) and socially constructed by participants communicating with someone, about something, for some reason; and that judgments of competence/incompetence involve evaluations about issues such as role, context, intent, timing, volume, movements, intonation, gender, age, taste, group membership, etc. (Bloom and Lahey, 1988; Kovarsky, Duchan, and Maxwell, 1999). In addition, the **dual goals of communication**—that of **transaction** or the exchange of information and that of **interaction** or the fulfillment of social needs (such as affiliation with other people, assertion of individuality, demonstration of competence, gaining and maintaining membership in social circles, etc. (Simmons-Mackie, 2008) are increasingly reflected in the texts.

Further, the texts increasingly reflect the fact that we have a responsibility to individuals with aphasia and their significant others to foster their membership in a communicating society and their participation in personally relevant activities (Simmons-Mackie, 2008). The texts also emphasize the belief that **two of the most important factors in positive**

human health for all individuals are living a life of purpose and quality connection to others.

The fifth edition contains 36 chapters organized into five sections. **Section I** covers basic considerations such as definitions of aphasia and stroke, incidence of stroke, the neural basis of language disorders, medical aspects of stroke, and the assessment of language disorders in adults.

Section II contains five chapters on principles of language intervention such as research methods appropriate to our field, treatment recovery, prognosis, and clinical effectiveness, teams and partnerships in clinical practice, as well as treatment of bilingual and biculturally diverse individuals. A number of issues related to service delivery are discussed.

Section III contains five chapters on psychosocial and functional approaches to intervention—models that focus on improving ability to perform communication activities of daily living. Such approaches consider the impact of aphasia on the well-being of the individual, their family, and the environment.

Section IV, the largest section, covers ‘Traditional Approaches to Language Intervention.’ It is divided into four units containing seven stimulation approaches, four cognitive neuropsychological and four neurolinguistic approaches, and three ‘specialized’ interventions.

Section V provides suggestions for remediation of disorders that frequently accompany aphasia or are related to or confused with aphasia; namely, traumatic brain injury, right hemisphere damage, dementia, apraxia, and dysarthria.

The chapters can be read in any order. In addition, all the chapters do not need to be read at one time. For example, when I teach our graduate course in adult aphasia, I typically use about 12 to 15 chapters as a core, and then refer to other chapters as they come up in class discussions, presentations or term papers, and/or when students ask questions about a specific individual that they are observing or working with in clinical practicum. I use the remaining chapters to give additional options, depth, and resources for actual work with individuals affected by aphasia.

Language Intervention Strategies in Aphasia and Related Neurogenic Communication Disorders—Fifth Edition can be used in classes for advanced undergraduate and graduate students in speech language pathology. Clinical aphasiologists who are no longer formal students, but who desire to

keep abreast of new ideas in their field will also find the material of interest. Further, the material will be valuable to students and professionals in nursing, medicine, and other health-related disciplines.

Acknowledgments

To those who have contributed to my personal life and professional career, past and present, I express my deep appreciation. I am also grateful to the authors and publishers who granted me permission to quote from their works.

Many concerned and dedicated people have helped bring this textbook to fruition. Sincere appreciation is extended to each. Special thanks are extended to Argye E. (Beth) Hillis for her professionalism and enthusiasm in organizing the section on cognitive neuropsychology. As editor, I would especially like to thank each contributor for helping to make

this text a kaleidoscope of enriching and rewarding experiences for me as well as for each of our patients. I am deeply appreciative of their caring and support and for many “one and only moments” of connection.

I am also thankful to the staff of Lippincott Williams & Wilkins for their dedication to making this a first rate text and for facilitating so many relentless details of this project. For the tireless support and help, I thank Peter Sabatini, Acquisitions Editor; Lisa Koepenick, Managing Editor; and Susan Katz, Vice President, Health Professions.

Section I

Basic Considerations

Chapter 1

Introduction to Language Intervention Strategies in Adult Aphasia

Brooke Hallowell and
Roberta Chapey

OBJECTIVES

The objectives of this chapter are to present a concise and comprehensive definition of aphasia, consider appropriate ways to refer to individuals with aphasia, explore conceptual frameworks for study and clinical practice in aphasia, review key etiologic and epidemiological factors related to aphasia, highlight the interdisciplinary nature of aphasiology, present a rationale for language intervention for adults with neurogenic communication disorders, and address future trends in aphasiology.

The present text grew out of a desire to bring researchers and practitioners together in adult neurogenic communication disorders to present an accurate and coherent picture of current practice in language assessment and intervention and to make it available in useful form. Foremost is the desire to coalesce significant thoughts on language intervention, while stimulating further study concerning the effectiveness of the approaches presented.

Before proceeding with the discussion of specific intervention strategies, we will consider several general issues that are relevant to clinical aphasiology. In this chapter we consider a brief definition of aphasia; ways to refer to people with aphasia; frameworks for conceptualizing aphasia; etiology and epidemiology; the interdisciplinary nature of aphasia; the importance of appreciating the life-changing effects of aphasia; a rationale for intervention; and future trends in aphasiology.

APHASIA BRIEFLY DEFINED

The study of aphasia is complex because of the variable manifestations of aphasia, the heterogeneity of its underlying

neurologic substrates, and the sophistication required to understand the mechanisms behind its associated symptomatology. Therefore, there are many ways of conceptualizing it. However, students and professionals interested in exploring the world of neurogenic communication disorders often need to be able to articulate a clear and concise definition of aphasia. Such a definition might be “**aphasia**” is an acquired communication disorder caused by brain damage, characterized by an impairment of language modalities: speaking, listening, reading, and writing; it is not the result of a sensory or motor deficit, a general intellectual deficit, confusion, or a psychiatric disorder (e.g., Brookshire, 1992; Darley, 1982; Goodglass, 1993).

What is critical to an adequate definition is the mention of four primary facts: it is neurogenic; it is acquired; it affects language; and it excludes general sensory and mental deficits.

1. **Aphasia is neurogenic.** Aphasia always results from some form of damage to the brain. The specific structures affected vary among cases, as do the means by which the damage may occur. Still, the underlying cause of aphasia is always neurologic. Aphasia is most often caused by stroke, but may also arise from head trauma, surgical removal of brain tissue, growth of brain tumors, or infections.
2. **Aphasia is acquired.** Aphasia is not characterized as a developmental disorder; an individual is not born with it. Rather, it is characterized by the partial or complete loss of language function in a person who had previously developed some language ability. It is important to note that most people with aphasia retain many linguistic abilities; many experience problems of reduced efficiency of formulation and/or production, reduced access to linguistic information still stored in the brain, and reduced retention of new linguistic information, not necessarily a complete lack of ability in any given area of language processing.

The term “childhood aphasia” refers to an acquired language problem in children; it is not, by definition,

applicable to children who never had language abilities to lose. (Childhood aphasia is not discussed in this text.) It should be noted, though, that children who have suffered neurologic incidents such as gunshot wounds, surgical removal of tumors, or even stroke, may develop a true form of “aphasia” if those incidents cause them to lose communication abilities they had gained earlier in life.

3. **Aphasia involves language problems.** Aphasia is often described as symbolic processing disorders, a multimodal problem of formulation and interpretation of linguistic symbols. In defining aphasia it is important to recognize that any or all modalities of symbolic communication may be affected: speaking, listening, reading, writing, and receptive and expressive use of sign language. Most cases involve at least some impairment in all language modalities.
4. **Aphasia is not a problem of sensation, motor function, or intellect.** Aphasia excludes general sensory and mental deficits. By definition, aphasia does not involve a problem of sight, touch, smell, hearing, or taste. Although aphasia may be *accompanied* by any number of other deficits in perceptual acuity, its definition excludes such deficits. Further, aphasia is not a result of general intellectual deterioration, mental slowing, or psychiatric disturbance. Aphasia is also not due to motor impairment. The exclusionary characteristics of the definition of aphasia are especially critical in the differential diagnosis of a wide array of neurogenic language, speech, cognitive, motor, and perceptual disorders.

A NOTE ON REFERRING TO PEOPLE WITH APHASIA

Before progressing with further study of aphasia and its management, it is important to note that the term “aphasic” is not a noun but an adjective, just as are most of the words we use to describe disabilities. While one might defend the stylistic use of the adjectival form as a label for a person who has aphasia (“an aphasic”), such labeling may convey a lack of respect for, and sensitivity toward, individuals who have aphasia (Brookshire, 2007).

Indeed, the World Health Organization (WHO) has launched worldwide efforts to modify the ways in which we refer to persons with disabilities, as discussed later in this and other chapters. The WHO classification emphasizes that disablement is not considered an attribute of an individual, but rather the complex interactions of conditions involving a person in the context of his or her social environment (WHO, 2001). Health-care professionals and researchers throughout the world are following suit by deemphasizing the reference to individuals according to medically based diagnostic categories, focusing instead on

their holistic functional concerns and what might be done to address them (Hallowell, 2007).

While, occasionally, the term “aphasic” may be used to refer to an “individual with aphasia” in the writings of diverse authors, there is a widespread movement among health care professionals to heighten sensitivity to individuals served by choosing terminology that does not objectify and label people primarily through their impairments or disabilities. Readers are encouraged to join this movement, and to help sensitize others to the importance of using person-first language. Guidelines for writing and talking about persons with aphasia and related disorders are summarized in Table 1–1.

CONCEPTUAL FRAMEWORKS OF APHASIA

Although it is simple to define the term “aphasia,” there are a number of in-depth definitions or frameworks for studying the nature of aphasia. An understanding of basic differences among ways of conceptualizing aphasia is essential to developing a solid theoretical framework of one’s own.

Propositional Language Framework

According to Hughling Jackson, aphasia is an impairment in one’s ability to make propositions, or to convey the intent of an utterance (Jackson, 1878). In referring to the “propositional” aspects of language, Jackson emphasizes the intellectual, volitional, and rational aspects of language that involve the use of linguistic symbols for the communication of highly specific and appropriate ideas and relationships. In a proposition, both the words and the manner in which they are related to one another are important. Jackson contrasts propositional aspects of language with subpropositional aspects, which he characterizes as inferior, automatic, highly learned responses (Goodglass & Wingfield, 1997; Head, 1915; Jackson, 1878).

Within this framework, a person with aphasia is seen as having difficulty communicating specific meaning and integrating words into particular contexts to express specific ideas and relationships. Patients may know words, but may habitually use them incorrectly, and often fail at embedding words in a variety of sentence forms. Jackson noted that even when propositional language is impaired, many patients retain automatic language. For example, even with severe propositional deficits, an individual may be able to name the days of the week, complete sentences such as “The grass is _____,” or produce highly learned responses such as “Hi. How are you?”

According to proponents of the framework, an individual with aphasia has an impairment in the use of spontaneous language to communicate *specific meaning*. The more propositional language required in a particular communication context, the more difficulty the patient has communicating.

TABLE 1–1

Guidelines for Writing and Talking about Persons with Aphasia and Related Disorders

Recognize the importance of currency and context in referring to individuals with disabilities.	There are always variances in the terms that particular consumers or readers prefer, and it is essential to stay current regarding changes in accepted terminology as well as to be sensitive to preferences for referents within a given communicative context.
Consider reference to “disabilities”.	Although the very term “disability” may be considered offensive to some (with its inherent focus on a lack of ability), it is currently generally preferred over the term “handicap” in reference to persons with physical, cognitive, and/or psychological challenges or “disabilities”.
Avoid using condition labels as nouns.	Many words conveying information about specific disabilities exist in both noun and adjectival forms, yet should primarily be used only as adjectives, or even better, modified into nouns corresponding to conditions. For example, it is not appropriate to call an individual with aphasia “an aphasic”. ¹ Likewise, it is not appropriate to call an individual with paraplegia “a paraplegic,” or to call persons with disabilities “the disabled”.
Use person-first language.	Person-first language helps emphasize the importance of the individuals mentioned rather than their disabilities. Although the term “an aphasic individual” would be preferred to the use of “an aphasic”, such labeling still conveys a disability-focused identity. It is more appropriate, for example, to refer to a “person with anomia” or an “individual with dementia,” than to an “anomic person” or a “demented individual”.
Consider use of the term “individual” or “person” rather than “patient”.	Consistent with the aim of focusing on individuals and their broad life contexts, rather than on people being treated in a medical context, use of the word “person” or “individual” is generally preferable to use of the term “patient”. In some contexts, such as in academic texts and articles, when people with and without language disorders are being discussed, use of the term “patient” may help to provide clarity of referents and to simplify explanations. In some contexts, the term “client” or “consumer” may be preferred to “patient” when referring to a person who is receiving professional services.
Avoid language of victimization.	Do not use language suggesting that clients are “victims” or people who “suffer” from various forms of disability. For example, say, “the client had a stroke” rather than “the client is a stroke victim.” Say, “She uses a wheelchair,” rather than “she is confined to a wheelchair.” Say “her leg was amputated . . .” instead of, “the client suffered an amputation of the leg”.
Avoid words with negative connotations.	Words that evoke derogatory connotations should be avoided in every context. These include such words and phrases as affliction, crazy, crippled, defective, deformed, dumb, insane, invalid, lame, maimed, mute, retard, and withered.
Encourage others in appropriate language use.	By modeling appropriate language in writing about persons with disabilities, including those with language disorders, students, clinicians and researchers take an important step in helping others to improve in this area. It is vital to help others learn to implement guidelines such as these directly through course work and other educational experiences. Likewise, polite and constructive corrections of others using inaccurate language helps encourage more positive communication as well as more enabling positive societal attitudes, widening the arena for empowering persons with disabilities.

¹Brookshire, R.H. (2007). *An introduction to neurogenic communications disorders*. St. Louis: Mosby – Year Book.
(Adapted from Hallowell, in press).

Assessment involves an analysis of the patient's ability to use spontaneous speech to express specific ideas. Intervention focuses on stimulation of the patient's ability to use propositional language.

Concrete-Abstract Framework

Goldstein and Scheerer (1948) observed that having an "abstract attitude" implies an ability to react to things in a conceptual manner. This attitude is necessary to isolate properties that are common to several objects, and for the formulation of concepts as opposed to sensory impressions of individual objects. It is also used to comprehend relationships between objects and events in the world. An abstract attitude gives the individual the power to inhibit actions or reactions and to use past experiences. These experiences help the individual organize perceptual rules and therefore to create and continue interactions with other people. Language that reflects an abstract attitude is propositional language. In contrast, the individual in the concrete attitude passively responds to reality and is bound to the immediate experience of objects and situations. Concrete language consists of speech automatisations, emotional utterances, sounds, words, and series of words (Goldstein & Scheerer, 1948).

In general, impairment in abstract attitude is reflected in propositional language. If one cannot abstract, one cannot symbolize or embed symbols in appropriate contexts. An individual who is impaired in abstract attitude, then, is unable to consider things that are possibilities rather than actualities, to keep in mind simultaneously various aspects of a situation, to react to two stimuli that do not belong intrinsically together, to inhibit reactions, and to ideationally isolate parts of a whole.

Goldstein and Scheerer (1948) developed a number of tests of ability to assume the abstract attitude. These tests include object-sorting tasks involving form, color, and combined color and form sorting. When observing sorting test results, one may ask: Is the sort concrete (perceptual) or abstract (conceptual)? Can the individual verbally account for the type of sort presented by the examiner (abstract)? The intervention implications of this framework would be to stimulate the patient to comprehend and produce language that is increasingly more abstract.

Thought Process Framework

Wepman (1972a) suggested that aphasia may be a thought process disorder in which impairment of semantic expression is the result of an impairment of thought processes that "serve as the catalyst for verbal expression" (p. 207). He noted that patients with aphasia frequently substitute words that are associated with words they are attempting to produce, and that the remainder of the individual's communicative effort appears to relate to the approximated rather

than the intended word. An inaccurate verbal formulation may lead to interference with thought processes, as there is a drive to establish consonance between the thought process and the actual utterance. For example, if a patient is trying to say "circle" and instead utters "square," the concept of circle may be modified to be consistent with the utterance, and the patient may begin to think of a circle as a square.

Individuals who cannot retrieve the most appropriate lexical symbol for a context are impaired in their ability to communicate a number and variety of specific propositional ideas. When the continued efforts relate to the approximated rather than the intended word, spontaneous language becomes even more impaired.

Within a framework in which aphasia is seen primarily as a disorder of thought process, assessment involves determining whether individuals can follow a train of thought in their communication or spontaneous language, and whether they can expand on topics and ideas. For Wepman (1972b, 1976), the first stage of therapy is thought-centered or content-centered discussion in which patients are stimulated to attend to their thoughts and remain on topic. During the second stage of therapy, patients are encouraged to elaborate on various topics.

Unidimensional Framework

A unidimensional view of aphasia relates language behaviors to a single common denominator. The expressive and receptive, as well as the semantic and syntactic components of language are considered to be inseparable. This view suggests that damage to the language mechanism results in general language impairment in which there is an effect on all aspects of language. Aphasiologists who subscribe to this framework do not promote the use of Broca's-Wernicke's, fluent-nonfluent, sensory-motor, receptive-expressive, or input-output dichotomies in aphasia.

One of the most popular and in-depth unidimensional theories, proposed by Schuell and her colleagues (Schuell, Jenkins, & Jimenez-Pabon, 1964), regards aphasia as a general language impairment that crosses all language modalities: speaking, listening, reading, and writing. These authors noted that the behaviors impaired in aphasia involve integrations that cannot be attributed merely to organization of motor responses or to events in outgoing pathways; rather, they involve use of an ability that is dependent on higher-level integrations.

According to proponents of this framework, aphasia is not modality-specific. Rather, it involves the inability to access or retrieve words and rules of an acquired language for communication (Schuell et al., 1964). The person with aphasia has lost functional spontaneous language, or the ability to use connected language units to communicate according to the established conventions of the language.

Schuell's concept of the cause of this general language breakdown reflects a broad and dynamic view of the language process.

The assessment implications of the unidimensional framework involve an analysis of the patient's ability to comprehend and produce language within all four modalities, and in contexts ranging from single words to spontaneous discourse. Schuell's test, the Minnesota Test for Differential Diagnosis of Aphasia (MTDDA) (Schuell, 1973) is based on this model (see Chapters 4 and 17).

The intervention applications are similarly unidimensional and multimodal. Treatment focus is on stimulation: the use of strong, controlled, and intensive auditory activation of the impaired symbol system to maximize patient reorganization of language. The clinician manipulates and controls specific dimensions of stimuli to make complex events happen in the brain, thus aiding the patient in making maximal responses (see Chapter 17).

Microgenetic View

Several authors challenge the notion that language production can be explained by an array of cortical speech centers and connecting pathways that convey memories and images from one processing center to another. Brown (1972, 1977, 1979) proposes a conceptual framework in which language processing is conceived as an event that emerges over different levels of the brain corresponding to different levels of evolutionary development, not across specific cortical areas. Phylogenetically older limbic mechanisms are thought to mediate early stages in cognition and linguistic representation, while the more recently evolved left lateralized neocortex (encompassing Broca's and Wernicke's areas) mediates the final stages in cognition and linguistic processing. Having evolved from common limbic structures, the anterior and posterior language zones are considered to be fundamentally united. Language is considered to be processed simultaneously by complementary systems in the anterior and posterior part of the brain, rather than sequentially from one component to the next. The function of cerebral pathways is considered to be the coordination of different regions of the brain rather than the mere conveyance of information between regions.

According to this view, varying forms of aphasia correspond to lesions of brain structures that have emerged at varying stages of evolution. A lesion in one of the language areas of the brain gives rise to the relative prominence of an earlier stage of language processing. Thus, the symptoms of aphasia serve to magnify the processing events that, in normal language, would be mediated by the lesioned area. Adherents to this framework envision treatment as facilitating the transition from one stage to the next in the microgenetic sequence.

Multidimensional Frameworks

Proponents of a multidimensional framework conceptualize aphasia as having multiple forms, each corresponding to a different underlying site of lesion and having a characteristic list of hallmark features. For individuals who hold a multidimensional view of aphasia, assessment involves determining what symptomatology is present and subsequently classifying a patient in one category or another. Some conceptualize aphasia dichotomously, for example, as Broca's versus Wernicke's, fluent versus nonfluent, semantic versus syntactic, or anterior versus posterior. Usually, such dichotomies are associated with the cerebral localization of the lesions that result in aphasia. The Boston Diagnostic Aphasia Examination (BDAE) (Goodglass, Kaplan, & Baressi, 2001), the Western Aphasia Battery (Kertesz, 1982; Kertesz & Poole, 1974), and the Language Modalities Test for Aphasia (Wepman & Jones, 1961) reflect such classification systems. Intervention, according to this framework, is oriented toward specific deficits. That is, the clinician attempts to rehabilitate a specific language modality (such as speaking) or behavior (such as confrontation naming or phonemic production) that is found to be impaired (c.f., Cubelli, Foresti, & Consolini, 1988).

Classification of Multidimensional Types of Aphasia

For the sake of simplicity and presentation of basic terminology, one may consider the basic subtypes of aphasia across different multidimensional classification schemes to fall into the categories of "fluent," "nonfluent," and "other" aphasias. The reader should be aware, though, that the terms fluent and nonfluent are not highly descriptive terms in and of themselves. It is important to specify what is meant by the use of these terms when describing the language of any individual patient. An individual may appear to be nonfluent for any of a variety of reasons, or according to any of a large array of measures. Generally, persons with aphasia are considered fluent if they are able to speak in spontaneous conversation without abnormal pauses, abundant nonmeaningful filler phrases, or long periods of silence. Nonfluent patients tend to have a reduced rate of speech and to express less communicative content per unit of time than normal speakers do. Of course, patients who are completely nonverbal are nonfluent. Damasio (1998) presents an excellent synopsis of the various categorical terms used throughout the history of the study of aphasia. A more thorough discussion of the classification of aphasia according to neuroanatomic substrates is presented in the next chapter.

Fluent Aphasias

There are three basic types of fluent aphasia: conduction aphasia, Wernicke's aphasia, and transcortical sensory aphasia.

Wernicke's Aphasia. The critical features of Wernicke's aphasia are impaired auditory and reading comprehension and fluently articulated but paraphasic speech (Goodglass

et al., 2001) in which syntactic structure is relatively preserved. In many cases, patients with Wernicke's aphasia present with logorrhea, or press of speech, characterized by excessive verbal production. Paraphasias are most often in the form of sound transpositions and word substitutions (Goodglass, Quadfasel, & Timberlake, 1964). Patients with Wernicke's aphasia experience naming difficulty that is severe in relation to their fluent spontaneous speech (Goodglass et al., 1964). Neologisms are frequent. Those who produce frequent neologistic expressions are often unintelligible and are sometimes referred to as having "jargon aphasia" (Wepman & Jones, 1961). Patients with Wernicke's aphasia also have difficulty reading, writing, and repeating words (Damasio, 1998). They often demonstrate a lack of awareness of their deficits, especially compared to patients with other types of aphasia. Some authors and many clinicians use the term "receptive aphasia" to refer to the disability of patients with Wernicke's aphasia because of their primary deficit in the area of linguistic comprehension. Likewise, because lesions that lead to this form of aphasia tend to be located in the temporal lobe, Wernicke's aphasia represents a classic form of "posterior" aphasia.

Conduction Aphasia. The speech of persons with conduction aphasia is fluent, although generally less abundant than the speech of those with Wernicke's aphasia (Damasio, 1998). A hallmark feature is impaired repetition of words and sentences relative to fluency in spontaneous speech, which is often normal or near normal. Auditory comprehension is also relatively spared (Goodglass et al., 2001). Most patients "repeat words with phonemic paraphasias, but often they will omit or substitute words, and they may fail to repeat anything at all if function words rather than nouns are requested" (Damasio, 1998, p. 35). Literal paraphasias repeatedly interfere with speech.

Transcortical Sensory Aphasia (TSA). Individuals with TSA have fluent, well-articulated speech with frequent paraphasias and neologisms (Goodglass et al., 2001). Global paraphasias occur more frequently than phonemic paraphasias (Damasio, 1998). A key feature that differentiates TSA from conduction aphasia is intact repetition ability. Auditory comprehension is generally poor. Confrontation naming is impaired, and the patient may offer an irrelevant response or echo the words of the examiner (Goodglass et al., 2001).

Nonfluent Aphasias

There are three basic types of nonfluent aphasia: Broca's, transcortical motor, and global aphasia.

Broca's Aphasia. Broca's aphasia is the most classic form of nonfluent aphasia. It is often considered the "opposite" of

Wernicke's aphasia (Damasio, 1998, p. 35). The essential characteristics of Broca's aphasia include awkward articulation, restricted vocabulary, agrammatism, and relatively intact auditory and reading comprehension (Goodglass et al., 2001). Typically, writing is at least as severely impaired as speech. Persons with Broca's aphasia are usually aware of their communicative deficits, and are more prone to depression and sometimes catastrophic reactions than are patients with other forms of aphasia. Some authors and clinicians use the term "expressive aphasia" to refer to the disability of patients with Broca's aphasia because of their primary deficit in the area of language formulation and production. Likewise, because lesions that lead to this form of aphasia tend to be located in the frontal lobe, Broca's aphasia represents a classic form of "anterior" aphasia.

Transcortical Motor Aphasia (TMA). In patients with TMA, repetition is intact relative to "otherwise limited speech" (Goodglass et al., 2001). Such patients exhibit phonemic and global paraphasias, syntactic errors, perseveration, and difficulty imitating and organizing responses in conversation (Damasio, 1998; Goodglass et al., 2001). Confrontation naming is usually preserved, but auditory comprehension is impaired.

Global Aphasia. Global aphasia is a disorder of language characterized by impaired linguistic comprehension and expression. It is often considered a combination of both Wernicke's and Broca's aphasia. Patients with global aphasia tend to produce few utterances and have a highly restricted lexicon. They have little or no understanding in any modality and little or no ability to communicate effectively (Wepman & Jones, 1961).

Other Forms of Aphasia

Anomic Aphasia. Anomic aphasia is a form of aphasia characterized primarily by significant word retrieval problems (Damasio, 1998; Goodglass, 1993; Goodglass & Wingfield, 1997). It is differentiated from the symptom of anomia, or dysnomia, which is typical in most forms of aphasia. Speech is generally fluent except for the hesitations and pauses associated with word-finding deficits. Grammar is generally intact.

Primary Progressive Aphasia. Primary progressive aphasia is a type of aphasia that has an insidious rather than an acute onset. The term "primary" refers to the fact that deficits in language are the primary symptoms noted, with cognitive skills remaining intact relative to linguistic skills. The term "progressive" refers to the fact that the condition is degenerative, with communication skills worsening over time. The underlying etiology for progressive aphasia may be any of a number of degenerative diseases affecting the brain. Many patients with this form of aphasia eventually

present with significant cognitive deficits as part of a syndrome of dementia (Ceccaldi, Soubrouillard, Poncet, & Lecours, 1996; Damasio, 1998).

Alexia and Agraphia. Alexia, a deficit in reading ability, occurs in most forms of aphasia, especially in those forms involving significant auditory comprehension deficits, such as Wernicke's aphasia or TSA. Consequently, it is infrequently considered a form of aphasia in and of itself. There are some rare patients, though, who present with deficits in reading that are markedly more severe than other communicative deficits, such as auditory comprehension and speech. Such forms of alexia may occur with or without agraphia, a deficit in writing ability. Forms of aphasia involving alexia with and without agraphia are described in formidable detail by Damasio and Damasio (1983), Goodglass (1993), and Geschwind (1965).

Exceptions to Multidimensional Aphasia Subtypes

Numerous systems for the multidimensional categorization of aphasia have been proposed. Further, most textbooks addressing aphasia offer creative means of categorizing the various subtypes of aphasia based on derivations of previous authors' suggestions. Acknowledging the diversity in diagnostic criteria and nomenclature used throughout the history of the study of aphasia, Damasio (1998) refers to the task of classifying the subtypes of aphasia as a "necessary evil" (p. 32). Most aphasiologists might agree with Damasio that "attempting to review the classification systems of aphasia is probably foolhardy" (p. 32). Most clinical aphasiologists attest to the fact that it is common to meet patients with forms of aphasia that do not fit neatly into any one category described according to a known multidimensional classification scheme (c.f., Caplan & Chertkow, 1989). Even an individual with a form of aphasia that fits a particular classification at one point in time may demonstrate a different form of aphasia as his or her condition evolves. Patients with right or bilateral cerebral dominance for language functions, subcortical lesions, degenerative conditions, traumatic brain injury, and multiple or unknown sites of lesion often present further challenges to the classification of aphasia subtypes, as explored in other chapters of this book. Still, it is essential that those studying aphasia and working with people who have aphasia understand traditional multidimensional models of classification. Such an understanding helps ensure improved communication among clinicians and researchers, improve the validity and reliability of diagnostic reporting, clarify theoretic differences in how experts differ in their ways of conceptualizing aphasia, and highlight the similarities and distinctions between one's idealized concept of any subtype of aphasia compared to the actual manifestations of aphasia in an individual patient.

Psycholinguistic/Problem Solving/Information Processing Framework

Psycholinguistic approaches to language recognize its three integrated and interrelated components: cognition, language, and communication (Muma, 1978), as well as the integration of language content, form, and use (Bloom & Lahey, 1978). **Content** involves meaning. **Language** refers to the structures of language or the rule-based systems of phonology, morphology, syntax, and semantics. **Communication** involves the use, purpose, or function that a particular utterance or gesture serves at any one time and its contextual realization. **Cognition** involves the acquisition of knowledge of the world, and the continued processing of this knowledge. Cognition refers to all of the mental processes by which information is transformed, reduced, elaborated, stored, recovered, and used (Neisser, 1967). Cognition can be operationally defined as the mental operations in the Guilford (1967) Structure-of-Intellect Model, namely, recognition/understanding; memory; and convergent, divergent, and evaluative thinking (see Chapter 17).

In a psycholinguistic framework, aphasia may be defined as an acquired impairment in language content, form, and use and the cognitive processes that underlie language, such as memory and thinking (convergent, divergent, and evaluative thinking). The impairment may be manifested in listening, speaking, reading, writing, and sign language, although not necessarily to the same degree in each.

Aphasia may be seen as an impairment in problem solving and information processing. Problem-solving and information processing both involve the use of all five cognitive operations (recognition/understanding; memory; and convergent, divergent and, evaluative thinking); the four types of content (figural, symbolic, semantic [content, form, and use], and behavioral [use/pragmatics]; and the five products or associations [units, classes, relations, systems, and transformations] of the Guilford (1967) model (see Chapter 17). The specific components that are used depend upon the problem presented and/or the information being processed.

Within this model, assessment of individuals with aphasia centers on an analysis of the cognitive, linguistic, and communicative strengths and weaknesses of each individual. Intervention focuses on the stimulation of these abilities, but especially on the stimulation of the cognitive processes underlying language comprehension and production (see Chapter 17).

Body Structure and Function, Activity, and Participation Framework

The WHO has launched a worldwide effort to redefine functioning and disability in an effort to heighten awareness of its holistic components and the complex interaction of conditions within each individual and in the environment

that affects each individual's functioning. An earlier classification scheme proposed by the WHO, the International Classification of Impairments, Disabilities and Handicaps (ICIDH) employed the general terms "impairment," "disability," and "handicap," while a more recent scheme, the ICIDH-2, employed the terms "impairment," "activity," and "participation," to refer to the various contextual aspects of disabling conditions one might experience. The two primary levels within the most recent WHO International Classification of Functioning, Disability and Health (ICF) are (1) body structure and function and (2) activity and participation (WHO, 2001).

For individuals with aphasia, **body structure and function** refers to impairments of brain and brain functions. **Activity limitations** primarily involve the four language modalities: speaking, listening, reading, and writing as well as tasks necessary for daily living, such as conversing with the nurse or family member, writing a check, making a phone call, reading a paper or menu, and so forth. These modalities have been the traditional focus of assessment and intervention in aphasia. During the past 20 years, such tasks have increasingly been the focus of care.

The constructs of **activities and participation** capture the notion of engagement in daily life and realizing immediate and long-term real-life goals. This might include playing golf, shopping for clothes, getting a job, going on vacation, participating in clubs and organizations, and so forth. We may discuss limitations of "activities" in a similar way to our use of the term **disability**. We may discuss limitations of "participation" in a similar way to our use of the term **handicap**. For people with aphasia, these constructs represent the ability to use language in context. **Environment** is another key construct in the ICF. It includes the assistive technology, relationships with and support from others, support services, policies and regulations, physical environmental factors, and the attitudes of individuals with aphasia and their significant others.

The WHO classification schemes provide a framework for moving away from the classic biomedical model and take into consideration the organic and the complex functional consequences of disease. Viewing aphasia in this framework helps us consider social exclusion and inclusion as fundamental to the context in which people with aphasia communicate and engage in daily life activities. People with aphasia are not seen as solely responsible for the social consequences of their aphasia. The framework highlights the dynamic interaction of important variables such as social support, risk factors, causes, genetics, capabilities, environmental factors, and life habits of social participation in examining health, handicap, and disability. For example, consistent and dependable support from friends and family will likely decrease the impact of impairment; a depressed, uninvolved spouse may increase it. All individuals in the environment—and the environment itself—impact functioning and participation in

life (see Chapter 10). Therefore, assessment and treatment focus not just on the restoration of language functions, but also on individual communication of wants and needs and the social and environmental supports that might contribute to full participation. Assessment and treatment target all major areas in the classification scheme from day one.

This framework also helps clinicians and researchers focus on the core features of health and well-being. It encourages us to focus on seeing aphasia as a contextualized life-affecting condition requiring resources and compensatory and adaptive services for full life participation (Parr, Byng, & Gilpin, 1997). Health, well-being, and quality of life are considered essential to understanding aphasia and in helping those affected by it. Vitally related to a focus on life participation is the Life Participation Approach to Aphasia (LPAA Project Group, 2000) (see Chapter 10).

ETIOLOGY AND EPIDEMIOLOGY OF STROKE AND APHASIA

Stroke

Stroke, or cerebrovascular accident (CVA), is the most prevalent cause of aphasia. A stroke occurs when blood flow to an area of the brain is interrupted by the blockage of a blood vessel or artery, or by the rupturing of an artery. Blood carries essential nutrients, especially glucose and oxygen, to brain cells. Since brain cells do not have the capacity to store these nutrients, they are in need of constant blood supply. Even brief periods of interruption in blood supply to the brain can have lasting devastating effects on brain tissue (see Chapters 2 and 3).

Stroke is the third leading cause of death in the United States and the most common cause of adult disability (American Heart Association, 2006). In the United States alone, approximately 700,000 individuals experience a stroke each year (Centers for Disease Control and Prevention, Division for Heart Disease and Stroke Prevention, 2006). According to Zivin and Choi (1991), roughly 30 percent of those who have a stroke die, and "20 to 30 percent become severely and permanently disabled" (p. 56). For at least 40 percent of those who survive, stroke is a seriously disabling disease. Many survivors have lasting problems with movement and motor control of the body, perceptual deficits, cognitive problems, and swallowing disorders, as well as problems of speech and language.

There are several types of stroke. Chapters 2 and 3 contain a discussion of the most common forms of stroke leading to aphasia, namely thrombotic, embolic, and hemorrhagic strokes.

Incidence of Aphasia

Statistics regarding the incidence of aphasia and of the various subtypes of aphasia are variable, owing to subject

sampling and description methods (c.f., Scarpa, Colombo, Sorgato, & DeRenzi, 1987). Marquardsen (1969) estimates that approximately one-third of patients who survive the first week of stroke have aphasia. Pedersen, Jorgensen, Nakayama, Raaschou, & Olsen (1995) report incidences as high as 40% in patients evaluated within the first three days of stroke. Scarpa et al. (1987) estimate that about 55% of patients with strokes affecting the left hemisphere have aphasia when examined 15 to 30 days after a stroke. Approximately 80,000 Americans develop aphasia each year, and about one million people in the United States—about one in 300 people—currently have aphasia (National Institute for Deafness and Other Communication Disorders, 2006).

Risk Factors for Stroke and Aphasia

Diagnoses of hypertension, heart disease, diabetes, and high cholesterol are factors that increase an individual's likelihood of experiencing stroke and aphasia, as are lifestyle factors of smoking, stress, inactivity, excessive consumption of alcohol, and dietary intake high in cholesterol, fat and sodium (NIDCD, 2006; Silvestrelli et al., 2006).

Although some studies have reported gender differences in the incidence of aphasia and in the location of associated lesions (Kertesz & Sheppard, 1981; Kimura, 1980; McGlone, 1980; Wyller, 1999), other researchers have discounted such findings (Hier et al., 1994; Pedersen et al., 1995; Scarpa et al., 1987). The prevalence of stroke is higher among men up to the age of approximately 80 years, after which it becomes higher in women. Women are, on average, six years older than men when they experience a first stroke (Roquer, Rodríguez-Campello, & Gomis, 2003). A majority of studies indicate that the case-fatality rate is higher in female than in male stroke patients; there is also some evidence, albeit relatively weak, indicating a better functional outcome in men (Roquer et al., 2003). Gender differences in risk factor profile and treatment response appear to be weak.

Handedness does not appear to be significantly associated with stroke incidence or severity (Pedersen et al., 1995). Given the low incidence of left- compared to right-handed individuals, the heterogeneity of left-handed people in terms of cerebral dominance for language, and also the fact that researchers commonly exclude left-handed individuals from aphasia studies, data are lacking as to the etiology and epidemiologic associations between handedness and aphasia.

While advancing age is consistently associated with stroke (Stegmayr, Asplund, & Wester, 1994), reports of the influence of age on the incidence of aphasia within stroke patient populations have not been substantiated in studies employing controlled sampling and subject description

methods (Habib, Ali-Cherif, Poncet, & Salamon, 1987; Miceli, Caltagirone, Gainotti, Masullo, Silveri, & Villa, 1981). Although the risk of acquiring aphasia increases with age, it is important to note that age has not been causally linked to aphasia.

Data from the 42-year-long Framingham Study conducted by the National Institutes of Health (Willich, 1987) suggest that strokes are twice as likely to occur between 6:00 a.m. and noon than at any other time of the day and that more than half (especially hemorrhagic strokes) occur on Mondays. Other studies have confirmed this finding, attributing it to the fact that those times correspond to periods when the body's supply and demand for oxygen is at its greatest level of imbalance—that is, when there is an increase in oxygen requirements simultaneous with reduced levels of blood flow (Flack & Yunis, 1997).

Racial, Ethnic, and Cultural Factors Influencing Incidence of Stroke and Aphasia

Many researchers report an influence of racial and ethnic origins on the incidence of stroke and aphasia. Stroke mortality is generally reported to be substantially higher in African American and Hispanic populations than in Caucasians (Gaines, 1997; Hoyert, Heron, Murphy, & Kung, 2006; Sacco et al., 1998). Discrepancies among reports on the relationship of race and ethnicity to stroke and aphasia may be attributable to sampling methods and to the sophistication and accuracy of diagnostic methods (c.f., Gillum, 1994, 1995). Most of the racial differences in the incidence of stroke and aphasia may be accounted for by differences in cultural influences on such lifestyle factors as diet, exercise, smoking, and access to health care services (Kuller, 1995). Persons of lower socioeconomic status also have higher risk factors for stroke, further influencing epidemiologic studies of stroke and aphasia (Centers for Disease Control and Prevention, 2006; Feigin, 2005; Feigin et al., 2006).

The role of race, ethnicity, socioeconomic status, and culture have important implications not only for the incidence of aphasia, but also for its diagnosis and treatment. It is for this reason that an entire chapter of this book and several components of other chapters are devoted to multicultural issues pertinent to intervention in adult aphasia.

Geographic location appears to play an important role in the prevalence and incidence rates of stroke and aphasia. For example, the southeastern region of the United States has been labeled by many as the "Stroke Belt" because of higher stroke mortality rates than other geographic areas, even when researchers account for age, gender, and race. Regional differences appear to be primarily influenced by the levels of risk factors such as high blood pressure, obesity, poor diet, and smoking, not on the physical properties of the areas involved (Casper et al., 1995; Centers for Disease Control and Prevention, 2006; Gaines, 1997).

Prevention

Data pertaining to risk factors enable researchers, clinicians, and laypersons to better reduce the likelihood of any individual experiencing the life-altering consequences of stroke and aphasia. A summary of strategies to prevent stroke at the individual level is provided in Table 1–2. Of course, public health programs to support health and wellness and access to health care are critical factors in prevention, as well as in recovery through medical and rehabilitative treatment following stroke (Centers for Disease Control and Prevention, Division for Heart Disease and Stroke Prevention, 2006). Recognizing the tremendous cost-saving advantages of preventing stroke, many health insurance companies have launched programs to promote wellness and help reduce consumers' risk of stroke (Thomas, 1997). Key lifestyle changes to reduce the risk of stroke and aphasia include dietary modification (e.g., reduced cholesterol and sodium intake, increased dietary fiber, vitamin therapy, moderation of consumption of caffeine and alcohol, and weight reduction in overweight patients), increased physical activity, smoking cessation, and stress reduction (He & Whelton, 1997; Gottlieb, 2006; Khaw, 1996; Labarthe, Biggers, Goff, & Houston, 2005; Shinton, 1997).

TABLE 1–2

Summary of Strategies to Prevent Stroke

- If you are overweight, lose weight. Maintain proper weight.
- Lower intake of salt or maintain low salt intake.
- Eat fruits and vegetables daily.
- Take in sufficient amounts of potassium.
- Keep cholesterol intake low.
- Maintain a low-fat diet.
- Engage in no more than moderate alcohol consumption.
- Be physically active. Exercise regularly. Engage in regular resistance training.
- Drink several glasses of water daily.
- Develop and nurture a calm, relaxed, optimistic, and even-tempered attitude.
- Get a flu shot.
- If you smoke, quit.
- Reduce exposure to second-hand smoke.
- Seek medical treatment for disorders that increase risk of stroke, including diabetes, atrial fibrillation, sickle cell disease, carotid artery disease, and heart failure.
- Seek medical advice. A doctor may recommend andarterectomy, aspirin or other blood-thinning therapy, medicines that help lower blood pressure, or alternatives to drugs known to raise blood pressure.
- Know the warning signs of stroke; seek medical attention as soon as symptoms occur.

Numerous pharmacologic treatments reduce the risk of stroke by helping to control hypertension and blood lipids (Centers for Disease Control and Prevention, 1999). In light of the increased risk of stroke in the early morning hours and on Mondays, scheduling of stressful tasks at times other than these is advised, as is the careful timing of the daily administration of antihypertensive medications (Flack & Yunis, 1997; Metoki, 2006).

Many preventive health programs focus on the core features of positive human health, well-being and quality of life, namely, leading a life of purpose, quality connection to others, positive self-regard, and a sense of mastery and accomplishment (Kahneman, Diener, & Schwarz, 1999). Active intervention programs focusing on these factors is especially important for patients and their significant others to prevent further illness such as additional strokes in individuals with aphasia (see section “Impairment, Activities, Participation in Life”) and disease in their significant others.

Etiologies Other Than Stroke

Much of the empirical literature on aphasia is based on the study of patients who acquired aphasia because of a cerebrovascular accident. There are two good reasons for this. First, the majority of patients who have a clear and definite diagnosis of aphasia have had a stroke. Second, because stroke patients tend to have well-defined, localizable focal lesions, the etiologies associated with their manifestations of aphasia can be documented in research reports and controlled for in experimental paradigms, making such patients attractive research participants. Still, it is important to acknowledge that many other etiologies may be associated with aphasia. For example, patients who have experienced traumatic brain injury, brain surgery, infections, tumors, degenerative conditions, or exposure to neurotoxic agents may present with aphasia. The diffuse brain damage and frequently ill-defined sites of lesion associated with such etiologies preclude a large volume of controlled research pertaining specifically to aphasia in these complex populations. It is nonetheless important to recognize and treat patients who have aphasia regardless of the underlying cause. The Centers for Disease Control and Prevention, Division for Heart Disease and Prevention (2006) report that approximately 1.4 million adults per year in the United States experience a traumatic brain injury, far exceeding the number who have strokes. Approximately 43,800 new cases of brain and central nervous system tumors are diagnosed annually in the United States (Central Brain Tumor Registry of the United States, 2005). Millions more are diagnosed each year with other neurologic disorders affecting language abilities (e.g., dementia, Parkinson's disease, multiple sclerosis).

While the nature of aphasia is not always best studied with non-stroke populations, there is a growing body of treatment research pertaining to such populations. This

book includes several chapters that address issues especially relevant to intervention with patients with traumatic brain injury and varied forms of dementia. Additionally, much of what has been learned about the treatment of aphasia in stroke patients may be applied to the treatment of acquired neurogenic communication problems in other patient populations.

Other Acquired Neurogenic Disorders

The study of aphasia is vitally related to the study of other acquired neurogenic communication disorders. Clinical aphasiologists are ideally trained in the diagnosis and treatment of a host of neurogenic conditions and have a solid understanding of their underlying neuropathologies. Academic knowledge and clinical expertise in the areas of dementia and other cognitive disorders, right-brain damage, traumatic brain injury, motor-speech disorders, confusional states, dysphagia, and normal aging are essential to excellence in clinical aphasiology. Also essential is competence in interdisciplinary research and clinical collaboration, given that individuals who experience any acquired neurogenic communication disorder are likely to also experience multiple additional concomitant disorders and medical conditions.

Aging and Communication

The past three decades have brought an increasing interest in age-related changes in adults. Toward this end, numerous professionals have measured cognition, perception, sensation, mobility, communication, and other neurologic and psychological systems in an attempt to identify key variables that may or may not change with age. Although an increase in incidence with age is reported for many diseases and other problems affecting the cardiovascular, pulmonary, gastrointestinal, genitourinary, hematologic, musculoskeletal, metabolic, and endocrine systems (Abrams & Berko, 1990), some research has focused on positive changes and functioning in the elderly. The “myth . . . that to be old is to be sick, sexless and senile” (Frady, Gerdau, Lennon, Sherman, & Singer, 1985) is being countered by many vigorous and independent aging adults. In fact, gradual improvement has been seen in the overall health of elderly people (Manton, Stallard, & Corder, 1998; National Academy on an Aging Society and Merck Institute of Aging and Health, 2004; Philip, 2004). The majority of those who are over 85 are continuing to care for themselves (Elias, 1992; U.S. General Accounting Office, 2002).

Studies suggesting relationships between age and health or cognitive factors are often confounded by concomitant problems faced by elderly individuals. For example, those who perform poorly on mental ability tests may have other problems, such as depression, amnesia, dementia, vitamin deficiencies, or alcoholism. Additionally, they may be

hindered by medications, including sedatives and/or nonsteroidal anti-inflammatory drugs, or by environmental insults such as pollution and stress.

New neuroimaging and behavioral methods, as well as evolving technology for the molecular study of the nervous system, have allowed researchers to conclude that, despite the loss of neurons with aging, the brain undergoes continuous adaptation as it ages. Evidence of neurobiologic changes that may come with age can be derived from animal research, which suggests that elderly animals are as capable of growing new connections between brain cells as are younger animals (van Praag, Shubert, Zhao, & Gage, 2005; Wu, Zou, Rajan, & Cline, 1999). This also appears to be true in humans (Abrous, Koehl, & Le Moal, 2005; Eriksson et al., 1998; Jin et al., 2006; Saurwein-Teissl, Schonitzer, & Grubeck-Loebenstien, 1998). Mesulam (1987) claims that age-related changes may underlie “wisdom,” suggesting that the progressive death of neurons and the sprouting of new connections may actually be healthy and a sign of maturity in the most positive sense.

INTERDISCIPLINARY APPROACHES TO APHASIOLOGY

The study of aphasia and related neurogenic communication disorders is inherently interdisciplinary (see Chapter 8). Although clinical practice in intervention for patients with aphasia requires specific training, certification, and/or licensure in much of the world, the study of aphasia does not fall within the bounds of any single discipline. Disciplines that help understand the nature of neurogenic communication disorders and provide the most effective intervention include speech-language pathology, audiology, neuroscience, cognitive science, biology, engineering, physics, psychology, pharmacology, linguistics, communication, social work, counseling, anthropology, sociology, multiculturalism, mathematics, rehabilitation, physiatry, neurology, gerontology, physical therapy, occupational therapy, music therapy, and health care administration. This list is far from exhaustive. It is interesting to note that many of the disciplines just mentioned are also hybrid ones, drawing from basic science, theory, and practice in a variety of content areas. Thus, the student or professional who is truly committed to the study of aphasia must also be committed to lifelong learning across disciplinary boundaries.

LIFE-CHANGING EFFECTS OF APHASIA

Within a matter of minutes, the lives of individuals who have aphasia change completely. They may feel that they are prisoners in their own minds. Many, through the effects of neurologic impairments, may feel that they are prisoners in their own bodies as well. Some want to move and walk but

cannot; many have much to say but are significantly limited in their ability to express themselves. Persons who were employed prior to acquiring aphasia may be unable to maintain employment, leading not only to financial stress but also to feelings of isolation, frustration, and worthlessness. Some people with aphasia are lonely and desperate. Others tolerate the condition remarkably well.

Despite worldwide efforts to improve the ways that individuals with disabilities are treated and regarded, negative attitudes toward and discomfort with persons with communicative and physical disabilities remain. Individuals with stroke and aphasia are susceptible to attitudinal barriers, lack of important information, loss of companionship with loved ones, marginal social status, rejection, distrust, stigmatization, and loss of esteem (Boone & Zraik, 1991; Croteau & LeDorze, 2006; Love, 1981; Murphy, 2006; Post & Leith, 1983).

Patients' significant others are usually dramatically affected by the onset of aphasia in a friend, colleague, or loved one. The onset of acquired aphasia, so life-changing in practically every dimension of daily living, inspires many to appreciate just how central communicative ability is to being and feeling human.

Language: The Human Essence

The need for socialization is the core of human existence, and the ability to communicate with others is the essence of that socialization. Language is basic to what Chomsky (1972) calls the "human essence." More than any other attribute, language distinguishes humans from other animals. It is the most basic characteristic of the intellect and the very means through which the mind matures and develops. Language enables individuals to describe and clarify their thoughts for themselves and others.

Human experience and interaction are welded to language. According to Goodman (1971), the ability to share experience through language is a means of homeostasis that enables human beings to maintain and/or restore an equilibrium in which they can survive. Goodman also observes that language is the basis of personality, revealing our innate being and our psychic ties with the world.

Language is also the essence of maturity, which is defined as an ability to relate warmly to and intimately with others — with their goals, aspirations, and hopes. It involves a "fitting in," carrying one's share of personal and social responsibility, and conveying one's seasoned intelligence. Thus, definitions of maturity involve and revolve around the ability to use language effectively.

Insofar as persons with aphasia are impaired in their ability to use language, they are impaired in their human essence. Part of the personality often appears lost, and the ability to maintain interpersonal relationships, to convey wants and needs, and to be a mature self-reliant, self-actualized person is impaired.

There is tremendous variability in how aphasia affects an individual's sense of self and social ability. The effects may be disproportionate to the degree of neurologic impairment. Even mild deficits may be traumatizing to persons who closely identify with their active roles as communicators. Others with severe neurologic impairments and language deficits tolerate the effects of their condition with remarkable serenity.

EVIDENCE-BASED PRACTICE

Evidence-based practice is a construct receiving increasing attention from researchers, clinicians, patients, and health insurance companies, as well as agencies that rate quality of care in a wide array of health care contexts. As with many other health-related disciplines, the frequency of use of the term in the neurogenic communication disorders literature has expanded dramatically over the past decade. It refers to the skilled use of empirical support to make diagnostic and intervention decisions (c.f., Sackett, Rosenberg, Gray, Hayes, & Richardson, 1996; Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). The concept of using evidence to inform practice is not a new one. However, it has become a growing focal point due to: the expansion of our knowledge base; the increased accessibility of data and other information via recent advances in print- and web-based publishing; the growing demand for accountability from consumers, employers and insurance companies; and the continuous quality improvement- and outcomes-focused programs in which we engage as clinicians to ensure that we provide the best services we can. The "evidence" we use to inform our clinical decisions may come in the form of expert opinion, or from research involving a variety of methods, including case studies, randomized clinical studies, and randomized controlled clinical trials (c.f., Frattali & Worral, 2001; Robey, 1998; Robey & Schultz, 1998). The way we incorporate the evidence is ideally influenced by our careful consideration of the methodologic quality and validity of specific research studies, our own clinical judgment about the relevance and importance of research findings to a specific patient, the values of the patient, the feasibility of applying research findings in a given intervention context, and our own and others' expert opinion (c.f., Woolf, Grol, Hutchinson, Eccles, & Grimshaw, 1999).

The Academy of Neurologic Communication Disorders and Sciences (ANCDS) has developed evidence-based practice guidelines founded on careful literature reviews and analysis by teams of clinical researchers in specialty areas within neurogenic communication disorders. Examples of guidelines published to date include those on cognitive-communicative disorders resulting from traumatic brain injury (Turkstra, Ylvisaker, Coelho, Kennedy, Sohlberg, & Avery, 2005). ANCDS writing groups are now developing guidelines for additional areas, including aphasia

and dementia. The American Speech-Language-Hearing Association (ASHA) has supported the development of evidence-based clinical practice guidelines based on reviews of the research literature in several areas of clinical practice, and has recently initiated the National Center for Evidence-Based Practice in Communication Disorders. Information about related initiatives is updated regularly online (ASHA, 2007).

As clinicians we require a basic knowledge of the processes used to engage in and document evidence-based clinical practice. We must also keep abreast of the literature regarding which assessment and therapeutic techniques are effective with specific types of patients and under what conditions. It is critical that we continuously find, document, and evaluate our practices and test whether our therapeutic techniques are effective.

RATIONALE FOR LANGUAGE INTERVENTION IN APHASIA

A rationale for language intervention in persons who have aphasia is based on the belief that language is vital to one's human essence and that treatment can affect a change in a patient's communicative performance. Aphasia is not considered by most to be a disorder that can be cured. Still, skilled intervention enables many individuals to be able to comprehend and produce language and to communicate more effectively. Through intervention, aphasiologists attempt to heighten each patient's potential to function maximally within his or her environment, to facilitate meaningful relationships, and to restore self-esteem, dignity, and independence (Wepman, 1972a).

It is unfortunate that many posttrauma and poststroke patients with good potential for rehabilitation are left untreated. Many individuals have the capacity to communicate more effectively and yet are not enabled to do so (Wepman, 1972a). Quality health care means going beyond the provision of basic physical care and meeting the holistic needs of patients with high standards and dignity. Individuals should be granted the right to be treated by qualified clinicians providing the best techniques known. Not to allow persons to communicate to the best of their ability is to deprive them of their own human essence.

FUTURE TRENDS

The explosion of new knowledge and new technology is leading scientists to a progressively greater understanding of the brain's biology. Molecular answers are now increasingly available for questions we have addressed only indirectly. New and evolving imaging methods provide promise for richer information about the nature of neurogenic disorders

in adults, and about their treatment. New approaches to pharmacologic intervention are producing promising preliminary results related to facilitation of cerebrovascular recovery following stroke or brain injury, as well as cognitive improvement through neurotrophic factors. Biologic interventions hold promise for stimulating or repairing injured brain areas. The future may also bring tissue transplantation, perhaps using stem cells, and electronic prostheses, perhaps using cortical electrode grids to facilitate function (Wineburgh & Small, 2004). Emerging technology will continue to expand our alternatives as aphasiologists for assessment and treatment.

Research in all the areas related to the study of aphasia will continue to illuminate our understanding of neurogenic communication disorders. Many of these research areas are explored further in this book. It is important that aphasiologists continue to learn about how the brain organizes language and to reflect on how this kind of knowledge can affect the growth and development of new approaches to treatment. The more we know about how intervention changes brain function, the more effective we can make our intervention approaches. The accelerated emphasis on evidence-based practice within our profession and the emergence of additional collaborative efforts among researchers and clinicians to enhance the evidence base in our discipline bode well for improved efficacy, efficiency, outcomes, accountability, and quality in our services.

Demographic characteristics of patient populations will continue to stimulate new development in adult language intervention. Increased life expectancies and the progressive aging of the world's population will continue to influence the nature of the patients served by clinical aphasiologists, as will the growth of multilingual and multicultural populations. Other important influences will include the increased incidence of certain relevant etiologic and associated risk factors such as obesity, hepatitis, and HIV and AIDS (ASHA, 1989a; Centers for Disease Control and Prevention, 2006; Larsen, 1998; Flower & Sooy, 1987).

RATIONALE FOR THIS TEXT

The primary purpose of the present text is the presentation of various models of intervention for adult patients with aphasia and for patients with related disorders. Such models can provide a framework with which to focus therapy, to generate intervention tasks, and to analyze empirically the efficiency of rehabilitation efforts. Some of these strategies have appeared in part or in whole in previous literature; others have not. It should be recognized, however, that it is not the purpose of this text to assess any of the models or to resolve the inconsistencies in these approaches. These

functions are better performed in appropriate professional journals.

It is hoped that this text will provoke theoretic speculation and that those chapters that are rich conceptually will prompt the collection of further data and generate the production of new approaches. The readings are organized into sections to help shape the reader's perspective on the field. However, the sections of the book—and its chapters—may be used in any order.

KEY POINTS

1. There are four essential features to a definition of aphasia.
2. The term “aphasic” is an adjective, not a noun.
3. Varied theoretic frameworks influence the way one conceptualizes aphasia and therefore may influence the diagnosis and treatment of aphasia.
4. Multiple etiological factors are associated with aphasia, the most common of which is stroke.
5. Traditional classification schemes help to elucidate various manifestations of aphasia, but are often limited in terms of characterizing the conditions of individual patients.
6. The study of aphasia is interdisciplinary.
7. A solid rationale for language intervention in adult aphasia is based on the notion that language is essential to one's human essence and that treatment can affect a change in a patient's communicative competence.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Write your own definition of the term “aphasia,” employing each of the four components mentioned for an ideal definition. Compare your definition with those of your colleagues. How might the way one conceptualizes aphasia influence one's choice of words in defining aphasia?
2. Create an interactive exercise for students and clinicians to practice the use of appropriate terms to refer to individuals with a variety of neurogenic language disorders.

3. Review the means of reducing stroke risk in Table 1–2. Considering yourself a role model for an individual at risk of stroke (and repeat strokes), what specific steps would be important for you to undertake to demonstrate a lower stroke risk in your own life style? Develop a personal action plan for reducing your own stroke risk.
4. A background in basic terminology used in the study of communication disorders is assumed by the authors of this book. Reviewing terminology as presented in other texts may be helpful. Define in your own words the following terms used to describe the symptoms associated with aphasia:
 - agraphia
 - alexia
 - anomia
 - catastrophic reaction
 - logorrhea
 - neologism
 - paraphasia (including the terms literal, phonemic, semantic, verbal, and global paraphasia)
 - perseveration
 - press of speech
 - transposition

Note that some authors use the prefix *dys-* rather than *a-* for many of these terms, referring, for example, to dysnomia, dyslexia, dysgraphia, and even dysphasia rather than using the corresponding terms anomia, alexia, agraphia, and aphasia. What is the literal semantic distinction between terms beginning with *dys-* as compared to *a-*? The choice of prefixes in the usage of such terms among aphasiologists appears to be a function of stylistic convention more than a function of the literal significance of the prefixes in question.

5. Explain why many patients with “fluent” aphasia are also considered to have “receptive” aphasia.
6. Describe the hallmark features of each of the classic subtypes of aphasia described: Wernicke's aphasia, transcortical motor aphasia, conduction aphasia, Broca's aphasia, global aphasia, transcortical sensory aphasia, anomic aphasia, alexia, and primary progressive aphasia. As you read the upcoming chapter, it will be helpful to continue to reflect on how these hallmark symptoms are associated with the underlying neuropathologies of aphasia. As you consider diagnostic issues in aphasia as discussed further in this text, it will be helpful to consider further how the way in which one conceptualizes aphasia is relevant to the diagnostic process.
7. How might the way you conceptualize the nature of aphasia, and classify its subtypes, influence your own assessment of an individual with aphasia? How might it influence treatment?

Chapter 2

Neural Basis of Language Disorders

Hanna Damasio

OBJECTIVES

This chapter considers the neural basis of abnormal language processing and is based on the study of pathologic neuroanatomy in patients with aphasia due to focal brain damage. Aphasia refers to a compromise in the process of comprehending language, formulating language, or both, which occurs in a language-competent and intellectually competent individual. Specifically, aphasia is a breakdown in a two-way translation process that establishes the relation between thought and language. As a consequence, individuals with aphasia have an inability to translate, with reasonable fidelity, a nonverbal set of images (thoughts) into linguistic symbols and grammatical relationships (or they have the inverse problem, translating a received language message into thought).

Aphasia is a defect in language processing and not a defect of perception or movement or thought. Deafness, even when due to central processes, precludes comprehension of language through the auditory channel but not through the visual channel. Incoordination of speech movements causes dysarthria but not a linguistic breakdown of speech output. A thought disorder such as schizophrenia does not cause aphasia but rather produces a correct linguistic translation of a deranged thought process. As discussed in other chapters of this text, aphasia can compromise varied aspects of language processing (e.g., syntax, the lexicon, the phonemic and morphemic morphology of a word). In each individual patient several or even all of these aspects can be compromised, but the emphasis of the defect can also fall on one particular aspect only.

Aphasia is not the exclusive province of auditory-based languages. Languages based on visuomotor communication, such as American Sign Language (ASL), can also be

compromised following focal brain damage, along similar symptom clusters (Bellugi, Poizner, & Klima, 1983).

Most often aphasia is the result of cerebrovascular disease leading to stroke, but it can also appear following head injury, cerebral tumors, and degenerative diseases such as Alzheimer's or Pick's. The constellation of defects does not really depend on the underlying pathologic process but rather on the specific brain region that becomes affected. The differences one might witness between aphasias caused by some of these pathologic processes, or others, have more to do with the way the process affects the underlying brain tissue than with a specific effect on the language dysfunction. (For example, see Anderson, Damasio, & Tranel, 1988, 1990; Damasio, 1987a.)

Most aphasic syndromes are seen in disease processes affecting the left hemisphere given that the vast majority of individuals share a left-hemisphere language dominance, even when they are left-handed. However, in some instances, some left-handers develop aphasia after lesions of the right hemisphere (or may fail to show aphasia after lesions in language areas of the left hemisphere), possibly because both hemispheres are more involved in language processing than is standard. Even more rarely, we can witness either the presence of aphasia with a right-hemisphere lesion in a right-handed person, or conversely, the absence of aphasia with a typical left-hemisphere insult also in a right-handed subject. These cases are known as "crossed aphasia" and "crossed non-aphasia," respectively.

HISTORICAL OVERVIEW

The history of aphasia and the history of neuroscience share the same starting point: neuroscience began with the description, in 1861, of a patient who had lost the ability to communicate through the spoken word because of damage to the left frontal operculum. The original description was outlined by Paul Broca (1861), and it formed the basis for what was later coined Broca's aphasia, a severe disruption of language output which far exceeded a difficulty in language comprehension. About a decade later Carl Wernicke was to

describe another seminal patient with aphasia (Wernicke, 1874, 1886). The cause was another lesion of the left hemisphere but this time in the posterior temporal region rather than in the frontal lobe. So began what was later termed Wernicke's aphasia, in which the deficit in language comprehension far exceeded the disruption of language output. It did not take long to transform these observations of specific language deficits, which occurred after circumscribed areas of left-hemisphere damage, into generalizations about the neural basis of language. The idea that the left hemisphere was the site of human spoken language became accepted. With it came the idea that there were brain "centers" responsible for this function—an anterior center responsible for the production of language located in the frontal operculum or Broca's area and a posterior center responsible for language comprehension, located in the posterior half of the superior temporal gyrus or Wernicke's area. Further studies of patients with differently placed lesions and slight variations of the presenting deficits helped cement the traditional view, which mapped language-related brain areas to Broca's and Wernicke's areas, and their anatomic connection through a unidirectional fiber tract, the arcuate fasciculus, which carried speech signals from Wernicke's area to Broca's area. This cartoon of the key set of structures necessary to receive and produce language still pervades most textbooks and monographs on the subject, and even some modern texts on cognitive science and linguistics continue to use this phrenologic picture of the language brain despite their otherwise non-phrenologic models of the processes of thought and language. In the meantime, however, much has occurred in the history of aphasia. This includes a major backlash against localizationism that occurred along with the advent of behaviorisms in psychology, an approach that led to the opposite point of view—namely, that nothing but the whole brain was responsible for cognition. During the heyday of this approach, virtually all and any part of the brain was seen as equipotential, and language processes were no longer localized. The other initial historical development occurred when Norman Geschwind, working in the mid-1960s, struck a healthy balance between the excesses of phrenology and those of behavioristic theories. With his landmark articles on disconnection syndromes (Geschwind, 1965) he placed the classical observations on the anatomy of aphasia in a new functional perspective. He also went further in the anatomic explanations he provided for some of the previously described aphasic syndromes and enlarged the original set of language-related areas to include the left supramarginal gyrus and the left angular gyrus, both located in the inferior sector of the parietal lobe (see also Geschwind, 1971). At about the same time, detailed evaluation of aphasic patients was beginning to be performed with measurement tools that considered the linguistic and cognitive

aspects of language processing. Modern test batteries and classifications of the aphasias started in earnest in the 1960s.

Over the years numerous other aphasia classifications have appeared, all having their origin in the difficulties encountered by previous classifications in the accommodation to the unavoidable variability in the presentation of patients with aphasia. I will not discuss the several available classification systems of aphasia, or their respective advantages and disadvantages. This topic is covered in other chapters in this book. In general, I will follow the separation of aphasic syndromes associated with the Boston and Iowa schools (Benton & Hamsher, 1978; Goodglass & Kaplan, 1982).

The availability of MR imaging and more recently 3-D reconstruction of the human brain has empowered the human lesion method and made way for a new wave of cognitive experiments. (For more on the lesion method see Damasio, 2000; Damasio & Damasio, 1989.) The results of these studies have shown that language processing is not "centered" on Broca and Wernicke's areas, but rather on systems composed of many neural sites working in close cooperation. Two of these sites include Broca's and Wernicke's areas. Language processing will, for instance, engage several regions of left temporal and prefrontal/premotor cortices in the left hemisphere, which lie outside the classical language areas (Damasio, 1990; Damasio, Damasio, Tranel, & Brandt, 1990; Damasio & Tranel, 1993; Goodglass, Wingfield, Hyde, & Theurkauf, 1986). It has also been shown that structures in the left basal ganglia, thalamus, and supplementary motor areas are engaged in language production (Damasio, Damasio, Rizzo, Varney, & Gersh, 1982; Graff-Radford, Damasio, Yamada, Eslinger, & Damasio, 1985; Graff-Radford, Schelper, Ilinsky, & Damasio, 1985; Naeser, Alexander, Helm-Estabrooks, Levine, Laughlin, and Geschwind, 1982).

The literature on language processing in normal subjects has grown immensely in recent years due to the availability of functional magnetic resonance (fMR), as well as, earlier on, developments such as positron emission tomography (PET) and several aspects of electrophysiology. Functional studies do address language processing and its neural underpinnings, but do so mostly on the basis of normal language in normal subjects. Given that this chapter is meant to address the neural basis of language disorders, I will not review the extensive literature on functional studies in normal language processing, but will rather concentrate on the "aphasias."

ANATOMICAL OVERVIEW

Sulci, Gyri and Cytoarchitectonic Fields

To understand the neural underpinnings of the aphasias, we must begin with an understanding of normal brain anatomy.

Knowledge of neuroanatomy has been gathered over the years mostly through the study of brains at the autopsy table, although today it is possible to study macroscopic anatomy at the computer screen, thanks to the technique of magnetic resonance (MR) imaging and to programs that manipulate MRI information and allow for 3-dimensional (3-D) reconstruction of brain tissue viewed at the computer screen. The brain anatomy reviewed in this chapter is based on normal brains, that is, brains of normal individuals without any neurologic or psychiatric disease. The brains I use have been reconstructed in 3-D from thin MR slices (1.5-mm thick). The slices are contiguous, T1-weighted, and obtained in the coronal direction. A collection of about 124 such coronal slices is stripped of scalp, meninges, blood vessels, cerebellum, and brainstem, and reconstructed in 3-D on the computer screen (of silicon graphics workstation, personal computers, or Apple workstations) using Brainvox (Damasio & Frank, 1992; Frank, Damasio, & Grabowski, 1997). Brainvox

is a family of programs developed to analyze normal and lesioned brains at the computer screen. It allows us to identify and color code sulci, gyri, lesions, or any structure on the 3-D rendered volume, on the original coronal slices, or on any slice obtained by slicing through the 3-D volume. Any such markings are immediately available on any 2-D view intersecting the marked structure and on the 3-D reconstructed brain. The 3-D reconstructed brain can be viewed in any direction, can be split into smaller regions, and can be measured volumetrically. Surface and linear measurements can also be obtained.

Figure 2-1 shows the left hemisphere of such a reconstructed normal brain seen from the lateral and mesial views. Some major sulci that divide the hemispheres into their basic constituents, the lobes and the gyri, are marked. (See also Damasio, 2005; Duvernoy, 1991; Ono, Kubik, & Abernathey, 1990; among others, for more anatomic information.) On the lateral surface the most prominent sulcus is

Figure 2-1. **A.** Lateral and mesial views of the left hemisphere of a brain reconstructed in 3-D from thin MRI slices using Brainvox. The major sulci are identified. Abbreviations are as mentioned in the text. **B.** The same lateral and mesial views of the left hemisphere, with the different gyri and their sulcal limits as seen in **A** (dark lines). The light gray lines show the remainder of the gyri limits (some are sulci, others are arbitrary lines). **C.** The same lateral and mesial views seen in **A** and **B**, here with Brodmann's cytoarchitectonic fields marked. (For more details on sulcal, gyral and cytoarchitectonic fields see Damasio, 2005.)

the sylvian fissure (SF), a mostly horizontal sulcus running anteroposteriorly. The SF separates the temporal lobe, below, from the frontal and parietal lobes, above. The posterior end of the SF usually shows an asymmetric course when the right and left hemispheres are compared (Damasio, 2005). It tends to be longer and lower on the left, and shorter and turning upward on the right. The other prominent sulcus, usually continuous, on the lateral surface of the hemispheres is the central sulcus (CS). It runs from the interhemispheric fissure (the separation between the two hemispheres) above, toward the SF, below, taking a posteroanterior course. It may or may not reach the sylvian fissure proper. This sulcus separates the frontal lobe, in front, from the parietal lobe (behind). Parallel to the central sulcus are two other sulci, which are more often than not subdivided into more than one segment. They are, anteriorly, the pre-central sulcus (preCS), and posteriorly, the post-central sulcus (postCS). Together with the central sulcus they define the pre-central and post-central gyri (preCG, postCG), respectively, the most posterior sector of the frontal lobe, often designated as the motor cortex (where the primary motor cortex or Brodmann's field 4 can be found), and the most anterior sector of the parietal lobe, the sensory cortex (where primary sensory cortices or Brodmann's fields 3, 1, and 2 are seen). Very often we speak of these two gyri as the "sensorimotor" cortices. There are two other prominent sulci to consider in the dorsolateral surface of the frontal lobe, namely the superior frontal sulcus (SFS) and the inferior frontal sulcus (IFS). Both run anteroposteriorly from the pre-central sulcus toward the polar region of the frontal lobe, usually stopping before reaching the pole. In relation to "language," the inferior frontal sulcus is probably the more important of the two, given that it forms the superior limit of the inferior frontal gyrus (IFG), in which we find the frontal operculum. The inferior frontal gyrus comprises distinct subdivisions corresponding to Brodmann's fields 44, 45, and 47. The combination of field 44 and 45 on the left is traditionally called Broca's area. Between the inferior frontal sulcus and the superior frontal sulcus lies the middle frontal gyrus (MFG) occupied by Brodmann's fields 46, 9, 8, and 6. The superior frontal sulcus constitutes the lateral and inferior limit of the superior frontal gyrus (SFG), which continues into the mesial surface of the hemisphere. On this dorsolateral aspect of the gyrus we find Brodmann's fields 9, 8, and 6. The most anterior sector of the frontal lobe, the polar region just in front of the three horizontal frontal gyri just described, also known as the frontal pole, is occupied by Brodmann's field 10.

In the temporal lobe there is one consistent sulcus, more or less parallel to the sylvian fissure, the superior temporal sulcus (STS). Together with the sylvian fissure it delineates the superior temporal gyrus (STG), which corresponds to Brodmann's field 22. Another sulcus, also parallel, can be seen on the lateral surface, the inferior temporal sulcus

(ITS). This sulcus is constituted, more often than not, by several small segments and can be difficult to recognize. It creates the separation between the middle temporal gyrus (MTG) containing Brodmann's field 21, above, and the inferior temporal gyrus (ITG) containing Brodmann's field 20, below. The posterior sector of both these gyri contain Brodmann's field 37, which continues into the inferomesial surface of the temporal lobe.

The parietal lobe is also subdivided by a prominent anteroposteriorly running sulcus, the intraparietal sulcus (IPS), starting at the post-central sulcus and going in the direction of the occipital lobe. This sulcus is more easily seen when looking at the brain from above (Fig. 2-2), and it separates the inferior parietal lobule (IPL), containing Brodmann's field 40 and 39, from the superior parietal lobule (SPL), containing Brodmann's field 5 and 7. The inferior parietal lobule is itself subdivided into two major gyri, namely the supramarginal gyrus (SMG), anteriorly (Brodmann's area 40), sitting on top of the sylvian fissure and around its posterior end, and the angular gyrus (AnG), or Brodmann's field 39, sitting behind and below the former, around the posterior end of the superior temporal sulcus.

No sulcal demarcation exists between the parietal, temporal, and occipital lobes on the lateral surface of the hemispheres.

On the mesial surface of the hemispheres, several major sulci are to be considered. One is the cingulate sulcus (CingS), continuous or subdivided into several segments, more or less parallel to the contour of the corpus callosum (CC). The corpus callosum is the midline white-matter structure containing the fibers connecting the cortices of the two hemispheres. Together with the pericallosal sulcus, directly around the corpus callosum, it creates the limit of the cingulate gyrus (CingG), containing prominently Brodmann's fields 23 and 24, plus several other regions buried within the sulcus itself. At its posterior end, the cingulate sulcus turns upward in what is known as the ascending branch of the cingulate sulcus.

In the mesial aspect of the temporal lobe there is one consistent sulcus, parallel to the long axis of the temporal lobe, the collateral sulcus (ColIS), which separates the fifth or parahippocampal gyrus (parahipG), containing Brodmann's field 28, from the inferotemporal region, the name often given to the temporal cortices between the collateral sulcus and the superior temporal sulcus described earlier (see also Fig. 2-2 for a better view of this sulcus). This inferotemporal region also includes the inferior temporal gyrus (ITG) and the fourth temporal gyrus (4thTG), containing both Brodmann's fields 20 and 37.

Mesially, the parietal lobe, the sector behind the ascending branch of the cingulate sulcus, is clearly separated from the occipital lobe by a sulcus running superoinferiorly and slightly posteroanteriorly, the occipitoparietal sulcus (OPS). The parietal region in front of this sulcus is also known as the precuneus (preCu) or Brodmann's field 7.

Figure 2-2. **A.** The inferior and superior views of the brain with markings of the most important sulci seen in those views. **B.** The same views as in **A**, here with identification of the gyri. It is important to note that these views show a very large surface of brain, something that viewing only the lateral and mesial aspects, as in Figure 2-1, may not be evident.

No distinct sulcus separates the occipital from the temporal lobe. However, in the mesial aspect of the occipital lobe itself there is a distinct and consistent sulcus, running anteroposteriorly—the calcarine fissure (CF)—whose two lips contain the primary visual cortex or Brodmann’s field 17. The calcarine fissure separates the mesial aspect of the occipital lobe into two sectors: the supracalcarine region (sCR), or cuneus (CU), containing Brodmann’s fields 18 and 19, and the infracalcarine region (iCR), also containing Brodmann’s fields 18 and 19.

Typically, the occipitoparietal sulcus and the calcarine sulcus join just behind the posterior end of the corpus callosum, which is also known as the splenium. The cortex between the splenium and the juncture of the occipitoparietal and calcarine sulci is usually referred to as the “retrosplenial” area, which contains several different cytoarchitectonic areas.

Most of the cerebral cortex is actually not readily visible in any of the views we have been dealing with but rather are

hidden within the hemispheric sulci, something that can be more easily appreciated if we look at coronal cuts throughout the hemispheres (Fig. 2-3). Furthermore, two surfaces of cortex are completely hidden from view when we look only at lateral, mesial, inferior, or superior views. These are the insula (In) and the Heschl’s gyrus (HG), the latter also known as primary auditory cortex containing Brodmann’s fields 41 and 42 (Fig. 2-3). Heschl’s gyrus occupies the superior surface of the superior temporal gyrus. This structure divides the superior temporal gyrus into two distinct segments, one anterior and one posterior to it, both containing Brodmann’s field 22. The posterior sector is also known as the planum temporale, which typically shows a marked asymmetry between the right and the left hemispheres, being usually larger on the left, where it constitutes the major portion of the classical Wernicke’s area. The insula is also completely hidden. It can be found by opening up the sylvian fissure, separating the temporal lobe from the frontoparietal operculum. (See Damasio, 2005, for images depicting all these hidden structures.)

Figure 2-3. Two coronal cuts through the same brain seen in Figures 2-1 and 2-2, and whose left hemisphere is depicted on the right. The lines on the 3-D-reconstructed hemisphere represent the placement of the cuts seen on the left. Note that most of the cortical rim is actually not on the visible surface of the hemisphere but rather buried within the sulci. The ventricles appear as clearly delineated black structures. The subcortical gray areas, as well as the insula, can easily be identified in these cuts.

Abbreviations are those used in the text. (The coronal slices are presented according to the radiologic convention, with the right hemisphere on the left and the left hemisphere on the right. This convention is respected in all illustrations. Brain slices are always presented from anterior to posterior or from the most inferior view to the most superior view.)

Figure 2-4. 3-D reconstruction of the brain of a patient with stroke. Acutely the patient had Broca's aphasia and mild right-arm and facial paresis as a result of an infarction in a middle branch of the MCA (pre-central artery). Recovery was fairly quick. In the chronic epoch there were no motor defects and language had improved remarkably. The lesion occupies the anterior half (lower two-thirds) of the pre-central gyrus, not damaging the motor cortex in the central sulcus (arrows) in the left hemisphere. The lesion also damages the posterior sector of the inferior frontal gyrus (the pars opercularis of the frontal operculum). It does not damage insula or basal ganglia, which can be seen to be intact in the coronal slices. In summary, it is a lesion that partially damages premotor cortices 6 and 44, but leaves most of Broca's area intact.

We should also refer briefly to some of the more important subcortical gray matter structures (Fig. 2–3). Within the temporal lobe, in the depth of the parahippocampal gyrus, we find the hippocampus proper (Hip) and the amygdala (Amy). Within the frontal lobe we find the basal ganglia (BG) with its separate constituents, the caudate nucleus and the lenticular nucleus.

Vascular Supply of the Cerebral Hemispheres

Before we begin our discussion about the neurologic underpinnings of the aphasias, we need one more aside, namely, a very brief overview of the brain's vascular supply. This is important as the most common cause of aphasia is a vascular lesion, and because the vascular lesions causing aphasia have allowed us to use the lesion method efficiently to find the neural underpinnings of language disorders.

The brain's vascular supply comes from the internal carotid artery (the external carotid giving blood supply to the extracranial tissues). (See also Day, 1987; Damasio, 1987b; Lazorthes, Gouaze, & Salamon, 1976; Szilda, Bouvier, Hori, & Petrov, 1977; and Waddington, 1974, for more detail of the vascular supply of the brain.)

The blood supply for each hemisphere comes mostly from the internal carotid artery (ICA), which is subdivided into two major branches: the anterior cerebral artery (ACA) mesially, and the middle cerebral artery (MCA) laterally. The ACA supplies most of the mesial and orbital sectors of the frontal lobe and the mesial sector of the parietal lobe. The MCA provides the blood supply for most of the inferior and lateral sectors of the temporal lobe, and the lateral sector of the frontal, parietal, and occipital lobes. The blood supply for the mesial occipital and temporal lobes comes from the posterior cerebral artery (PCA), a branch of the basilar artery.

The mesial aspect of the most anterior sector of the temporal lobe gets its blood supply from the anterior choroidal artery (antChA), a branch of the internal carotid artery before the internal carotid subdivides into middle and anterior cerebral arteries. The three main vascular territories mentioned, the ACA, MCA, and PCA, are interconnected in each hemisphere and to the opposite hemisphere by smaller vessels, the communicating arteries, forming what is called the circle of Willis.

The area at the edges of each of the three main territories receives capillaries from the three arterial territories as they meet. This “horseshoe” region occupies a sector on the superior frontal gyrus, the superior parietal lobule and the angular gyrus, and the posterolateral aspect of the occipital lobe, continuing on the inferior surface of the temporal lobe toward the temporal pole. It is normally designated as the watershed area. It is important to have an idea about this region for two specific reasons. First, because of its dual blood supply, this region is more resistant to infarction.

Second, because its supply is achieved by terminal, thinner vessels, the region is more vulnerable to severe decreases in arterial blood pressure. In such events, as, for example, in cases of cardiac arrest, this is one of the regions that suffers the most intense deprivation of oxygen. In a stroke caused by a severe and sustained drop in blood pressure, these areas may be compromised. When this happens in the left hemisphere the consequence can be an aphasia of the transcortical type.

Another region is supplied by terminal arteries, but does not have dual blood supply: the region of the basal ganglia. This region gets its blood supply from multiple, thin, and fragile perforating vessels that leave the stem of the middle cerebral artery at almost right angles. This configuration makes them very vulnerable to sudden decreases in blood pressure in the main supplying vessel as well as to arterial blockage by emboli. Damage in these territories in the left hemisphere may lead to infarcts in the basal ganglia causing “atypical aphasias.”

Because the blood supply to the brain is carried out by small vessels that penetrate the hemispheres through the cortex in the direction of the underlying white matter, an obstruction of any of the major supply vessels tends to create an area of infarct that is broader on the surface than in the depth. It is the reason for the well-known and traditional description of the image of a stroke as a wedge-shaped form with the base turned toward the cortex.

NEUROANATOMICAL CORRELATES OF THE APHASIAS

Classic Aphasias

Broca's Aphasia

Broca's description of the language impairment seen in his patient Leborgne suggests that the condition was worse than what we associate today with a typical Broca's aphasia. The speech output was so sparse that it was largely confined to the word “tant,” and comprehension of spoken language was also severely compromised (Broca, 1861). In modern terms, the disorder that began the history of aphasiology and whose lesion became associated with Broca's aphasia, would probably be described as a global aphasia. Usually, Broca's aphasia is characterized by sparse agrammatical discourse, but not by complete absence of speech.

Even today, there are still unresolved issues about the anatomical underpinnings of Broca's aphasia. For instance, in 1978 Mohr and collaborators pointed out that infarctions confined to the inferior frontal gyrus cause only a brief period of mutism, which resolves into effortful speech but generally does not cause significant linguistic deficits (Mohr, Pessin, Finkelstein, Funkenstein, Duncan, & Davis, 1978). They claimed that such lesions do not cause a Broca's aphasia in the proper sense. The same investigators suggested

Figure 2-5. 3-D reconstruction of the brain of a patient who acutely also had Broca's aphasia together with facial and arm paresis as a result of an infarction in the territories of the anterior and middle branches of the MCA (pre-frontal and pre-central arteries). Compared to the image in Figure 2-4 the damage is larger anteriorly. This patient also recovered but was left with mild weakness in the right arm and with language deficits that were still classified as a mild Broca's aphasia. The lesion occupies the inferior third of the entire pre-central gyrus, involving the central sulcus region in the left hemisphere (Brodmann's fields 6 and 4). It also involves the posterior two-thirds of the inferior frontal gyrus corresponding to the entire frontal operculum (pars opercularis and triangularis and even part of pars orbitalis); all of Broca's area is involved (fields 44, 45, and part of 47). It is only the outer rim of the inferior frontal gyrus that is spared (arrows). The lesion also extends further into the underlying white matter than in the previous case (Fig. 2-4). It damages insula but does not damage the basal ganglia (see the two lower coronal cuts on the right).

that the lesion necessary to produce the more severe language disturbance usually classified as Broca's aphasia is far larger, requiring the involvement of all of the frontal operculum and of the insula. In our experience, chronic and long-lasting language deficits conforming to the characteristics of a Broca's aphasia in the chronic epoch do indeed require damage of a sizable area of the frontal operculum and surrounding tissue. However, in the acute epoch of the condition, a small and circumscribed infarct of the frontal operculum can also produce a nonfluent language deficit with all the characteristics of a typical Broca's aphasia (Fig. 2-4). Similar findings have been described by Tonkonogy and Goodglass (1981). These authors pointed out that a small lesion involving the frontal operculum had caused linguistic deficits in the acute epoch, although the deficits were not long-lasting. In the same study, the authors showed that an equally small lesion placed in an immediately posterior position, in the rolandic operculum, did not cause any phonemic, lexical, or syntactical processing difficulties, but rather dysarthric and dysprosodic speech output (see also Schiff, Alexander, Naeser, & Galaburda, 1983).

When language deficits are classified as a Broca's aphasia in the acute phase and when they persist for months, it is

usually the case that damage in a large sector of the inferior frontal gyrus is found, as seen in Figure 2-5, for example. (See also Alexander, Naeser, & Palumbo, 1990, and Naeser & Hayward, 1978.) In other cases, the infarct may be in the territory of most of the anterior branches of the MCA and will have damaged not just the cortex of the frontal operculum (Brodmann's fields 44 and 45), but also have extended into the underlying white matter and involved the insula and the basal ganglia, as well as the inferior sector of the pre-central gyrus. Other such chronic Broca's aphasias will have started as a global aphasia in the acute period. (See also the section on Global Aphasia, below, and Fig. 2-9.)

Wernicke's Aphasia

There has never been the same degree of controversy in relation to the symptom complex or to the anatomical correlate of the prototypical fluent aphasia: Wernicke's aphasia. Wernicke's original description of the language impairment and of its underlying brain damage (Wernicke, 1886) is consonant with contemporary investigations (Damasio, 1981, 1987a; Kertesz, 1979; Kertesz, Harlock, & Coates, 1979; Kertesz, Lau, & Polk, 1993; Knopman, Selnes,

Figure 2-6. 3-D reconstruction of the brain of a patient who acutely presented with Wernicke's aphasia and right hemianopsia as a result of an infarction in the territory of the temporal branches of the MCA. The visual field persisted in the chronic epoch as did the aphasia. The lesion involves most of the dorsolateral aspect of the left temporal lobe. The superior and middle temporal gyri are completely occupied by damaged tissue (Brodmann's fields 22, 21, and part of 37), as well as the inferior sector of the supramarginal gyrus (field 40), and the anterior sector of the angular gyrus (field 39). The damage extends deep into the underlying white matter, destroying the posterior segment of the insula and reaching the ventricle in the posterior cuts (see coronal slices 2 and 3). Cortical areas that are destroyed beyond the insula include the primary auditory cortices in the transverse gyrus of Heschl (fields 41 and 42) and all of the surrounding superior temporal gyrus (field 22), which in the posterior portion forms Wernicke's area (also seen in the coronal slices on the right).

Niccum, & Rubens, 1984; Mazzocchi & Vignolo, 1979; Naeser & Hayward, 1978; and Selnes et al., 1983; 1984; 1985, among others). A typical case of Wernicke's aphasia due to an infarct of the temporal arteries is depicted in Figure 2-6. The lesion is seen in the posterior sector of the superior temporal gyrus (Brodmann's field 22). This region is the core of Wernicke's area. The lesion also extends into the posterior region of the middle and inferior temporal gyri (part of Brodmann's fields 37, 20, and 21), and into part of the inferior parietal lobule, destroying the lower sector of the supramarginal and the angular gyri (Brodmann's fields 40 and 39). In such cases, recovery is limited and a severe fluent aphasia may persist for months. A noticeable aphasia may persist for years.

Conduction Aphasia

When damage is limited to the supramarginal gyrus (Brodmann's field 40) the result is a fluent aphasia, distinct from Wernicke's aphasia, known as "conduction aphasia." The fundamental clinical characteristic of conduction

aphasia is a severe inability to repeat verbatim a heard sentence. In severe cases, even single words are not repeated. This repetition deficit is disproportionately severe in comparison to the ability to produce spontaneous speech or to understand speech. (See Benson, Sheremata, Bouchard, Segarra, Price, & Geschwind, 1973; Geschwind, 1965; Konorski, Kozniowska, & Stepien, 1961; Liepmann & Pappenheim, 1914, for the early descriptions of the syndrome and its underlying brain damage, and Damasio & Damasio, 1980; Kertesz et al., 1979; Naeser & Hayward, 1978; Rubens & Selnes, 1986, among others, for later descriptions.)

Typical cases of conduction aphasia are often caused by damage to the supramarginal gyrus (see Fig. 2-7 for an example). This is the case of a patient who, at age 33, suffered an intracerebral hemorrhage to the left parietal lobe that lead to the diagnosis of an intracerebral arteriovenous malformation (AVM). To excise the entire malformation, the neurosurgeon had to remove the entire supramarginal gyrus, while being able to spare the entire superior temporal gyrus. After surgery this patient presented with a

Figure 2-7. 3-D reconstruction (in this instance from a thin-cut CT scan) of the brain of a patient with conduction aphasia resulting from an arteriovenous malformation that ruptured and bled. The condition required the subsequent surgical removal of most of the supramarginal gyrus. In the chronic epoch this patient continues to display a mild conduction aphasia. The lesion involves the supramarginal gyrus (Brodmann's field 40). Wernicke's area is mostly intact.

typical conduction aphasia. She was unable to repeat even short sentences, for example, "Take this home." As is typical of conduction aphasia, comprehension of the sentences to be repeated was preserved. For example, asked to repeat "The orchestra played and the audience applauded," verbatim, the patient failed entirely. Yet, when asked about the meaning of the sentence she paraphrased it as "There was music and they liked it, they clapped." Even today, almost 20 years after the onset of her aphasia, this patient has difficulty in repeating sentences longer than three or four words, although her other acute deficits, for example, her naming impairment, have improved remarkably.

Damage to the cortex of the supramarginal gyrus and to its underlying white matter compromises the arcuate fasciculus,

the pathway that connects posterior and anterior language areas as first described by Dejerine (1906). Geschwind (1965) proposed that the inability to repeat was a result of damage to the pathway and although the essence of this explanation may well be correct for some cases of conduction aphasia, it may not be adequate for all. It is certainly the case that conduction aphasia can result from somewhat different lesion patterns. In 1980 we described patients with lesions in left auditory cortex and insula, without involvement of supramarginal gyrus, who presented with a typical conduction aphasia (Damasio & Damasio, 1980). Rubens and Selnes (1986) also described a similar presentation with exclusively left insular damage. Interestingly, the arcuate fasciculus seems not to course exclusively in the depth of the supramarginal gyrus as described by Dejerine but may instead

be a large sheath of white matter whose lower segment courses under the insula (Galaburda & Pandya, 1983).

Global Aphasia

While occlusion of some of the anterior branches of the middle cerebral artery causes a nonfluent Broca's type of aphasia, and occlusion of posterior temporal and parietal branches causes a fluent, Wernicke's type of aphasia, occlusion of the middle cerebral artery itself, prior to its branching, causes extensive damage to frontal, parietal, and temporal regions, and results in a more severe language deficit known as "global aphasia." As the description indicates, the ensuing deficits involve both production and comprehension of language, and patients may be left with little speech other than for stereotyped and automated words and stock sentences. This sort of stroke also causes a severe restriction of movement in the right side of the body, a right hemiplegia. A typical image of the brain lesion of such a patient is shown in Figure 2-8. The signs of global aphasia—namely, little language output, severe comprehension deficits in both oral

and written form, inability to repeat, and inability to write—may appear in association with more restricted lesions. A large left frontal-lobe lesion, involving not only Broca's area but extending into other frontal gyri, the pre- and post-central gyri, the supramarginal gyrus, the insula, and the basal ganglia, sparing the temporal lobe altogether, may present as a severe global aphasia. Such an "acute" global aphasia may resolve into a less severe albeit remarkable language deficit and be eventually classified as a severe Broca's aphasia (see Fig. 2-9 for an example).

One other anatomical presentation of global aphasia deserves mention. The severe and pervasive linguistic deficit of global aphasia, which is usually accompanied by a right hemiplegia, may, on occasion, present without any motor deficits (see Legatt, Rubin, Kaplan, Heaton, & Brust, 1987, and Tranel, Biller, Damasio, Adams, & Cornell, 1987). Such a presentation is the consequence of two separate lesions due, for instance, to multiple emboli causing infarctions in both anterior and posterior branches of the middle cerebral artery. In other words, instead of a blockage of the main trunk of the artery, at the level of the stem, resulting in one

Figure 2-8. MAP-3 of the brain of a patient with a large left MCA infarct resulting in severe global aphasia and right hemiparesis. (MAP-3 is a technique that allows the 3-D visualization of lesions of individual subjects in a common normal target brain. For details about the technique see Damasio, 2000, 2005, and Frank et al., 1997). The lesion involves most of the frontal-lobe structures in the territory of the anterior branches of the MCA, including the inferior frontal gyrus with Broca's area (Brodmann's fields 44, 45, and 47), most of the sensorimotor cortices in the pre-central and post-central gyri (fields 6, and 4, and 3, 1, and 2), and the supramarginal gyrus (field 40), as well as all of the superior temporal gyrus (fields 22, 41, and 42), including Wernicke's area (W). The insula and the basal ganglia, as well as the white matter in the frontal and parietal lobes, are also damaged.

Figure 2-9. 3-D reconstruction of the brain of a patient with a large infarct in the territory of the anterior frontal branches of the left MCA as well as the anterior-temporal branches. This patient also presented acutely with a right hemiparesis and global aphasia. In the chronic epoch, however, language had improved enough to have the aphasia reclassified as a severe Broca's aphasia. The infarct involves prefrontal cortices in both the inferior and part of the middle-frontal gyri (Brodmann's fields 45, 47, and part of 46 and 9), premotor regions in the same gyri (Brodmann's fields 44 and 6), sensorimotor regions in the pre- and post-central gyri (Brodmann's fields 4, 3, 1, and 2), the anterior sector of the superior temporal gyrus (Brodmann's field 22), and the dorsolateral sector of the temporal pole (Brodmann's field 38). The insula is equally damaged and the infarct extends deep into the subcortical structures, damaging the basal ganglia (caudate and putamen), as seen in the coronal cuts on the right. The important feature to note is that the primary auditory cortex (Brodmann's fields 41 and 42) in Heschl's gyrus is only partially damaged (see cut 4) and that both Wernicke's area (posterior Brodmann's field 22) and the supramarginal gyrus (Brodmann's field 40) are spared, as can be seen in the two cuts in the bottom row and in the 3-D-reconstructed hemisphere on the left.

large lesion, more peripheral blockages occur and thus result in more than one lesion. As described in Tranel et al. (1987), there may be an area of infarct in the left prefrontal/premotor cortices, and then another in the left posterior temporal-parietal region, sparing the sensorimotor cortices in between (Fig. 2-10). As is to be expected from the lesion placement, patients with this form of global aphasia recover faster and better than do those with classic global aphasia.

Transcortical Aphasias

The transcortical aphasias are characterized by normal word and sentence repetition. Transcortical sensory aphasia is

diagnosed when a patient presents with fluent paraphasic speech and with poor auditory comprehension but with intact word and sentence repetition. There is a practical value in recognizing this type of aphasia as separate from Wernicke's aphasia because it indicates to the clinician that both the primary auditory cortices (Brodmann's fields 41 and 42 in the transverse gyrus of Heschl) and the posterior sector of the superior temporal gyrus (Wernicke's area proper) are spared. In transcortical sensory aphasia, the damage is posterior and inferior to the above-mentioned regions. It may involve the angular gyrus (Brodmann's field 39) and the posterior sector of the middle temporal gyrus (Brodmann's field 37).

Figure 2-10. T2-weighted MR image and MAP-3 of the brain of another patient who acutely presented with global aphasia, but this time without hemiparesis. This patient improved rapidly and was eventually left with only a mild language deficit. Note the two separate areas of infarction in the left hemisphere: the more anterior lesion is in the territory of the anterior branches of the MCA, damaging the superior sector of the frontal operculum in the inferior frontal gyrus (Brodmann's field 45), and the posterior sector of the middle frontal gyrus (field 6); the more posterior lesion is in the territory of the posterior branches of the MCA, damaging the supramarginal gyrus (field 40) and probably a portion of the posterior sector of the superior temporal gyrus (field 22). The sensorimotor cortices in the pre- and post-central gyri, the insula, and the basal ganglia are intact, as is most of the frontal operculum and most of Wernicke's area (which, however, is not completely spared).

On occasion the lesions may extend into the lateral aspect of the occipital lobe (Brodmann's fields 19 and 18) or into more anterior sectors of the middle temporal gyrus (Brodmann's field 21) See Alexander, Hiltbrunner, & Fischer, 1989b; Damasio, 1981, 1987a; Freedman, Alexander, & Naeser, 1984; and Kertesz et al., 1979, among others.) In some instances, this same type of aphasia can be detected with exclusively subcortical lesions underlying the cortical regions mentioned above, as described in Damasio (1987a). See Figure 2-11 for an example of a transcortical sensory aphasia.

When patients present with a nonfluent language deficit and preserved repetition, we talk about a transcortical motor aphasia. The location of the lesions responsible for this type of aphasia is less consistent than for the transcortical

motor type. We may find transcortical motor aphasia in patients with small subcortical lesions located immediately anterior to the frontal horn of the left lateral ventricle, a part of the so-called anterior watershed area (Fig. 2-12). We also may find transcortical motor aphasia with lesions in the left frontal lobe involving prefrontal and premotor cortices (Brodmann's fields 10, 9, 46, 8, and 6, respectively).

Isolation of the Speech Areas

The combinations of the lesions described for transcortical motor aphasia with those responsible for transcortical sensory aphasia may result in an extensive lesion that isolates the "speech area." Patients with such lesions have a

Figure 2–11. 3-D reconstruction of the brain of a patient who presented with a fluent aphasia but intact repetition. This is a typical presentation of transcortical sensory aphasia. The cause of the syndrome was an acute intracerebral hemorrhage in the left hemisphere. In the chronic epoch, after resolution of the hemorrhage, we see an area of encephalomalacia in the left angular gyrus (Brodmann's field 39) and underlying white matter but no damage to the posterior sector of the superior temporal gyrus. There is also evidence of some enlargement in the anterior sector of the sylvian fissure, possibly due to atrophy in the frontal gyri. However, no brain-tissue damage can be detected in these regions.

severe dual deficit in language comprehension and intentional language formulation, associated with a remarkably preserved capacity for aural repetition of even long sentences, devoid of any proper comprehension of sentence meaning. The repetition is achieved with so much ease that it is best described as echolalia, the immediate and rather accurate repetition of any verbal material received auditorily. When asked a question the patient may actually repeat the question verbatim instead of providing an answer. Geschwind described one of these rare cases, which was due to severe carbon monoxide poisoning (Geschwind, Quadfasel, & Segarra, 1968). The underlying pathology was a watershed infarction nearly occupying the totality of the watershed region between the anterior and middle cerebral arteries and the posterior and middle cerebral arteries.

Crossed Aphasia

As mentioned earlier, the diagnosis of crossed aphasia applies when a fully right-handed subject has a lesion in the right hemisphere and becomes aphasic as a consequence of that lesion (Fig. 2–13). The incidence of such cases is low (Alexander, Fischette, & Fischer, 1989a; Castro-Caldas, Confraria, & Poppe, 1987). The same sort of individuals may fail to develop aphasia following lesions located in “language-related” areas of the left hemisphere, a situation known as “crossed non-aphasia” (Fig. 2–14).

Atypical Aphasias

With the advent of the modern neuroimaging techniques, beginning with early CT scans in 1972 and then with MRI

Figure 2-12. 3-D reconstruction of the brain of a patient who suffered a relatively small infarct in the left hemisphere, in the region of the anterior watershed territory. The external surface of the brain is intact, including all of the cortical mantle in Broca's and Wernicke's areas. The area of damage can only be seen in the coronal slices as an area of decreased signal in the white matter just anterior to the frontal horn of the left ventricle (see the first coronal cut). It extends posteriorly lateral to the lateral ventricle. It does not damage the caudate nucleus or the insula. This patient showed the typical presentation of transcortical motor aphasia.

scans since the early 1980s, it became possible to identify the neural underpinnings of some aphasic presentations that were classified as "atypical". The atypicality was usually the result of a mixture of features of nonfluent and fluent aphasia that produced a blend quite distinctive from the severe and all-encompassing deficits of a global aphasia.

In the early 1980s several authors provided anatomical evidence for the connection between such a mixture of symptoms and infarcts in the basal ganglia. More specifically, the infarcts were located in the left hemisphere, in the head of the caudate nucleus, and in the putamen (Aran, Rose, Rekate, & Whiteaker, 1983; Brunner, Kornhuber, Seemiuller, Suger, & Wallesch, 1982; Damasio et al., 1982; Damasio, Eslinger, & Adams, 1984; Fromm, Holland, Swindell, & Reinmuth, 1985; Naeser et al., 1982). No aphasia at all is seen when the damage occurs in the right hemisphere. The vascular territory affected here

was that of the striate arteries, a set of small terminal arteries arising from the stem of the middle cerebral artery. When infarcts are placed more laterally, involving only the lateral aspect of the putamen and the external and extreme capsules, and even the anterior insula, no aphasia is observed although the patient may show dysarthria and dysprosodia.

The early reports, based on relatively low-resolution scans of the 1970s, raised the possibility that there might be undetected damage in cortical regions. In a postmortem study, however, Barat and colleagues demonstrated that there was no damage outside the basal ganglia (Barat, Mazaux, Bioulac, Giroire, Vital, & Arne, 1981). Under the microscope, no area of abnormality could be seen in the cortical language areas. Modern, high-resolution MR scans confirm that this syndrome does occur as a result of damage to the left basal ganglia without involvement of the cortical language regions (Fig. 2-15).

Figure 2-13. T1-weighted MR image and MAP-3 of a right-handed patient with an infarct in the territory of the right anterior branches of the MCA (pre-frontal, pre-central, and central) and the territory of the anterior and middle temporal arteries. He presented with a left hemiparesis, visual neglect, anosognosia, visuospatial deficits, and severe atypical aphasia—a typical presentation for a “crossed aphasia.” There is damage to the right hemisphere in the frontal operculum of the inferior frontal gyrus (part of Brodmann’s fields 44, 45, and 47), the sensorimotor cortices in the lower tier of the pre- and post-central gyri (fields 6 and 4, and 3, 1, and 2), the inferior sector of the supramarginal gyrus (field 40), most of the anterior sectors of the superior temporal gyrus (field 22), the auditory cortices in Heschl’s gyrus (fields 41 and 42), as well as extension into insula and deep structures such as the basal ganglia. There is no sign of damage in the left hemisphere.

The occurrence of aphasia with damage in the left thalamus has been noted with vascular lesions (Alexander & Loverme, 1980; Cappa & Vignolo, 1979; McFarling Rothi, & Heilman, 1982; Mohr, Wafters, & Duncan, 1975), and with thalamic tumors (Arseni, 1958; Cheek & Taveras, 1966). The modern neuroimaging techniques have helped establish a precise anatomical basis for these aphasia (Archer, Ilinsky, Goldfader, & Smith, 1981; Cohen, Gelfer, & Sweet, 1980; Graff-Radford & Damasio, 1984; Graff-Radford, Damasio, et al., 1985; Graff-Radford, Schelper, et al., 1985). Lesions in the anterior nuclei of the left thalamus, involving mostly the lateroventral and anteroventral nuclei were related to aphasia of the transcortical type (Fig. 2-16). Lesions of the left thalamus that spare the anterior nuclei, and lesions of the right thalamus, result in sensory and motor deficits but not in aphasia.

Anomic Aphasia

Difficulty in producing the words that denote concrete entities presented visually, the most typical situation of “confrontation naming,” is often present in most types of aphasia. On occasion, however, such a deficit is disproportionate in relation to other language deficits, or can even occur in isolation, something that was noted as early as 1898 by Pitres (Pitres, 1898). In such situations, it may be reasonable to use the label “anomic aphasia” or “amnesic aphasia.”

In 1986 Goodglass called attention to the fact that a dissociation between the production of words denoting actions and those denoting concrete entities could be found in patients with both nonfluent and fluent aphasia, respectively (Goodglass et al., 1986; see also Daniele, Giustolisi, Silveri, Colosimo, & Gainotti, 1994). In 1984 Warrington and Shallice had called attention to the presentation of different

Figure 2-14. CT scan and MAP-3 of the brain of a right-handed patient with a very large left MCA infarct followed by a partial frontotemporal brain resection. Neither the infarct nor the subsequent surgery resulted in aphasia; there was only mild dysarthria. The patient, however, did present severe impairment of visual memory, visuoconstructional abilities, and some degree of anosognosia. These symptoms are suggestive of a lesion in the nondominant hemisphere, suggesting reversed language dominance in this right-handed subject. We would talk about a “crossed non-aphasia.”

Figure 2-15. A. T1-weighted MR image of a patient who presented acutely with a left basal ganglionic hemorrhage and an atypical aphasia. This scan, obtained in the chronic epoch, shows a lesion in the head of the caudate nucleus and the putamen, as well as the internal capsule. However, there is no damage to cortical regions in the frontal operculum, nor to posterior temporal cortices. **B.** T2-weighted MR image of a patient who presented acutely with dysarthria, but no aphasia, as a result of a ventriculostriatal infarct affecting the posterior sector of the putamen. Most of the putamen is, however, spared, as is the caudate nucleus.

Figure 2-16. CT scan of a patient who presented acutely with an atypical aphasia due to an infarct of the anterior thalamic arteries. There is a low-density lesion in the anteromesial region of the left thalamus.

patients with category-specific semantic impairments (Hart, Berndt, & Caramazza, 1985; Hillis & Caramazza, 1991; Semenza & Zettin, 1989; Silveri & Gainotti, 1988; Warrington & McCarthy, 1994; Warrington & Shallice, 1984).

The possible anatomical underpinnings for such category-specific word retrieval deficits only began to be elucidated over the past decade. Today there is ample evidence that the inferotemporal cortex of the left cerebral hemisphere can be segregated into distinct areas whose damage causes category-specific word retrieval defects for visually presented concrete entities (Caramazza & Hillis, 1991; Damasio et al., 1990; Damasio & Tranel, 1993; Damasio, Grabowski, Tranel, Hichwa, & Damasio, 1996; Hillis & Caramazza, 1991; Miozzo, Soardi, & Cappa, 1994; Perani, Cappa, Bettinardi, Bressi, Gorno-Tempini, Matarrese, & Fazio, 1995; Tranel, Damasio, & Damasio, 1997; Tranel, Logan, Frank, & Damasio, 1997). Convergent findings have come through functional studies of nonlesioned brains (Buchel et al., 1998; Bunn et al., 1998; Damasio et al., 1996; Frith, Friston, Liddle, & Frackowiak, 1991; Martin et al., 1996; Mazoyer et al., 1993; Nobre et al., 1994; Ojemann, 1983; 1991; Petersen et al., 1988; Schlaghecken, 1998).

Work from our laboratory has shown that lesions located exclusively in the left temporal pole can cause deficits in the retrieval of proper names for unique persons, in the presence of normal recognition of those persons (Damasio et al., 1996; Damasio, Tranel, Grabowski, Adolphs, & Damasio, 2004). Such deficits are not seen with lesions in the temporal pole of the nondominant hemisphere although damage to the right temporal pole may result in a deficient recognition of unique persons (Tranel, Logan, et al., 1997). (See Damasio et al., 1996; 2004, and Tranel, Logan, et al., 1997, for details of the testing procedures required to separate the processes of recognition and name retrieval.) When the lesion extends into the left anterior sector of the inferior temporal lobe, in addition to damaging the temporal pole, the deficit encom-

passes not only the retrieval of words denoting unique persons but also those of nonunique animals. If the lesion spares the temporal pole but damages the anterior sector of the IT region, the deficit may be limited to the retrieval of words denoting animals alone. Again, recognition is not affected (in order for recognition of animals to be affected, the lesions must involve the mesial occipitotemporal cortices, especially those in the right hemisphere). When the retrieval of words denoting nonunique manipulable tools is the predominant feature of a naming deficit, the lesion usually involves the left posterior IT region at the level of the lateral occipitotemporal junction. See Figure 2-17 for a summary of lesions producing category-specific deficits.

We should consider here another group of patients who often present with pure naming deficits in the early stages of disease, the so-called “progressive aphasia.” The term refers to subjects who show a progressive impairment in language performance, usually starting with a deficit in unique name retrieval, later proceeding to encompass deficits in the retrieval of words denoting nonunique entities, and finally encompassing more typical features of aphasia. The underlying damage is usually found in the left temporal lobe in the form of atrophy. The atrophy usually starts in the polar region and gradually comes to involve more of the temporal region, especially in IT regions. Many of these patients have a progressive degenerative disease, for example, a variant of Pick’s disease. On occasion, the disease may affect first the frontal lobe, with particular atrophy in the inferior frontal gyrus. In such cases, the presenting signs are those of difficulty retrieving words denoting actions and words denoting relationship of entities.

Mutism

Mutism is a condition that is not strictly an aphasia but is often taken as such. For instance, patients with akinetic mutism do not have abnormal language: they simply do not

Figure 2-17. 3-D reconstruction (**A, C, D**) and MAP-3 (**B**) of the brains of four different patients with anomia. **A.** A subject with left temporal lobectomy who after surgery was left with severe impairment of naming of unique persons whom the patient could, however, recognize. The excised area was limited to the temporopolar region (Brodmann's field 38). **B.** A subject with a resection of an arteriovenous malformation in the anterior sector of the left temporal lobe. After surgery there was a lesion in the anterior sector of the middle and inferior temporal gyri (fields 21 and 20) without extensive damage to the temporal pole. This subject showed a deficit in retrieval of words denoting living entities such as animals, which he could, however, recognize. There were no other aphasic symptoms, nor were there deficits in the retrieval of unique names. **C.** A subject with left temporal lobectomy, more extensive than the one depicted in **A**. In this case the excision included the temporopolar region (field 38) as well as the most anterior sector of the middle and inferior temporal gyri (fields 21 and 20). This subject not only showed impairment in retrieving the name of unique persons he still recognized, but also showed deficits in retrieving words denoting animals. Once again there were no other language deficits. The damage in this patient could be described as a sum of the damage seen in **A** and **B**. **D.** A subject with a lesion in the posterior sector of the left middle and inferior temporal gyri and the anterior sector of the occipital gyri (Brodmann's fields 37 and 19). This subject showed deficits in the retrieval of words denoting manipulable tools, in the setting of some further cognitive deficits that would characterize her as having a transcortical sensory aphasia. (For more details about lesions causing naming deficits see Damasio et al. 2004.)

communicate in any form or fashion. They do not speak spontaneously; they do not speak when spoken to; and they fail to show any intention to communicate with the interlocutor. This attitude is in sharp contrast with that of the patients discussed so far. A hallmark of patients with aphasia is the intent to communicate albeit with incorrectly found language. Akinetic mute patients are usually immobile, in body and speech. Akinetic mutism occurs with lesions of the anterior cingulate gyrus, either bilateral or unilateral, usually as a result of infarcts of the anterior branches of the anterior cerebral artery. Rupture of an anterior communicating aneurysm can produce vascular spasm in both anterior cerebral arteries

and also cause such infarcts. The patients may remain akinetic and mute for weeks or months and eventually recover without language deficits. Predictably, the recovery is speedier with unilateral infarcts. See Figure 2-18 for an example of such a lesion. When the lesion occurs only in the supplementary motor area (mesial section of Brodmann's field 6), the condition is restricted to mutism, with only minor akinesia. During the recovery of the latter sort of patient, the condition may resemble a transcortical motor aphasia.

► *Acknowledgment*—This work was supported by NIH Program Project Grant P01NS19632.

Figure 2-18. CT scan and MAP-3 (mesial view of the left hemisphere) of a patient who suffered the rupture of an anterior communicating aneurysm and had, as a result, an infarct in the territory of the middle branches of the ACA (internal-frontal and paracentral arteries). The patient presented suddenly with what was thought to be right hemiplegia and mutism. The infarcted region occupies the anterior cingulate gyrus (Brodmann's field 24 and part of field 23), and the mesial aspect of the superior frontal gyrus, including the supplementary motor area (field 6) and part of the mesial motor region (field 4). It was soon recognized that in fact there were some motor deficits in the right leg but that there were no motor deficits in the right arm. The patient was simply akinetic. The patient improved over a period of a few weeks and began using sparse, non-aphasic language that in time became completely normal.

KEY POINTS

1. The anatomical descriptions of classic Broca's and Wernicke's aphasia have stood the test of time. The location of the lesions that can produce those aphasia is, in essence, the same that was proposed originally.
2. The notion of "language centers" derived from those early anatomical studies did not prevail. All aspects of language performance depend on the concerted functioning of multi-component systems. The deficits caused by a lesion in a specific location correspond to the removal of the contribution of a particular anatomical component toward the overall function of the system.
3. The traditional Broca's and Wernicke's "language areas" are not sufficient to explain all that goes on in language production and comprehension. Many other areas must be added to the list if we are to explain normal language processing and account for the language deficits due to focal brain lesions.

Chapter 3

Medical Aspects of Stroke Rehabilitation

Anthony G. Mlcoch and
E. Jeffrey Metter

OBJECTIVES

Stroke is a leading cause of death and disability. Each year, it is estimated that nearly 731,000 individuals will suffer from the sequelae of stroke, including death, paralysis, sensory loss, mental status changes, and speech and language disturbances (Broderick et al., 1998). By definition stroke is a "... sudden and severe attack ..." implying that the signs of stroke occur abruptly with little warning and are usually persistent (Dorland's Illustrated Medical Dictionary, 1994). The etiology of stroke is vascular in origin and is due to an interruption of blood flow to various brain regions or to bleeding within the brain or spinal cord. The term "cerebrovascular accident" (CVA) is used synonymously with the term "stroke" to denote this vascular etiology. Keeping in mind the sudden onset, the persistent nature, and the vascular origins, the World Health Organization (1989) defines stroke as a series of "... rapidly developing clinical signs of focal (or global) disturbance of cerebral function, with symptoms lasting 24 hours or longer or leading to death with no apparent cause other than of vascular origin."

It is important for the health-care professional to know the warning signs of stroke, how strokes are manifested, diagnosed, and treated for several reasons. First, the nurse, physical therapist, occupational therapist, or speech pathologist may be the first to recognize that a stroke is occurring. As will be reviewed in this chapter, early detection of the signs of stroke are critically important since acute treatment may minimize the effects that a stroke will have on the individual. Second, these professionals will be working with others or within a dedicated team of stroke professionals. A command of the stroke vernacular is necessary to communicate effectively with these professionals and to develop and participate in a plan of treatment for the stroke victim. Lastly, the health-

care professional will be responsible for counseling the patient and his or her family, providing information pertaining to the prognosis, treatment, and outcome of stroke. An understanding of the pathogenesis, diagnostic procedures, and the purpose of various treatments is obviously needed.

The purpose of this chapter is to provide the information outlined above. It will review the risk factors (epidemiology), the etiology and diagnosis of stroke including the major neuroimaging procedures, and the current acute and chronic stroke treatments. In addition, future research directions for treatments and their effect on stroke recovery will be reviewed.

EPIDEMIOLOGY

Stroke ranks third behind heart disease and cancer as cause of death in the United States. Approximately 158,000 deaths occur per year in the United States, which is 1 in every 15 deaths (Thom et al., 2006). The annual incidence is approximately 2 per 1,000, with about 1.7 per 1000 being first events, while the prevalence rates are between 4 and 8 per 1000 (Thom et al., 2006). These numbers imply that for 2003 approximately 2.4 million individuals were living after suffering from a stroke, with 700,000 individuals having suffered from a stroke, and about 20% having died related to the stroke. The event rates are higher for men and African Americans. The overall cost of stroke is estimated at 58 billion dollars for 2006. Costs will continue to rise as more individuals survive a stroke, as can be seen with the increase prevalence of noninstitutionalized stroke survivors, which has risen from 1.5 million in the early 1970s to 2.4 million in the early 1990s (Thom et al., 2006).

The incidence of stroke increases exponentially with age and is primarily a disorder of the elderly. For example, for white females the incidence rate increases from 0.8 per 1000 women for 45 to 54 year olds to 16.5 per 1000 women at ages greater than 85 years (Thom et al., 2006). About 1 in 4 men and 1 in 5 women aged 45 will have a stroke if they live to an age of 85 (Bonita, 1992).

Epidemiologic studies (see Whisnant, 1983) demonstrated that the annual incidence of strokes declined from the 1950s through the 1970s. However, from 1980 the rates have been increasing. For example, in Rochester, Minnesota, the incidence of stroke increased from 1980 to 1984 (Broderick, Phillips, Whisnant, O'Fallon, & Bergstralh, 1989) and from 1985 to 1989 (Brown, Whisnant, Sicks, O'Fallon, & Wiebers, 1996). The increases are likely due to improved diagnostic methods caused by the introduction of CT scanning and better identification of hemorrhagic strokes (Mayo, Goldberg, Leve, Danys, & Bitensky, 1991). More recently, the stroke death rate has been declining and went down by 18.5% from 1993 to 2003 (Thom et al., 2006).

Preventive measures may contribute to lowering the incidence of major disability and mortality as well. Table 3-1 lists factors that have been associated with increased risk for stroke. Many of these factors can be altered by life style changes, proper counseling, and earlier recognition of changes in patient health status. Improved recognition and treatment of such factors have helped to reduce the incidence of stroke. As an example, the improved treatment of hypertension by lowering blood pressure has been shown to decrease the incidence of stroke and myocardial infarctions (Veteran's Administration Cooperative Study Group on Antihypertensive Agents, 1970; SHEP Cooperative Research Group, 1991). The recognition of transient ischemic attacks (described below) can also forewarn of impending disaster and appropriate referral becomes critical. Improved recognition and treatment of such factors have helped to reduce the incidence of stroke.

Stroke-related mortality results from the stroke itself and from other vascular diseases, particularly coronary artery disease and associated heart attacks. Early mortality varies

between 17% and 34% during the first month post stroke (Bonita, 1992), with 7.3% mortality for ischemic and 33.1% for hemorrhagic stroke observed in the Atherosclerotic Risk in Communities (ARIC) Cohorts (Rosamond, 1999). The most significant factors associated with early mortality have been alteration in consciousness, which implies a greater and more extensive stroke, and increasing age (Truscott, Kretschmann, Toole, & Pajak, 1974). Myocardial infarction, congestive heart failure, and hypertension have been correlated with early mortality in some studies (Ford & Katz, 1966). Late mortality occurs after the initial hospitalization and is much higher than for the general age-adjusted population.

The scope of the problem becomes more clear when examining what becomes of stroke survivors. In the Framingham Heart Study Cohort, 43% of elderly stroke survivors had moderate to severe disabilities that were more prevalent in the oldest individuals (Kelly-Hayes, et al., 2003). Marquardsen (1969), in an extensive review of the literature, noted that of unselected stroke survivors, 1% to 25% were able to return to work, 50% to 75% were able to walk unaided and discharged home, and 20% to 30% required continued institutionalization. Held (1975) notes, "the percentage of patients who can resume their capability to earn wages is lower than in virtually all other handicaps, physical or intellectual." From these observations it is apparent that stroke can have a devastating effect on the patient and the entire family.

STROKE ETIOLOGY

The most common cause of stroke-like illnesses are related to vascular disease. A partial differential diagnosis for stroke is shown in Table 3-2. The two main mechanisms are related to either loss of blood circulation to parts of the brain through thrombosis with infarction or to hemorrhage of blood into or surrounding the brain. Both mechanisms result in rapid disruption of the ability of neurons to function properly, and if severe and persistent, to the death of neuronal tissue. Resulting symptoms depend on the area of the brain damaged, and the effect that the damaged region has on the remainder of the brain.

The circulation to the brain arises from two pairs of arteries: the internal carotids and the vertebrals. The carotid arteries course in the anterior aspects of the neck and divide into an external and internal branch. The internal carotid artery proceeds to enter the cranium and supply much of the forebrain. The internal carotid artery bifurcates into the anterior and middle cerebral arteries, which supply the cerebral hemispheres over the anterior and much of the lateral surfaces of the cerebral hemisphere (Williams, 1995; Parent, 1996).

The vertebral artery is the first branch of the subclavian artery and proceeds into the cranium through the foramen

magnum. The two vertebral arteries unite to form the basilar artery. The basilar artery continues along the midline of the pons. At the upward end of the pons, the artery divides into two posterior cerebral arteries, which proceed posteriorly to the inferior medial surfaces of the hemispheres to the occipital lobes. The artery supplies blood to those regions including the brain stem, inferior and medial aspects of the hemispheres, and the occipital area.

At the base of the brain, interconnections occur between the carotid and vertebral arteries, forming a circular passage that allows for mixing of blood from the anterior and posterior circulations. This interconnection is called the circle of Willis. Collateral circulation, which refers to the ability of blood from separate brain arteries to redistribute to other

brain areas, is extensive, including the circle of Willis, connections between the external and internal carotids, between the left and right anterior cerebral arteries via the anterior communicating artery, and connections between the three cerebral artery systems. Collateral circulation is particularly important when the principle artery to a region becomes compromised. If collateral circulation is adequate, no brain damage may occur. This is accounted for by the ability of collateral arteries to take over and supply an adequate blood supply to the affected internal carotid (Gillilan, 1980).

Ischemic Strokes

Ischemic strokes occur with the complete or partial occlusion of arteries. When blood flow to a region falls below a critical level needed to maintain cellular function and to remove accumulating toxic waste (e.g., lactic acid), cells begin to die and an infarct develops with necrosis and loss of tissue bulk (Plum & Posner, 1980; Raichle, 1983). Typically, in ischemic regions, there will be an inner zone of infarction with a surrounding zone of ischemia called the penumbra (Schlaug et al., 1999). The goals of treatment are to prevent the infarction by early intervention and to protect the ischemic zone by preventing the infarct from getting larger and thus limit functional disability.

The most common causes of ischemic strokes are thrombotic and/or embolic occlusion of the artery related to atherosclerosis. Atherosclerosis is a proliferation of the smooth muscle cells in the intima of the arterial wall with an expansion and deposition of lipid within the associated connective tissue (Ross & Glomset, 1973; Ross, 1980). Atheroma deposition within the arterial wall results in narrowing or stenosis of the artery. If the stenosis reaches a critical level, usually considered greater than about 70%, changes occur in distal blood flow. As stenosis increases and flow becomes stagnate, the likelihood of thrombosis within the artery increases. A second change results from injury to the friable and easily damaged atherosclerotic lesion, with the development of an ulcer. The blood system responds to the ulcer as it would to any other injury within the arterial wall with the laying down of fibrin material, platelet adhesion, and trapping of blood cells. This deposition is called a "thrombus." It can either occlude the blood vessel, which is called a thrombosis, or break apart and be released into the bloodstream as an embolus, which can occlude a distal artery. Embolism can result from thrombus formed for any reason, not just from ulcerated arterial lesions. Other sites of embolic material include the atria of the heart, with embolus formation in relationship to the presence of atrial fibrillation, and the left ventricle of the heart when the chamber has been significantly damaged by a myocardial infarction. These two mechanisms—thrombosis and embolus—are the principle causes of ischemic strokes. The clinical picture with ischemic stroke, as with any neurologic disorder, depends on

the regions of the brain damaged and the involved artery (Table 3-3).

Hemorrhagic Strokes

A hemorrhagic stroke results from the rupture of a blood vessel within the intracranium. The hemorrhage can occur within three different spaces: the parenchyma of the brain, the subarachnoid space, or the subdural space. The most frequent type of hemorrhage that would result in consultation with a speech-language pathologist would be an intraparenchymal hemorrhage. Such hemorrhages occur secondary to rupture of a small artery within the brain, or occasionally by bleeding from a complex of abnormally formed blood vessels, called an arteriovenous malforma-

tion. Intracerebral hemorrhage causes symptomatology by mass displacement of brain tissue, increased pressure in adjacent and distal brain regions, and tissue destruction at the site of bleeding. Current imaging techniques allow for the identification of even small hemorrhages, which have a good prognosis.

Clinical features are relatively distinct depending on type and location of the hemorrhage. The onset frequently occurs during activity or exertion. The patient has the sudden onset of a severe headache, with rapid development of alteration of consciousness. Neurologic symptoms are similar to corresponding strokes resulting from infarctions (Table 3-3).

Transient Ischemic Attacks

Transient ischemic attacks (TIA) are particularly important for the speech-language pathologist to understand because an individual who has such an attack is at a high risk of having a stroke. In fact, there is a 10% to 20% chance of having a stroke within one year, and a 30% to 60% chance of having one in five years. Half of the strokes occur within 24 to 48 hours after the TIA (Albers et al., 2002).

Because of the high risk associated with TIA, it is important to understand clearly what does and does not constitute an attack. A TIA is a brief focal cerebral event in which the symptoms develop rapidly. The duration of an attack ranges from 2 to 30 minutes, to as long as 24 hours, while most are less than 2 to 3 hours in duration. The patient may have two or more such attacks over a variable period of time (Joint Committee for Stroke Facilities, 1974). During a TIA, part of the brain has temporarily become ischemic, resulting in the clinical symptoms. With resolution of the ischemia, the symptoms disappear. Recently, an emphasis has been put on the fact that the vast majority of TIAs resolve in less than an hour (Albers et al., 2002). This focus on the short-term transient nature of TIAs is important as the use of thrombolytic therapy for ischemic stroke is most successful within 3 hours of onset. The ability to separate the two related conditions maximizes the therapeutic potential of the treatment.

Carotid territory TIAs show one or more of the following (Joint Committee, 1974): (1) Hemiparesis—muscular weakness or clumsiness of an arm and/or leg on one side of the body; (2) hemisensory changes; (3) transient aphasia; (4) amaurosis fugax—transient loss of vision in one eye; and/or (5) homonymous hemianopsia—transient loss of vision with an inability to see one side of the visual field.

Vertebrobasilar TIAs show a different combination of symptoms determined by the structures that receive the blood flow from this arterial complex. Symptoms include one or more of the following: (1) motor dysfunction involving one or more extremities; (2) sensory changes involving one or more extremities, usually including the face; (3) visual loss, both total or partial; (4) gait or posture instability with

ataxia, imbalance, or unsteadiness but not vertigo; and/or (5) double vision (diplopia), swallowing problems (dysphagia), dysarthria, or vertigo occurring in combination with the above.

The following are not considered as TIAs since each of the symptoms commonly occur and are not associated with stroke: (1) altered conscious or faints; (2) dizziness; (3) amnesia alone; (4) confusion alone; (5) seizure activity; (6) progression of motor or sensory symptoms; (7) vertigo alone; (8) diplopia alone; (9) dysphagia alone; (10) dysarthria alone; or (11) symptoms associated with migraine, such as scintillating scotomata (Joint Committee, 1974).

Diagnosis of TIAs is based on the transient clinical presentation, the absence of other explanations for the event, and the absence of evidence for ischemia on CT or MRI. MRI with diffusion-weighted images is the most sensitive in demonstrating the presence of small subtle infarctions that could be missed by CT.

Treatment for TIAs is successful at decreasing the risk of impending strokes. It attempts to prevent the formation of thrombus and the release of emboli. Two major approaches are being used (Sacco et al., 2006). The surgical approach is to remove the atheromatous material from within the carotid artery (i.e., endarterectomy). Recent cooperative studies have shown that carotid endarterectomies are beneficial to patients with recent hemispheric or retinal transient ischemic attacks (Barnett et al., 1991; Mayberg, et al., 1991; European Carotid Trialists' Collaborative Group, 1991). Patients with stenosis greater than 70% of the vessel lumen to their symptomatic carotid artery were less likely to incur a stroke after undergoing an endarterectomy than if they had received only antiplatelet treatment (e.g., aspirin). Patients with stenoses in the 50% to 69% range showed less consistent benefits (Barnett et al., 1998). However, there is a risk from the arteriogram required to define the anatomy of the blood vessels, and from the surgical procedure itself (Whisnant, Sandok, & Sundt, 1983). Endarterectomy seems warranted only when overall morbidity and mortality from the angiogram and surgical procedure are less than 5% (Sundt, Sandok, & Whisnant, 1975). Under the right circumstances, carotid endarterectomy can lead to a greater reduction of stroke risk than medical treatment (Sacco et al., 2006).

The second treatment approach is medical and consists of preventing thrombus formation. The main medical treatment has been antiplatelet agents such as aspirin. Aspirin decreases the stickiness of platelets so that they will not adhere to the atheromatous lesions. A number of studies have shown that the use of aspirin lowers the risk of subsequent TIA, strokes, and death, particularly in males (Fields, Lemak, Frankoski, & Hardy, 1977; Canadian Cooperative Study Group, 1978; Antiplatelet Trialists Collaboration, 1994). At present, the optimal dose of aspirin has not been determined and no dose has been shown to be definitely

most efficacious (Dalen, 2006). The low risk of complications other than gastrointestinal symptoms make this an appealing treatment.

Other antiplatelet medications may prove to be more beneficial either alone or in combination with aspirin, while having less risk of hemorrhage (Lutsep, 2006; Leonardi-Bee et al., 2005). It is unclear whether using these other medications is superior to aspirin, but frequently a combination with aspirin may give some further reduction in risk.

Other recommendations for stroke prevention address many current public-health policies for improved cardiovascular health. Hypertension, diabetes mellitus, lipid abnormalities, obesity, cigarette smoking, and inadequate physical activity are associated with increased risk for stroke. Each of these can be addressed to lower the risk for vascular events including stroke (Sacco et al., 2006).

In subjects with atrial fibrillation, rapidly irregular beating of the heart not associated with rheumatic heart disease, anticoagulation has been found to be a better treatment than antiplatelet therapy (Koudstaal, 2006). Anticoagulants prevent the formation of the thrombus, thus preventing the release of emboli, and can reduce the risk of subsequent stroke by almost 70%. The risk of anticoagulants is bleeding, and this can be a high risk. In using these medications, bleeding parameters of the blood, primarily the prothrombin time, need to be followed carefully and adjusted. In general, the physician attempts to keep the value at 2.0 to 3.0 International Normalized Ratio (INR) for atrial fibrillation, which minimizes the bleeding risk (Sacco et al., 2006). In general, treatments for TIAs can reduce the risk of subsequent strokes by 20% to 40%.

Other Causes

A large number of other disorders can result in stroke-like syndromes (Table 3–2). Such illnesses include brain tumors, chronic subdural hematomas, infections of the brain, multiple sclerosis, residual of head trauma, and so on. At times clinical clues suggest that what appears to be a stroke may be something else. Recognition of such differences in clinical course suggest that something is occurring other than a “simple stroke.” The key is that over time the patient is not showing normal recovery, but rather is becoming worse. This can appear as slowly increasing weakness, seizures, increasing confusion, aphasia, or the development of new signs or symptoms that were not noted previously.

DIAGNOSIS

A diagnosis is made based on a history, physical examination, and diagnostic studies. The history is the most important part of the evaluation. Without adequate information, the physician typically does not know what to look for. The purpose of the physical examination is to confirm the history.

In making a neurologic diagnosis, answers are needed to several key questions. The first question is whether the problem is based on a nervous system dysfunction. For example, a patient being seen because of a sudden episode of loss of consciousness lasting two to three minutes, could have had a seizure which is of neurologic origin, or a syncope episode (faint), which is usually not neurologic but more likely of cardiovascular origin. The second question asks where in the nervous system does the dysfunction occur? Can the clinical picture be explained by a single or multiple lesion. The third question is what is the etiology of the lesion. The answer to these three questions dictates the nature and extent of intervention.

DIAGNOSTIC STUDIES

The role of diagnostic studies in stroke patients is to help identify the location, etiology, and pathophysiology of the problem. Stroke is associated with disease in a number of other body organs and caused by other medical conditions.

Laboratory Evaluation

A variety of non-atherosclerotic causes of stroke syndromes can occur (Table 3–2). Routine tests are usually done to define hematologic, connective tissue, and inflammatory disorders. Typically blood studies include counts of the red and white blood cells. A screening panel is done that examines blood electrolytes (sodium, potassium, chloride, bicarbonate, and calcium), glucose level, and liver and kidney function. Other blood tests include syphilis serology, as well as screening tests for connective tissue diseases. Routine studies also include an electrocardiogram to evaluate the heart. Additional cardiac studies are frequently done, including 24-hour ambulatory monitoring of the heart and transthoracic or transesophageal echocardiography. These tests are done because of their low cost, safety, and high return of information that may not be available from other sources.

Noninvasive Carotid Studies

Since carotid endarterectomy has become an appropriate therapy for non-hemorrhagic strokes related to atherosclerotic disease, techniques are needed to evaluate the extent of disease at the carotid bifurcation. The ideal would be to have a procedure that would be 100% accurate in detecting the extent of disease, and would carry no risk. The accepted procedure to evaluate this area is cerebral angiography, but this carries a definite risk. Other tests have been developed that can evaluate the carotid bifurcation and intracranial arterial structure with 80% to 90% accuracy and far less risk, with 3% to 5% false-positives in experienced laboratories.

Ultrasound approaches are used to study the carotid bifurcation. The first is based on the doppler effect, that is, a sound source that moves towards you has a higher pitch than if it is standing still, and a lower pitch if it is moving away from you (Evans, McDicken, Skidmore, & Woodcock, 1989). Doppler imaging registers echoes of ultrasound waves in relation to the velocity of blood flow. It presents an image of the vessel lumen and in particular the blood column. The second approach uses B-scan mode ultrasonography, which registers echoes related to variations in the acoustical carrying properties of tissues. It images the vessel wall instantaneously as a real-time image.

Doppler techniques have been applied to the study of intracranial arteries. The procedures allow for the estimation of whether intracranial arterial stenosis, aneurysm, or arteriovenous malformations are present. The procedure is valuable in assisting the physician in understanding the blood-flow dynamics in patients with complex cerebrovascular problems (Asslid, 1992).

Cerebral Angiography

Cerebral angiography represents the “gold standard” for determining the nature and extent of the vascular abnormality in cerebral blood vessels. Angiography is particularly necessary when considerations are being made to do a surgical procedure, or when clinical diagnosis is uncertain. Typically, the procedure is carried out by placing a small-bore tube into the femoral artery in the groin and passing it up the artery to the aortic arch and into the appropriate arteries, including both carotid arteries and a vertebral artery. When in place, contrast medium is forced through the tube and into the arterial circulation, while x-ray pictures are taken in rapid sequence over a 10- to 20-second period. Pictures are taken in several planes, resulting in three-dimensional reconstruction of the arteries. In the hands of a good angiographer, the risk is typically less than 1% morbidity and mortality. The major risk from this procedure is the development of a stroke during or shortly after the procedure.

Magnetic resonance angiography has been developed; it takes advantage of the power of magnetic resonance imaging (MRI) (see below) and has become the most common approach for studying the cerebral arteries. This technique offers the advantage of imaging carotid and intracerebral circulation without the use of injected contrast media (Ruggieri, Masayk, & Ross, 1991).

Brain Imaging

The techniques examined so far have studied what occurs within the blood vessel. An important issue for the physician is the kind and extent of the brain damage that has occurred.

This can be studied by several imaging technologies. Two types of neuroimaging methods have emerged that enable the physician to obtain three-dimensional images of the central nervous system; those that measure the transmission of energy through tissue such as computed transmission tomography, and those producing images from natural or introduced energy sources, which include magnetic resonance imaging, positron emission tomography, and single photon emission tomography.

Transmission tomography examines differential tissue absorption of externally administered energy and includes standard radiography and computer tomography (CT). In standard radiography, the brain is irradiated by x-ray. The x-rays that are unabsorbed or transmitted through the brain are recorded by sensitive film or a video image device (fluoroscopy). This provides a planar or two-dimensional image that has excellent spacial but poor contrast resolution (i.e., the ability to distinguish white matter from gray matter). CT obtains three-dimensional images of the brain by measuring the amount of transmitted radiation using multiple detectors placed around the head. The amount of transmitted radiation at each integral point (pixel) is then calculated using a dedicated computer. A three-dimensional image of the brain is constructed using this information.

CT studies brain structure, pathology, and anatomy. Contrast between structures depends on the amount of x-ray absorbed and the thickness, density, and atomic number of the structures. For example, bone, which contains a high concentration of calcium, absorbs x-ray much more readily than other tissues, and is clearly delineated by both conventional radiography and CT. Distinctive structures within the brain are more difficult to see because specific gravity differences between adjacent structures are small. CT is capable of differentiating tissues with small absorption differences. With standard x-ray, resolution is basically continuous, while with CT it is dependent on pixel size, since each pixel represents an average value of transmitted radiation within its borders (Oldendorf, 1981; Ketonen, 1997). CT is commonly used when a patient first presents with an acute event, and is being considered for immediate treatment to identify an intracerebral hemorrhage or other potential causes for a stroke-like presentation (Moonis & Fisher, 2001; Bonaffini, Altieri, Rocca, & Di Piero, 2002).

Emission tomography produces images utilizing data from internal energy sources. Such sources include magnetic, radionuclides injected intravenously, intraarterially, or by inhalation, and the electrophysiologic characteristics of the brain. Emission techniques include MRI, positron emission tomography (PET), and single photon emission computed tomography (SPECT).

MRI does not use radioactive substances but examines the response of selected elements in response to a large magnetic field. Current techniques are primarily concerned with the study of proton distribution—water. The resolution of MRI

is on the order of CT, but has better contrast in distinguishing gray from white matter. The technique is particularly useful in studying the posterior fossa, where CT has difficulty.

MRI utilizes a very different set of physical properties, taking advantage of the behavior of nuclei as small dipoles or very weak magnets. Under normal circumstances, the axes of the nuclei point in random directions. In a strong magnetic field, the nuclei line up so that their dipoles are either parallel or antiparallel with the field. The nuclei can flip back and forth between the parallel and antiparallel positions, which requires energy absorption and the emission of a radiowave. MRI uses this property, by applying a radiofrequency wave, to the fixed magnetic field, encouraging nuclei to flip back and forth (resonate) between parallel and antiparallel positions and measuring the radiowaves emitted in the process (Bradley, 1982).

Each element in a magnetic field resonates at specific frequencies, making the physical properties of the fields specific to a given element. Hydrogen is most commonly scanned because of its excellent resonating ability and abundance in tissue as a component of water and all organic molecules. Two measures usually studied are magnetic relaxation times “T1” and “T2,” and are dependent on nuclear density and environment. T1 is the “thermal relation” or “spin-lattice” reaction time and represents the time for the nuclei to become aligned and magnetized when placed in a magnetic field. T1 depends on the physical properties of the sample, for example, liquids are held together by looser forces than are solids, and will become magnetized more quickly than solids, and will have a shorter T1.

T2 is the “spin-spin” or “transverse” relaxation time. Nuclei tend to spin much as a top does. As a top spins it points perpendicular to the ground when under stable conditions. If a second energy source is applied (as by touching it with a finger), it begins to wobble. The wobble represents a torque, which describes a second axis of rotation for the top. Nuclei in a strong magnetic field when pulsed by a radiofrequency wave behave in a similar manner. T2 is a measure of how well and how long this wobble is maintained, following the radiofrequency pulse. For solids, T2 is very short, because of the fixed rigid structure of the molecules, while it is long for liquids (Bradley, 1982).

In ischemic strokes, MRI is more sensitive than CT. Recent techniques have added new methods to the standard T1 and T2 imaging. A diffusion-weighted image (DWI) applies two gradients across the radiofrequency pulse that leads to an image with hyperintensity in an ischemic region due to the accumulation of intracellular water early in the process. DWI can be useful in differentiating stroke subtypes, extent of the damage, and appropriateness for specific acute therapy (Moonis & Fisher, 2001; Bonaffini et al., 2002), but it is not necessarily better than other approaches (Hand et al., 2006). Perfusion weighted images show

changes in ischemic regions outside the area of primary infarction. When PWI is used with DWI, PWI abnormalities outside those shown by DWI represent the penumbra, which is brain tissue potentially salvageable (Schlaug et al., 1999). MRI can be useful with acute brain attacks in making the decision for thrombolytic therapy. The limitation is that the decision for therapy has to be made quickly, which typically precludes time for MRI, and favors the use of CT.

MRI can be used to study blood flow. Such applications are being used to study how the brain responds to specific tasks.

PET and SPECT are two tomographic techniques based on the technology of detecting gamma-ray emissions from intravenous injected radioisotopes. PET and SPECT are designed to measure functional changes such as regional cerebral blood flow (rCBF), metabolism, and neurotransmitters. These methods are distinguished by the type of radiopharmaceuticals and equipment each employs. The half-lives of these isotopes are usually short, necessitating the availability of a cyclotron, which adds considerable expense to the procedure. These isotopes are also unique since the annihilation of their electrons produces two gamma photons that discharge at 180 degrees from each other. Detection of both photons is made by a gamma camera with a series of parallel gamma-ray detectors. Using a dedicated computer, the site at which the dual photons were emitted is located with excellent accuracy.

SPECT also employs isotopes that are injected intravenously. At present only two SPECT radioisotopes are approved by the Federal Food and Drug Administration for clinical use: N-isopropyl-p-iodoamphetamine (IMP) and ^{99m}Tc hexamethylpropylene amine oxide (HMPAO). These radiotracers have relatively long half-lives and do not require an on-site cyclotron. They are either made from kits or are shipped directly from the manufacturer. They also differ from those isotopes used by PET in that they emit one gamma photon. The site at which the photon was emitted is located by using a collimator, which is a lead shield with a series of holes cut into it. The collimator is mounted on the head of the gamma camera. Spatial resolution is less than the other imaging methods.

SPECT has not been used extensively in the diagnosis of stroke. The reason is that while SPECT detects focal and diffuse changes of cerebral blood flow (CBF), it is insensitive to the specific etiology, such as discerning whether the observed behavioral changes are ischemic, neoplastic, or metabolic. At best the physician requests a SPECT scan in those cases where the CT and MRI are negative and the patient exhibits mental status changes that are stroke-like. In these cases SPECT might be helpful in determining whether these changes are secondary to a progressive dementia or to neuropsychiatric disease (Talbot, Lloyd, Snowden, Neary, & Testa, 1998).

Brain Imaging in the Study of Aphasia

X-ray Computed Tomography

CT has been a powerful tool in correlating brain structural abnormalities with speech and language pathology. Within the past 10 to 15 years, CT has been supplanted by MRI serving the same role. However, CT studies were the first to describe the relationship between lesion site and type of aphasia (Hayward, Naeser, & Zatz, 1977; Naeser & Hayward, 1978; Kertesz, Harlock, & Coates, 1979; Mazzocchi & Vignolo, 1979; Noel, Bain, Collard, & Huvelle, 1980). Specific lesions have resulted in specific aphasia syndromes in a manner consistent with classical descriptions. The pre-rolandic/post-rolandic separation of nonfluent and fluent aphasias seems well supported by CT (Naeser & Hayward, 1978; Kertesz et al., 1979). A number of cases do not fit within the model (Mazzocchi & Vignolo, 1979; Metter, Wasterlain, Kuhl, Hanson, & Phelps, 1981). For example, investigations using CT have demonstrated that the location of brain lesions can be predicted from aphasia type with reasonable accuracy; however, the reverse does not appear to be true (Noel et al., 1980). In general, larger lesions result in poorer outcome and more severe aphasia than do small single lesions (Kertesz et al., 1979; Yarnell, Monroe, & Sobel, 1976). Lesion localization independent of size may also be critical for recovery, as noted by the poor prognosis of patients with lesions involving the posterior superior temporal and infrasyllabic supramarginal regions, which are associated with poor comprehension (Selnes, Knopman, Niccum, Rubens, & Larson, 1983). Some large lesions are less devastating than very critically placed smaller lesions. The value of knowing the site of brain lesions in predicting the recovery potential of patients with aphasia has been demonstrated (Selnes et al., 1983). Such information may be of value in planning language therapy for aphasic patients. Patients without lesions in specific areas may benefit from early intensive therapy to facilitate recovery.

CT has been particularly valuable in the identification of subcortical lesions and their correlation to language disturbance. Subcortical infarctions of the dominant hemisphere with basal ganglia involvement have resulted in aphasia that is characterized by word-finding difficulties, phonemic paraphasia, intact repetition, and rapid recovery (Brunner, Kornhuber, Seemuller, Suger, & Wallesch, 1982). A specific type of "thalamic speech" has also been recognized that characterizes the aphasia associated with thalamic CT lesions, with paucity of spontaneous speech, hypophonia, anomia, perseveration, and neologisms with intact comprehension and word repetition (Alexander & LoVerme, 1980).

Positron Emission Computed Tomography

Glucose is the main substrate used by the brain to produce the energy required for it to function. Normal brain function

is dependent on the availability and utilization of glucose. Flourodeoxyglucose (FDG) positron emission tomography (PET) studies have demonstrated decreased cerebral glucose metabolism (hypometabolism) in the brains of stroke patients that extends beyond the zone of infarction as determined by CT (Kuhl, et al., 1980; Metter et al., 1981; Metter et al., 1985). Similar changes remote from the site of infarction have been found in many stroke cases (Kuhl et al., 1980; Metter et al., 1981; Lenzi, Frackowiak, & Jones, 1981; Baron et al., 1981; Martin & Raichle, 1983; Metter et al., 1987). Distant regions of hypometabolism suggest that the function in undamaged tissue may be aberrant, and might account for some aspects of the aphasic language disturbance and in the recovery process (Metter, Jackson, Kempler, & Hanson, 1992). Furthermore, functional activation studies in aphasia have shown changing brain organization with increasing activity in the right hemisphere (Muller et al., 1999; Heiss, Kessler, Thiel, Ghaemi, & Karbe, 1999; Cappa & Vallar, 1992).

Studies that examine brain regional blood flow and metabolism demonstrate that focal brain regions have clear effects on other parts of the brain. Such observations appear to allow for more unifying concepts regarding the development of aphasia following stroke. For example, it has been found that essentially all patients with aphasia studied by FDG PET demonstrated metabolic abnormalities in the left temporoparietal regions independent of where the structural lesion causing the aphasia is located (Metter et al., 1990). Furthermore, differences between Wernicke's, Broca's, and conduction aphasias were found to differ on the extent of metabolic abnormalities in the prefrontal cortex, a part of the brain not believed to be directly responsible for most aphasias (Metter et al., 1989). The data also suggested that language function may not be attributable only to the structural lesion, but rather to what occurs in other brain areas when the perisylvian region (which functions as a unit involved with language function) is structurally damaged.

Studying brain metabolism has also demonstrated aspects of the role of subcortical brain structures in aphasia (Metter, 1992). Differences in the location of subcortical structural damage are associated with differences in the location changes in overlying cortex. For most middle cerebral artery distribution strokes, the presence of subcortical extension of the infarct will be associated with frontal lobe hypometabolism. These metabolic changes and the associated subcortical structural changes are associated with the expressive aspects of the aphasia (Metter, Riege, Hanson, Phelps, & Kuhl, 1988).

Single Photon Emission Computed Tomography

Like PET, single photon emission computed tomography (SPECT) often detects areas of reduced cerebral blood flow larger than and remote from the ischemic lesion identified

on CT and MRI. These areas include subcortical infarcts resulting in cortical hypoperfusion, and cortical frontoparietal infarcts resulting in contralateral cerebellar diaschisis (Bogousslavsky, Miklossy, & Regli, 1988; Vallar et al., 1988; Megens, van Loon, Goffin, & Gybels, 1992; Okuda, Tanaka, Tachibana, Kawabata, & Sugita, 1994; Halkar, Sisterhen, Ammons, Galt, & Alazraki, 1997; Abe, Ukita, Yorifu, & Yanagihara, 1997). The behavior associated with this phenomenon (i.e., ataxia and aphasia) often resolves as perfusion returns to the remote region (Vallar et al., 1988; Megens et al., 1992). In addition to the distant effects associated with cerebral infarction, the size of the cerebral blood-flow defect is inversely correlated with stroke recovery (Lee, Hillman, & Holman, 1984; Defer, Moretti, & Cesaro, 1987; Bushnell et al., 1989; Giulibei, Lenzi, & Dipiero, 1990; Limburg, Royen, Hijdra, & Verbeeten, 1990; Gupta et al., 1991). That is, the larger the defect the less likely the patient will exhibit good recovery. Using SPECT, Yamaguchi, Meyer, Sakai, & Yamamoto (1980) showed that poor recovery from aphasia was associated with failure of increased cerebral blood flow in the frontotemporal regions in both cerebral hemispheres in response to counting, conversational speech, and listening to music. Similarly Knopman, Rubens, & Selnes (1983) and Cardebat et al. (1994) found that good recovery from aphasia was associated with increases of cerebral blood flow in the right inferior frontal region and the right middle temporal cortex, respectively, in response to a listening task. Good recovery appeared to be associated with reduced but not absent cerebral blood flow activity in the language region in the left cerebral hemisphere early following the stroke and with improvement in flow with recovery. The language regions remained hypoperfused during recovery in patients with poor language recovery (Tikofsky et al., 1985; Mlcoch, Bushnell, Gupta, & Milo, 1994).

Functional MRI (fMRI)

MRI offers an opportunity to study brain activity, as estimated by regional changes in blood flow, during the performance of specific activities, thus examining how brain regions are selectively responding to specific tasks. Currently, fMRI represents the most dynamic approach to understanding the impact of brain damage on language function in health and with aphasia, and during recovery from stroke (Wise 2003; Price & Crinion, 2005). Recent work suggests a sequential but complex response by the brain to aphasia resulting from an ischemic stroke. One study (Saur et al., 2006) suggests a sequential response by the brain to an ischemic stroke in a select group of aphasic subjects. During the acute phase immediately following the onset of the stroke, little activity is found in noninfarcted left hemisphere language areas. This is followed subacutely by increased activity in the left and activation of homologous regions in the right hemispheres. In the chronic phase, a

shift occurs back towards the left hemisphere. Others have noted persistent changes in the response in the right hemisphere to both speech production and to comprehension tasks (Price & Crinion, 2005). The reorganization with increasing activity in the contralateral hemisphere leads to an alternate strategy for language processing and communication. The new strategies can result in improved communication and language. The resulting improvements in language likely reflect the extent of damage and functional loss in the dominant language areas, and the ability of both the dominant and nondominant hemispheres to adapt.

TREATMENT

The treatment of a patient who has developed a stroke can be divided into two parts. The initial or acute therapy is directed to the preservation of life and to preventing expansion of the disability associated with the stroke. The second part or, chronic therapy, is directed towards rehabilitation with the reestablishment of as normal a life style as possible.

Acute Therapy

With ischemic strokes a region of infarction is surrounded by a zone whose tissue can either recover or progress to infarction. This zone is called the “ischemic penumbra” and extensive efforts have been made to develop methods to protect and improve blood flow to this region during the early stages of stroke. These include the use of vasodilators to increase cerebral blood flow and to increase arterial pressure in an attempt to force blood into the zone, and the use of corticosteroids, drugs aimed at reducing the swelling of the brain associated with the acute stage of stroke. Unfortunately, none of these neuroprotective methods have proved to be beneficial and until recently the medical treatment of acute ischemic stroke has been limited to the preservation of life.

In 1995 the National Institute of Neurological Disorders and Stroke Study Group (NINDS) reported a double-blind study to determine the efficacy of recombinant tissue plasminogen activator (t-PA) for the treatment of acute ischemic stroke. t-PA is a drug delivered intravenously and is essentially a “clot buster” in that it breaks the embolism apart, allowing blood flow to return to the deprived region of the brain. The NINDS found that patients who had received t-PA within 3 hours of onset of stroke symptoms demonstrated significantly better recovery at 3 months post-onset. As compared with a placebo control group, patients treated with t-PA were at least 30% more likely to have minimal or no disability at three months poststroke onset. The one negative result was that at 36 hours after onset there was a higher incidence of symptomatic intracerebral hemorrhage in the t-PA group (6.4% vs. 0.6%). However mortality was lower for the t-PA group at three months (17% vs. 21%).

Based on the findings of the NINDS study, t-PA received formal Food and Drug Administration approval in 1996 for the treatment of patients with acute ischemic stroke. To be eligible for this drug, the patient must have had the onset of symptoms of an ischemic stroke within 3 hours of taking the drug; had a CT scan showing no evidence of intracranial hemorrhage; had not had another stroke or serious head trauma within the preceding 3 months; had not undergone major surgery within 14 days; had no history of subarachnoid or intracranial hemorrhage; showed no evidence of significant hypertension; did not have a history of gastrointestinal or urinary tract hemorrhage within 21 days; and were not taking anticoagulants. Since approval t-PA has been shown to be an effective treatment of ischemic stroke in community hospitals as well large medical centers (Chui et al., 1998; Grand et al., 1998). However, since FDA approval t-PA has been substantially underused (Bambauer, Johnson, Bambauer, & Zivin, 2006), for three primary reasons. First, the population as a whole has not been educated as to the signs and symptoms of stroke and the importance of getting to the hospital immediately when they occur. Second, owing to the relatively high incidence of intracerebral bleeding, physicians have been reluctant to provide t-PA due to possible liability. Third, the t-PA procedure has not been adequately reimbursed. Hopefully, with better education of the population, physicians, and third-party payers, t-PA will be better utilized in the future.

For those patients who do not meet the above stringent criteria and cannot take t-PA, treatment is dependent on identifying the etiology, or where the stroke-producing emboli is formed; primarily from the internal carotid artery or the heart. Treatment of the former is by either removing the thrombus from the artery by a surgical procedure called a “carotid endarterectomy,” or by providing antiplatelets such as aspirin. CEA has been shown to significantly reduce the chances of having a second stroke (North American Symptomatic Carotid Endarterectomy Trial Collaborators, 1991a, 1991b; Mayberg et al., 1991; Haynes et al., 1994; Gasecki et al., 1994; Moore et al., 1995). The relative risk of having a second symptomatic stroke within 3 years is reduced as much as 50% after undergoing a CEA when compared to medically treated patients (ECSTC, 1991). On the other hand, if the etiology is cardiogenic, anticoagulants such as heparin and warfarin (coumadin) are given to prevent further embolization. Evidence suggests that such treatment reduces overall morbidity and mortality (Easton & Sherman, 1977; Ezekowitz & Levine, 1999).

Chronic Therapy

Chronic therapy begins as soon as the patient is medically stable. The goals of treatment are rehabilitative at this stage and are generally aimed at teaching or providing the means whereby the patient can walk, communicate, and carry out

activities of daily living (ADLs). Initially, this might be as simple as preventing contractures and decubiti (breakdowns and ulcerations of the skin) from forming, especially in seriously disabled patients. This entails passive ranging of a hemiparetic arm and/or leg and rotating the patient in his or her bed routinely. Another goal is to provide stimulation by either talking to the patient or having him or her actively participate in their ADLs and gradually getting the patient into a lounging or wheelchair for progressively longer periods each day. Early mobilization is advocated whenever possible (U.S. Department of Health and Human Services, 1995). This will help the patient actively participate in a rehabilitative program by preventing her or him from becoming deconditioned.

Formal rehabilitation entails the disciplines of physiatry; nursing; social services; psychology; and physical, occupational, speech-language, and vocational therapy. Rehabilitation programs can be conducted in a number of settings. There is evidence that patients do better in a dedicated stroke unit. Stroke care can be provided in a rehabilitation unit, nursing facility, outpatient clinic, or in the home. At present, recommendations are that rehabilitation units should be used for patients with multiple disabilities and those who can tolerate at least 3 hours of physical activity each day (U.S. Department of Health & Human Services, 1995; Duncan et al., 2005).

The goals and techniques utilized by each type of therapy are beyond the scope of this chapter. The extent and intensity of rehabilitation is still unclear (Kwakkel, Wagenaar, Koelman, Lankhorst, & Koetsier, 1997). Furthermore, the time of recovery varies. For example, continued improvement in language performance can be observed for many years following the onset of aphasia (Hanson, Metter, & Riege, 1989). An American Heart Association panel has stated that there are six major areas of focus in stroke rehabilitation: (1) dealing with co-morbid illnesses and complications; (2) maximizing independence; (3) maximizing psychosocial coping for both patient and family; (4) promotion of societal reintegration; (5) improving quality of life; and (6) preventing recurrent vascular events (Gresham et al., 1997; U.S. Department of Health & Human Services, 1995). However, it is important to note which factors affect overall stroke rehabilitation or outcome.

The severity of the neurologic impairment has been shown to have the most effect on the outcome of stroke recovery (Lorenze, DeRosa, & Keenan, 1958; Gersten, Ager, Anderson, & Cenkovich, 1970). Patients demonstrating severe to profound neurologic impairment and/or hemiplegia (vs. hemiparesis) tend to stay longer in the hospital and become less functional (Harvey et al., 1998). Degree of communication deficit also plays a role in the stroke recovery. Patients with global aphasia or hemineglect tend to respond poorly to rehabilitative efforts aimed at teaching ADLs and improving mobility (Paolucci et al., 1998).

Patients with these deficits are likely to be less independent than those with other types of aphasia (with better comprehension of spoken language) or without sensory neglect (the ability to attend to events in the left or right hemispace) (Paolucci et al., 1996). Lastly, the effects of psychiatric disorders such as depression and apathy may also have a negative effect on stroke recovery. Surprisingly, poststroke depression has not been found to be consistently correlated with outcome or length of stay on a rehabilitative unit (Eastwood, Rifat, Nobbs, & Ruderman, 1989; Sinyor et al., 1986). Stroke patients with depression are not less functionally competent but tend to have less active life styles than patients without depression (Clark & Smith, 1998). In contrast, patients demonstrating an “apathy syndrome” or “negative symptom complex” tend to stay longer in rehabilitation and are less functionally competent and independent at the end of treatment (Galynker et al., 1997; Clark & Smith, 1998). This type of patient is indifferent to the surrounding environment. He or she expresses no concerns about the effect of the stroke has on others, often explaining lack of motivation as being tired. He or she shows little or no ambition and makes feeble efforts at achieving independence. These patients respond poorly to rehabilitation regardless of their degree of physical disability (Dombovy, Sandok, & Basford, 1986; Schmel'kov, 1982). However, the clinician should not assume that this behavior is purposeful. It is often the sequela of brain damage such as “abulia” (lack of willfulness) associated with frontal lobe disease or “anosognosia” (lack of awareness of disability) resulting from right cerebral hemisphere or left temporal lobe damage.

RESTORATIVE NEUROLOGY

For many years it was believed that the brain was a static organ, hard-wired after puberty and immutable. Subsequently, brain damage resulted in a loss of function, and recovery from brain damage, such as from a stroke, was a result of a reorganizational process within the brain. In the past 20 to 30 years this concept has undergone a radical change. We now know that the brain is capable of and does produce new cells that have the ability to take over the function of damaged brain regions and that after a stroke the remaining neurons are capable under certain circumstances to either partially or completely take over the lost function. The term used to refer to the brain's ability to undergo structural and functional modifications is *brain plasticity* or *neuroplasticity*. These modifications happen as a result of neurologic injury and/or external stimulation (i.e., behavioral management such as the stimulation provided in speech and language therapy). These changes occur at all levels including the cortex, the subcortex—the level at which neurons network and communicate—the cellular, and the biochemical. What precipitates these changes has been of particular interest to researchers as well as to clinicians who treat stroke victims.

Specifically, research has concentrated on what can be done to enhance the brain's ability to learn after a brain injury, thus enhancing recovery. The term used to describe those treatments that modify or enhance brain plasticity is *restorative neurology* (Druback, Makely, & Dodd, 2004).

In the past 10 to 15 years researchers have concentrated on three methods to potentiate the brain: electrical cortical stimulation, transcortical magnetic stimulation, and neuropharmaceutical stimulation. While much of the work has been done with animal models, human translation studies have begun to emerge.

Electrical cortical stimulation (ECS) is a method by which subthreshold electrical impulses are applied to target cortical areas. "Subthreshold" refers to a level of brain stimulation that does not result in a motor or cognitive action such as stimulating the hand area of the motor cortex, resulting in the movement of that appendage. The thrust of the research has been to determine whether the application of ECS concurrently with rehabilitative therapy results in better recovery of function. That is, whether undamaged cortical regions can be enhanced or positively potentiated by subthreshold electrical stimulation.

Atkins-Mair and Jones (2003) studied both the behavioral and dendritic effects of combining ECS with motor-skill training in rats with induced motor cortex infarcts. In this study rats were trained on a skilled forelimb-reaching task and then underwent an operation that induced ischemic lesions to the sensorimotor cortex. Ten to 14 days later electrodes were implanted in the perilesional cortex. The rats then began 10 days of rehabilitative training at which time they either received 50-Hz (subthreshold) stimulation, 250-Hz stimulation, or no stimulation. Of the three groups, the subthreshold group demonstrated a significantly greater rate of improvement of forelimb movement. In addition, they showed a greater density of dendritic processes in the perilesional cortex, indicating that the structural cortical changes were associated with the positive potentiation of the brain.

In a similar study, Klein et al. (2003) investigated whether ECS with rehabilitative training enlarges the cortical region responsible for forelimb movement after focal ischemic infarct. To answer this question, cortical maps were made after rats underwent 2 weeks of a food-pellet task. An infarct to the forelimb cortical region was then induced and cortical electrodes were placed around the lesion. As might be expected the cortical region surrounding the infarcted area that represented forelimb movement was larger for rats receiving ECS than those found in rats receiving no stimulation during postinfarct training. Teskey, Flynn, Goertzen, Monfils, & Young (2003) in a nearly identical investigation found that rats receiving stimulation during retraining had larger polysynaptic potentials. They conjectured that training with ECS most likely results in "strengthened synaptic

efficacy," which in turn involves long-term cortical potentiation associated with learning.

ECS combined with motor training has also been studied in nonhuman primates. Plautz et al. (2003) found that monkeys receiving hand-movement training with subthreshold ECS 3.5 to 5 months after incurring an induced infarct to the motor hand cortical region demonstrated a significant improvement in addition to having a larger peri-infarct region representing the hand. Importantly, this study showed that poststroke interventions are not limited to the period immediately after the brain insult but can be successful after the period associated with spontaneous recovery.

ECS has been also studied on a limited basis with human subjects. Brown, Lutsep, Cramer, & Weinand (2003) presented a case report of a 65-year-old patient who had a right spastic hemiparesis secondary to a subcortical infarct. The infarct occurred 19 months prior to undergoing a combination of subthreshold epidural (electrodes placed on the dura above the cortical region of interest) motor ECS and occupational therapy for 3 weeks. Before treatment the patient was unable to flex or extend his fingers; after treatment he could pick up a pencil, print letters, and pick up ball bearings. Cramer et al. (2005) employed the same protocol on 13 patients with infarcts to the brain stem, cortex, subcortex, and subcortical/cortical regions. The strokes had occurred 9 to 68 months before receiving 3 weeks of physical therapy combined with epidural ECS to the motor cortex. In comparison to a sham group those patients who received ECS showed significant improvement of arm motion. Brown, Lutsep, Weinand, & Cramer (2006) used a protocol identical to that used by Cramer et al. (2005). In this study patients were limited to those who had cortical and/or subcortical strokes that resulted in upper extremity paresis. Like that found in the previous study, patients in the active treatment group improved significantly better than patients receiving rehabilitation treatment only. These studies tend to show that regardless of the infarcted region ECS of the motor cortex will enhance arm recovery even after the period of spontaneous recovery has ended.

Although more extensive large sample studies are needed, several observations were made with the above investigations. First, the combination of ECS and rehabilitative therapy appears to enhance recovery from stroke. Second, the behavioral changes induced by ECS appear to be correlated with changes in cortical representation as well as structural cortical changes (i.e., increased dendritic density). In turn this most likely represents the long-term potentiation of the brain. Last, ECS and epidural ECS appear to be well-tolerated and safe.

To date no studies have looked at the combination of ECS (cortical or epidural) and language treatment for patients with aphasia. However, as of this writing a project is ongoing at the Rehabilitation Institute of Chicago and the University of Chicago, looking at the effectiveness and

safety in combining epidural ECS and aphasia therapy. It is called the “Northstar project.” In this investigation sub-threshold epidural ECS is applied to the language region in the left cerebral hemisphere while the patient receives language treatment, 3 hours a day, 5 days a week, for 6 weeks. We anticipate the results from this study in the near future.

Transcranial magnetic stimulation (TMS) is another method that has been shown to be an effective way of potentiating as well as depotentiating the brain. TMS entails placing a figure-eight coil on the scalp and delivering a magnetic pulse to the underlying brain region. Slow pulses (1 Hz) reduce excitability of the region while rapid pulses (>3Hz) increase the excitability or potentiates the brain region of interest (Pascual-Leone et al., 1998; Hoffman & Cavus, 2002; Fraser et al., 2002). One area of TMS research has been to identify those intact cortical regions that may contribute to stroke recovery.

To determine whether the intact (undamaged) motor cortex has a role in recovery, Werhahn, Conforta, Kadon, Hallet, & Cohen (2003) applied TMS to the motor cortex of the intact and damaged cerebral hemispheres of chronic stroke patients with a paretic hand. In normal subjects, stimulating the motor cortex on one side of the brain results in abnormal motor performance in the contralateral hand and arm, but not by the ipsilateral hand and arm. When TMS was applied to the stroke patients, the stimulation of the intact cortex was associated with delayed reaction times of the contralateral nonparetic hand and not the paretic hand, while TMS to the damaged hemisphere resulted in delayed reaction times to the paretic hand and not the nonparetic hand. The pattern of response was similar in the healthy and the subjects with stroke. The investigators concluded that recovery of motor function was primarily due to the reorganization of the intact motor cortex of the damaged cerebral hemisphere.

Fridman et al. (2004) also found that the intact motor cortex of the affected hemisphere was capable of reorganizing impaired movement. TMS was applied to the primary motor cortex, dorsal premotor cortex, and ventral premotor cortex of the affected and intact cerebral hemispheres. TMS applied to the dorsal premotor cortex of the damaged hemisphere resulted in delays in the reaction times of the paretic hand.

In a treatment study, Takeuchi, Chuma, Matsuo, Watanabe, & Ikoma (2005) applied slow TMS (1 Hz) to the contralesional brain to determine whether deactivating this region would result in better motor improvement for patients with stroke. Using a double-blind method, they found that those patients receiving slow TMS to the contralateral region had a greater pinch acceleration than patients receiving sham TMS. This suggests that the contralesional region of the intact hemisphere actually inhibits rather than promotes recovery.

TMS has also been used to study the clinical recovery from aphasia. Specifically, it has been used to determine the relative importance of the right cerebral hemisphere of patients with aphasia. In a unique investigation, Naeser et al. (2005) administered slow TMS to the right Broca's area for 10 days in four patients with aphasia who were 5 to 11 years post-onset of a left middle cerebral artery stroke. As a group these patients were able to name significantly more pictured objects and at significantly reduced reaction times. This improvement was maintained for 2 months for one patient and 8 months for three patients. These researchers interpreted their results to indicate that activation patterns seen in the intact right cerebral hemisphere are “maladaptive.” That is, activation or hyperexcitability of regions on the intact right cerebral hemisphere often seen in PET and fMRI poststroke studies may interfere rather than promote aphasia recovery (such as that found in the use of slow TMS and hemiparetic recovery). In a study combining PET with fast TMS (4 Hz) Winhuisen et al. (2005) found that of 11 patients with aphasia, three demonstrated PET activation of the left inferior frontal gyrus (IFG), while the remaining eight patients showed activation of the IFG in both hemispheres. When fast TMS was applied to each of these regions, stimulation of the right IFG resulted in increased reaction times on a semantic task for five patients, while six patients showed a similar response when TMS was applied to the left IFG. However, lower verbal scores were associated without the right-sided TMS effect, indicating that while the right IFG may be important for language function in some patients, its compensatory value is more limited. That is, the left IFG may be better suited to assist language recovery.

In conclusion, more stroke recovery and treatment studies involving TMS are needed, especially studies that are double-blinded and employ a large patient sample size. However, the above investigations demonstrate several important trends that deserve further study, including the identification of cortical regions affecting recovery, those that inhibit recovery and thereby might be a maladaptive response of the brain to damage, and those that enhance recovery indicating that these regions are more predisposed to assisting recovery. In the future TMS may be an important adjunct to language treatment of stroke patients with aphasia. As we found with ECS, TMS may enhance recovery from aphasia, not as a monotherapy but in combination with language therapy.

The effects of pharmaceuticals on stroke recovery had also been studied. Much of this research has stemmed from the stroke patient's need for drugs for the treatment of complications that may compromise his or her health and overall recovery. These include seizures, hyperanxiety, depression, and hypertension. Many of these drugs have been shown to impede recovery in laboratory animals and the motor recovery of patients with stroke (Table 3–4)

TABLE 3-4

Common Drugs and Their Effect on Stroke Recovery in Laboratory Animals and Human Beings

Neurotransmitter Action	Clinical Use	Effects	
		Animal	Human
Norepinephrine agonists			
Amphetamine	Stimulant	+	+
Methylphenidate (Ritalin)	Stimulant	+	+
Norepinephrine antagonists			
Prazosin	Antihypertensive	—	ID
Clonidine	Antihypertensive	—	ID
Propranolol	Antihypertensive	NE	NE
Dopamine agonists			
Bromocriptine	Stimulant	ND	ID
Apomorphine	Stimulant	+	ND
Dopamine antagonists			
Haloperidol (Haldol)	Tranquilizer	—	ID
Spiroperidol	Tranquilizer	—	ND
GABA agonists			
Diazepam	Anxiolytic	—	ID
Phenytoin (Dilantin)	Anti-seizure	—	ID
Phenobarbital	Anti-seizure	—	ID
Carbamazepine (Tegretol)	Anti-seizure	NE	ID
Serotonin (5-HT) agonists			
Trazodone	Antidepressant	—	+
Desipramine	Antidepressant	+	ND
Fluoxetine	Antidepressant	NE	+
Amitriptyline (Elavil)	Antidepressant	NE	NE
Nortriptyline (Pamelor)	Antidepressant	ND	NE

Key: + positive effect; NE = negative effect; ID = insufficient data; ND = no data.

(Goldstein, Matchar, Morganlander, & Davis, 1990; Goldstein, 1995; also see Goldstein, 1997, 1998a, 1998b for a review).

Essentially these retrospective studies have shown that patients taking commonly prescribed drugs, including the antihypertensives clonidine and prazosin, dopamine-receptor antagonists, anxiolytics, and the antiseizure agent phenytoin, tend to demonstrate significantly poorer motor recovery and were less independent in their performance of ADLs. However, the major drawback to these retrospective studies is that it is difficult to determine whether the negative effect was due to the drugs or the disorders treated by the drugs (e.g., depression, anxiety, etc.). A double-blind prospective investigation of a specific drug or class of drugs is needed to determine their effect on stroke recovery.

Pharmacologic agents that specifically act on the central nervous system have been studied as to whether they enhance stroke recovery. These agents can be classified according to whether they increase production or retard metabolism (agonists), or impede production or enhance the metabolism (antagonists) of specific neurotransmitters such as norepinephrine (NE), gamma-aminobutyric-acid (GABA), serotonin (5-HT), and dopamine (DA). Of these only the effects of NE and DA agonists have been extensively studied in both animals and human beings after brain injury.

Norepinephrine is produced within the pons and the lateral tegmental areas of the midbrain and is projected to all areas of the cerebral cortex, and to specific thalamic and subthalamic nuclei. It acts on the sympathetic nervous system in

that it prepares the brain to cope with stressful situations and is associated with wakefulness and alertness. A reduction of NE has been found in rat and cat brain stems after cerebral infarction (Cohen, Waltz, & Jacobson, 1975). Based on the assumption that motor deficits secondary to cerebral injury might be reversed by increasing the production of NE, several investigations have looked at the effect that amphetamine, a powerful NE agonist, has on the motor recovery in laboratory animals (Feeney, Gonzalez, & Law, 1982; Boyeson & Feeney, 1984; Hovda & Feeney, 1984). The common finding of these studies is that amphetamine tends to accelerate the motor recovery in rats and cats after cerebral injury is induced and that the improvement is enduring. Also common to these studies is that improvement only occurred when amphetamine was given in conjunction with motor training. Amphetamine treatment alone did not accelerate recovery, indicating that this psychostimulant is a “performance-enhancing” drug.

Similar findings have been found in human beings. Crisostomo, Duncan, Propst, Dawson, & Davis (1988) showed that patients with stroke who took amphetamine with physical therapy demonstrated a rate of improvement 40% greater than patients who received physical therapy and a placebo. Walker-Batson, Smith, Curtis, Unwin, & Greenlee (1995) also showed that this accelerated recovery continues after the patient stops taking amphetamine and well past the period of spontaneous recovery. Hemiplegic patients who received 10 mg of amphetamine every fourth day for 10 sessions paired with physical therapy demonstrated continued accelerated motor recovery up to 12 months after the onset of stroke. Methylphenidate (Ritalin), another NE agonist, has also been shown to have a positive effect on stroke recovery (Grade, Redford, Chrotowski, Toussaint, & Blackwell, 1998). Patients with acute stroke receiving this drug exhibited significant improvements in mood, ability to carry out ADLs, and motor functioning. In addition the effects of combining motor training with amphetamine has also been shown to result in motor plasticity (i.e., the recruitment of brain tissue surrounding the infarcted region) (Tegenthoff, Cornelius, Pleger, Malin, & Schwenkries, 2004).

Combining amphetamine with language treatment of patients with aphasia has also been studied in open-labeled and double-blind placebo-controlled studies. Using a similar experimental paradigm, Walker-Batson and her colleagues (1991, 1992) studied six patients within 30 days of their strokes. Each was given 10 to 15 mg of amphetamine followed by a 1-hour session of intensive speech and language therapy every fourth day for 10 sessions. The Porch Index of Communicative Ability (PICA) was administered 3 days prior to initiation of treatment, 1 week after the treatment was terminated, then again at 3 months post-stroke onset. Comparisons of their 3-month PICA overall scores and their 6-month predicted overall PICA scores were

made. Of the six patients, four had achieved over 94% of their projected 6-month score at the end of the d-amphetamine and language therapy sessions. At 3- months post-onset, five of the six patients with aphasia demonstrated over 100% of their 6-month predicted score. Using a nearly identical treatment paradigm but this time in a double-blind placebo-controlled study, Walker-Batson et al. (2001) demonstrated again that combining amphetamine with language treatment accelerates aphasia recovery. Twenty-one patients with acute onset of aphasia were randomly assigned to either receive a 10-mg dose of dextroamphetamine or a placebo, combined with language therapy. One week after the 10 sessions of combined treatment, the amphetamine group demonstrated significantly greater language improvement. At 6 months the differences between the groups continued to increase but were found to be insignificant. Regardless, the two studies show that amphetamine can be a powerful adjunct to aphasia therapy. However, large sample, controlled studies, addressing the safety, the amount of dosage, and the dosing schedule, are needed before this psychostimulant can be prescribed as a “standard of care” for stroke patients with aphasia.

The neurotransmitter dopamine (DA) is produced in the substantia nigra and the ventral segmental regions and projected to the caudate nucleus, putamen, globus pallidus, and mesial frontal cortex. Dopaminergic agents such as Sinemet and bromocriptine have been used for many years to improve the initiation and ease of movement of patients with Parkinson's disease. Other uses include the treatment of akinetic mutism (Echiverri, Tatum, Merens, & Coker, 1988) and apathy due to bilateral thalamic strokes (Catsman-Berrevoets & Harskamp, 1988).

The effect of bromocriptine on stroke recovery from aphasia has been studied. Early studies were promising, indicating that this drug may improve the speech fluency of patients with nonfluent aphasia secondary to stroke (Albert, Bachman, Morgan, & Helm-Estabrook, 1988; Bachman & Morgan, 1988; Gupta & Mlcoch, 1992; MacLennan, Nicholas, Morley, & Brookshire, 1991; Sabe, Leiguarda, & Starkstein, 1992; Gold, VanDam, & Silman, 2000; Raymer et al., 2001). However, the data from these studies were generally episodal, employing a single-subject test-retest design without adequate experimental controls, such as including a placebo condition and blinding the patient and the examiner.

Four group double-blind, placebo-controlled investigations have been since undertaken (Gupta, Mlcoch, Sclaro, & Moritz, 1995; Sabe, Salverezza, Cuerva, Leiguarda, & Starkstein, 1995; Bragoni et al., 2000; Ashtry, Janghorbani, Chitsaz, Reisi, & Bahrami, 2006). The studies by Gupta and her colleagues (1991, 1992, 1995) and Sabe et al. recruited patients with chronic, nonfluent aphasia. In each study the patients took a daily dose (15 mg and 60 mg, respectively) of bromocriptine and after a wash-out period were placed on

placebo tablets. Language skills were measured before and after each phase (drug and placebo trials). Regardless of the dosage given in each study, bromocriptine had no effect on the patient's ability to speak fluently, to name objects, to write, and to understand spoken and printed language when compared to the placebo condition. Bromocriptine did not prove to be an effective treatment of chronic nonfluent aphasia. The third study, conducted by Bragoni et al. (2000) was different in that each patient was given a 60-mg dose of bromocriptine combined with aphasia therapy, though information pertaining to the type and intensity of treatment was not given. Of the eleven patients, six dropped out due to secondary side effects. The remaining five patients showed significant language improvement. High doses of bromocriptine were not found to be a reasonable treatment due to significant side effects. The last study by Ashtry et al. (2006) employed 38 patients with acute nonfluent aphasia who were randomly assigned to either a group receiving a 10-mg dose of bromocriptine or a placebo. At 4 months no difference was seen between the groups' verbal fluency, gesture to command, naming, or overall global language score, though each group had significantly improved from baseline.

Interestingly, the question of whether bromocriptine (or DA agonists in general) may be performance-enhancing drugs, like amphetamine, was not tested. Three studies used patients with chronic nonfluent aphasia while one used patients with acute-onset of aphasia in which drug administration was not tightly coupled with language therapy. In fact, three of the four studies did not provide language treatment to their patients. To date there has been no investigation of whether bromocriptine is performance-enhancing drug in either laboratory animals or human beings. Obviously a study of this type is needed.

FUTURE TRENDS

Since the fourth edition of this book was printed in 2000, some things have changed but much is unchanged in the diagnosis and treatment of stroke. For the most part, stroke remains a neurologic disease of prevention. The physician's responsibility is to identify those risk factors associated with stroke and to eliminate or minimize their potential effects by educating patients regarding the risks and associated diseases. Areas that need to be considered by the health-care provider include recommendations for implementing life style changes that can reduce the associated risks, by management of established diseases, and by treating the patient surgically (i.e., carotid endarterectomy) and/or pharmacologically (i.e., antiplatelet, antihypertensive, and anticoagulation therapy) as needed based on the specific needs of the individual patient.

In the past 15 years much effort has been directed at reducing the extent of functional brain damage resulting

from stroke. In an attempt to save the tissue surrounding the infarct (i.e., ischemic penumbra) many potential neuroprotective agents have been studied. Unfortunately, except for t-PA, none have been found to be effective in stopping the cascade of events resulting in brain-cell death. As reviewed, t-PA has the potential to reduce the degree of brain damage by quickly returning blood flow to the affected region. This will hopefully enhance the stroke patient's overall recovery.

The future of stroke treatment lies in how we view the brain. In the past we considered the brain as a "static organ," one that is "hard-wired" and changes little after puberty. We now understand that the brain is a "dynamic structure," one that is constantly changing as the environment requires and is continually adding new cells that may have the power to enhance the cognitive skills of the individual. It is this view that has lead researchers to the implantation of fetal brain-stem cells into the brains of patients with Parkinson's disease as well as adult brain-stem cells created by specialized tumors into patients with stroke. In addition, as was reviewed in the last section of this chapter, many new therapies are on the horizon that have the potential to enhance the brain's ability to learn, thereby increasing the effectiveness of stroke treatments such as language therapy. The importance of speech-language pathologists will lie in their ability to select the appropriate treatments. While the preliminary results (published and unpublished) from this research are mixed and in their infancy, it may potentially lead to an effective treatment of brain disorders, including stroke, within the near future.

KEY POINTS

1. Stroke is a neurologic disorder manifested by sudden changes in the patient's sensory, motor, cognitive, and/or speech and language skills.
2. Stroke is a neurologic disease of prevention and depends on eliminating or minimizing those risk factors associated with cerebrovascular disease.
3. Strokes are secondary to vascular disease including embolic, thrombotic, and hemorrhagic etiology.
4. Patients with transient ischemic attacks are at a high risk of having a major stroke within 5 years.
5. The initial examination of the patient with stroke should include procedures designed to identify where the vascular etiology emanates. These include noninvasive and invasive cerebral angiography and echocardiography.
6. Acute treatment is directed toward the preservation of life and limiting the area of cerebral infarction,

thereby preventing the expansion of disability associated with stroke.

7. Chronic therapy begins as soon as the patient with stroke is medically stable and is directed at his or her rehabilitation.
8. Commonly prescribed drugs can have a detrimental effect on stroke recovery.
9. The brain is a “dynamic structure” that is constantly adapting and adding new cells that may have the ability to enhance the cognitive skills of the individual.
10. In the future, electrical cortical, transcranial magnetic, and pharmaceutical stimulation of the brain may be used as adjuncts to behavioral stroke treatments, thereby enhancing the effectiveness of these therapies.

Chapter 4

Assessment of Language Disorders in Adults

Janet P. Patterson and
Roberta Chapey

OBJECTIVES

As a result of reading this chapter, reviewing the key points, and completing the learning activities, the reader will be able to:

1. Describe the dynamic process of assessment of adults with neurogenic communication disorders, considering the three interrelated components of cognitive abilities, linguistic skills, and pragmatic behavior.
2. Identify several instruments and procedures that assess an individual's communication abilities and deficits within the World Health Organization's International Classification of Functioning, Disability and Health.
3. State the theoretic foundation and practical application of several models of assessment of language and communication abilities, such as a cognitive neuropsychological model, a psycholinguistic model, or a functional communication model.
4. Identify standardized and nonstandardized assessment instruments and procedures that can be used during the differential diagnosis of persons with neurogenic communication disorders, such as aphasia, dementia, a motor speech disorder, and right hemisphere communication disorder.
5. Describe several instruments and procedures that can be used to assess an individual's functional communication abilities through structured testing and an observational profile.
6. Identify several variables, such as biographic variables, medical variables, or environmental variables, that influence assessment decisions and contribute to prognostic statements.
7. Define quality of life (QOL) as a concept; identify several measures to assess QOL in persons with neurogenic communication disorders, and describe how QOL contributes to the assessment process.

LANGUAGE

Language has three highly interrelated and integrated components: cognitive, linguistic, and pragmatic (Muma, 1978) (Fig. 4–1). The **cognitive** component refers to the manner in which individuals acquire knowledge about the world and in which they continue to process this knowledge. It refers to all of the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used (Neisser, 1967). Through the use of cognitive processes we achieve knowledge and command of our world; that is, we process information and use it to influence people and events in our environment. High-level cognitive processing activities such as planning and organizing are governed by the executive function system (Hillis, 2005). According to Chapey (1986) these processes can be defined operationally within the five mental operations in the Guilford (1967) Structure of Intellect (SOI) model: recognition/understanding/comprehension (attention/perception), memory, convergent thinking, divergent thinking, and evaluative thinking.

The **linguistic** component refers to language form and content. Language **form** consists of three rule systems that dictate the structure of an utterance in order to convey meaning: phonology, morphology, and syntax. Language **content**, or semantics, is the meaning, topic, or subject matter involved in an utterance (Plante & Beeson, 2004).

The **pragmatic** component refers to the system of rules and knowledge that guides the use of language in social settings (Bates, 1976). It includes knowledge of how to converse with, and what to say to, different partners in different contexts, and how to initiate, maintain, and terminate discourse events such as conversation and narrative (Craig, 1983). It also refers to the use, function, or purpose that a particular utterance serves. For example, the same form and

Figure 4–1. Modified from Murray & Chapey, 2001; Chapey 1994; Muma, 1978.

content, “It is cold in this room” can be used to report an observation or to indirectly request an action to turn up the thermostat.

Within this model of language, **adult aphasia** is defined as an acquired impairment in language production, comprehension, or cognitive processes that underlie language. Aphasia is secondary to brain damage and most frequently caused by stroke (LaPointe, 2005). It is characterized by a reduction or impairment in the ability to access language form or structure, language content or meaning, language use or function, and the cognitive processes that underlie and interact with language such as attention, memory, and thinking (Murray & Chapey, 2001). Aphasia is a multi-modality disorder, since it may affect listening, speaking, reading, writing, and gesturing, although not necessarily to the same degree.

Aphasia does not refer to single modality deficits including perceptual impairments such as agnosia, or motor impairments such as apraxia of speech or a dysarthria. **Agnosia** refers to an inability to imitate, copy, or recognize the significance of incoming sensory information in the absence of sensory deficit in the affected sensory modality (Bauer, 2006). For example, in auditory agnosia an individual would be unable to recognize an incoming auditory signal as the word “table” even though the auditory sensation is intact. **Apraxia of speech** is a motoric impairment that disrupts central motor planning and consequently, voluntary

positioning of the speech musculature and sequencing of muscular movements. This disruption is in the absence of impairment in muscular control (Duffy, 2005; Darley, Aronson, & Brown, 1975). **Dysarthria** is a group of motor speech deficits caused by impaired strength, speed, or coordination of the speech musculature (Duffy, 2005; Darley et al., 1975). Agnosia, apraxia of speech, and dysarthria can co-occur in an individual with aphasia. Therefore, an important part of assessment involves determining which, if any, of these disorders exist and subsequently defining the nature and extent of each particular disorder and its interaction with the aphasia.

Body Functions and Structures, Activities, and Participation in Life

Aphasia can also be defined within the context of the World Health Organization’s International Classification of Functioning, Disability and Health (International Classification of Functioning, Disability and Health: ICF, 2001; Towards a Common Language for Functioning, Disability and Health, 2002). The model classifies an individual’s functioning and disability as they are associated with health conditions. **Functioning** refers to body functions and activities and participation in life events; **disability** refers to impairments, activity limitations, and participation restrictions that prevent an individual from participating fully in

Figure 4–2. World Health Organization International Classification of Functioning Disability and Health (ICF, 2001)

his or desired life activities. This classification system proposes four levels, namely, (1) health condition (disorder or disease), (2) body functions and structures, (3) activity, and (4) participation. Figure 4–2 shows the WHO ICF model and illustrates the interrelatedness of the levels of the model as well as the environmental and personal factors that influence an individual's state.

One purpose of this model is to heighten awareness of the holistic components of functioning and participation in life activities, and the very complex interaction of conditions between an individual and his or her environment that affects functioning. That is, the WHO model takes into consideration both the organic and the functional consequences of the health condition. Fougeyrollas et al. (1997) expanded on this definition and attempted to show the dynamic interaction of important variables such as organic systems and capabilities, environmental factors, and life habits of social participation that contribute to functioning in what they termed the “Handicap Creation Process.” Included in an assessment of aphasia should be examination of the aspects of an individual's life that may overtly or unintentionally lead to creating a handicapping situation and preventing full participation in life.

For individuals with aphasia, body functions and structures refer to impairments of brain and brain functions. Activity limitations primarily involve the four language modalities of speaking, listening, reading, and writing, as well as tasks necessary for daily living such as conversing with a health-care provider or family member, writing a check, making a phone call, or reading a paper or a menu. Traditionally, the four language modalities, at the levels of impairment and activity limitations, have been the focus of

assessment and intervention in aphasia. In recent years, however, functional tasks have increasingly become the focus of diagnosis. This focus includes participation in daily life and the realization of immediate and long-term real-life goals (Chapey et al., 2001) such as playing golf, shopping for clothes, getting a job, volunteering, or participating in clubs and organizations. The effect of aphasia on an individual's pursuit and enjoyment of these activities is the concern of classifications such as ICF and the Handicap Creation Process.

The literature on aphasia and life participation supports the notion that the core features of positive human health or well-being involve leading a life of purpose, quality connection to others (zest for life comes from such interactions), positive self-regard, and mastery (Byng & Duchan, 2005; Kahneman, Diner, & Schwartz, 1999; Ryff & Singer, 1998). Subsequent to the loss of language due to stroke, all of these areas may be affected not only for the person with aphasia but also for significant individuals in that person's environment. This, in turn, has an impact on the health, well-being, and quality of life for the person with aphasia, as the relationship between an individual with aphasia and his or her family and friends is interactive with each influencing the other.

Further, without a reason or a cause to communicate there is no practical need for communication. Therefore, within this definition of aphasia as related to body functions and structures, activity, and participation, assessment and treatment must target all three areas from the outset and focus on a reason for the individual to communicate as much as on communication skills and ability to repair faulty communication. A result of using classifications such as these is an increased focus on the social and physical environmental factors that contribute to full participation in life (Chapey et al., 2001; Elman, 2005).

Assessment Defined

Assessment is an organized, goal-directed evaluation of the interrelated, integrated components of communication: cognitive, linguistic, and pragmatic. It also includes evaluation of an individual's quality of life, communicative interactions within the family or social unit, and role in the larger unit of society. An evaluation is carried out to determine a patient's language strengths and weaknesses and the degree to which language strengths can be fortified and language weaknesses modified (Chapey, 1994; Lahey, 1988; Murray & Chapey, 2001; Murray & Clark, 2006). Ideally, evaluation explores “the nature of the language impairment and indicate(s) what aspects of language performance are more appropriate for treatment” (Byng et al., 1990, p. 67). This type of in-depth assessment may seem contrary to current health-care philosophy, which underscores frugality and efficiency (Holland & Hinckley, 2002). However, it is essential that clinicians

advocate for the best-quality services for their patients, which includes requesting sufficient time and funding to complete a sensitive, valid, and reliable assessment from which to develop the most appropriate treatment goals and procedures. A thorough, specific, and detailed assessment is essential if one is to see patterns of a patient's communicative and cognitive behavior, describe the complexity of the behavior, and develop a hierarchy of therapeutic goals that are appropriate for the individual with a neurogenic communication disorder and his or her family. That is, there should be a strong connection between a clinician's definition of language and communication, the description of a patient's language and communication abilities, and the goals that are established for treatment (Chapey, 1994; Murray & Chapey, 2001). Indeed, as Brookshire (2003) states, clinicians "must work to ensure that gains in economy and efficiency do not come at the expense of their patients' impairments and do not compromise their ability to provide the most efficacious treatment for those impairments" (p. 206).

Assessment Goals

Assessment of communicative and cognitive abilities in a person with a neurogenic communication disorder is multifaceted and involves the person with aphasia as well as his or her family or caregiver. The purposes are: (1) to describe language behavior in terms of both strengths and weaknesses; (2) to identify existing problems; (3) to determine intervention goals; and (4) to define factors that facilitate the comprehension, production, and use of language (Chapey, 1994; Murray & Chapey, 2001). Within these general goals, specific assessment goals vary according to factors such as the stage of the disorder (i.e., acute or chronic), the setting in which the assessment occurs (i.e., a hospital, residential facility, outpatient facility, or patient's home), the severity of the communication disorder, and concomitant physical, emotional, or psychosocial disorders that may be present. Consideration should be given to identifying a patient's current communicative environment and needs, the modality of communication (i.e., verbal speech, gesture, writing, or another augmentative or alternative communication method (Buzolich, 1995; Garrett & Lasker, 2005) and any factors that may interfere with communication. Specific goals are divided into etiologic goals, cognitive/linguistic/pragmatic/life goals, and treatment goals (Table 4-1) (Chapey, 1986, 1994; Murray & Chapey, 2001).

Hallmarks of a Quality Assessment

The nature of the language or communication deficit in the patient with aphasia dictates the need to perform a high-quality and thorough assessment. Some of the characteristics that typify a quality evaluation include the following. (1) A current knowledge of significant characteristics and

TABLE 4-1

Specific Goals of Assessment

Etiologic Goals

1. Determine the presence or absence of aphasia.
2. Identify and definition of complicating conditions that have precipitated or are maintaining the communication deficit to determine whether they can be eliminated, reduced, or changed.

Cognitive, Linguistic, Pragmatic, or Life Goals

(For each of the following goals, behaviors are analyzed to specify the nature and extent of the strengths and weaknesses in that particular behavior.)

3. Cognitive abilities.
4. The ability to comprehend language content.
5. The ability to comprehend language form.
6. The ability to produce language content.
7. The ability to produce language form.
8. Pragmatic abilities.
9. Quality of life with aphasia.

Treatment Goals

10. Determination of candidacy for and prognosis in treatment.
11. Specification and prioritization of treatment goals.

patterns of the patient's language impairment, as well as restrictions to personal activities and participation in life based both on first-hand experiences with patients with aphasia as well as a dedicated review of the aphasia language and disability literature. (2) A collection of comprehensive and detailed language samples of a patient performing tasks at varying levels of difficulty. (3) Repeated observation of communicative behavior, abstraction of behavior patterns, and formulation of hypotheses to account for the language and communicative deficit. (4) A quantitative and qualitative description of performance to generate information regarding the course, extent, and scope of treatment. (5) Respect for each and every individual patient, including a patient's history and accomplishments as well as his or her future contributions to the family unit and to society.

THE ASSESSMENT PROCESS

Assessment in aphasia and related neurogenic communication disorders involves three interrelated components: **data collection, hypothesis formation, and hypothesis testing** (Chapey, 1994; Murray & Chapey, 2001; Whitworth, Webster, & Howard, 2005). **Data collection** is the process of obtaining information that is linked directly or indirectly to the language strengths and weaknesses of the patient

(Lahey, 1988). Information should be obtained from the individual with aphasia, family members, caregivers, and other persons within the individual's social network (Blackstone & Berg, 2003). **Hypothesis formation** involves categorizing the data or forming taxonomies based on regularities in the data or similarities observed in the collected information. Furthermore, it requires interpreting the data and making decisions regarding the presence of aphasia, candidacy for treatment, prognosis and appropriate treatment goals. **Hypothesis testing** is the third component germane to the assessment process, involving the ongoing assessment and analysis of target behaviors, treatment goals, procedures, and patient progress (Lahey, 1988; Whitworth et al., 2005).

Data Collection

The data collected during the assessment process are based upon reported observations of a patient's language and communication abilities as well as on direct observation of the individual during language tasks and communicative interaction (Lahey, 1988).

Reported Observations

Reported observations are those data gathered from persons who have assessed the patient or who are familiar with the patient's current communicative abilities and communicative, vocational, or social history. These observations may be collected via interviews and written correspondence as well as in a review of the patient's pertinent medical records. For example, the clinician may interview professional workers or review the written reports of physicians, nurses, nursing assistants, occupational therapists, physical therapists, neuropsychologists, and social workers who have already assessed or treated the patient. When possible, the patient's perceptions of his or her current language and communication strengths and weaknesses should also be explored. Likewise, family members, friends, and/or members of the community who live with or who have frequent contact with the patient can provide valuable information concerning the patient's current language skills, activities, and participation in life. These friends and relatives may be asked to keep a diary or log, or to complete checklists or rating scales that relate their perception of the patient's language abilities. For example, a spouse might compile a diary of how her husband typically makes his needs and wants known in different contexts or with different communication partners throughout the day.

One tool for gathering such information is the Communicative Effectiveness Index (Lomas et al., 1989). This index requires a respondent to rate the patient's current performance in communication skills in specific daily communicative situations, using a continuum from "not at all able" to "as able as before the stroke" (Table 4-2). The

TABLE 4-2

The Sixteen Items of the Communicative Effectiveness Index (CETI)^a

Please rate _____'s performance for that particular communication situation.

1. Getting somebody's attention.
2. Getting involved in group conversations that are about him or her.
3. Giving yes and no answers appropriately.
4. Communicating his or her emotions.
5. Indicating that he or she understands what is being said to him or her.
6. Having coffee-time visits and conversations with friends and neighbors (around the bedside or at home).
7. Having a one-to-one conversation with you.
8. Saying the name of someone whose face is in front of him or her.
9. Communicating physical problems such as aches and pains.
10. Having a spontaneous conversation (e.g., starting the conversation and/or changing the subject).
11. Responding to or communicating anything (including yes and no) without words.
12. Starting a conversation with people who are not close family.
13. Understanding writing.
14. Being part of a conversation when it is fast and a number of people are involved.
15. Participating in a conversation with strangers.
16. Describing or discussing something in-depth.

(From Lomas J., Pickard, L., Bester, S., Elbard, H., Finlayson, A., & Zoghail, C. (1989). The Communicative Effectiveness Index: Development and psychometric evaluation of a functional communication measure for adult aphasia. *Journal of Speech and Hearing Disorders*, 54, 113-124.)

respondent places a mark on a 100- mm line for each item. Comparison of multiple response opportunities across time can be used to examine changes in perception about an individual's communicative abilities.

Social Network Theory provides another means of gathering information about the communication needs and abilities of an individual and his or her communication partners (Blackstone & Berg, 2003). In Social Network Theory an individual is at the center of a series of concentric circles, each of which represents a communication partner. The partners in the circles nearest to the center have the closest relationship to the patient (Fig. 4-3). The partners in the outside circles represent communication partners who are unfamiliar with the patient but who may have a specific role in communicative interactions (e.g., transportation workers or wait staff at a restaurant). Using an interview procedure, the clinician discovers the communication needs of the interaction between the individual and these partners.

Activity 1: Circles of communication partners

Directions: Please fill out your circle of communication partners.

1. Who is in your 1st, 2nd, 3rd, 4th, 5th circle?
2. Write initials/role of each person on the appropriate circle.
For circle 5, write categories.
3. Raise your hand when you are finished.

Figure 4-3. Blackstone, S., & Berg, M. (2003). *Social Networks: A Communication Inventory for Individuals with Complex Communication Needs and Their Communication Partners*. Monterey CA: Augmentative Communication, Inc. *Reprinted with Permission.*

Time, reliability and validity may present barriers to reported observations. For example, if an individual does not quickly and easily interact with a clinician, and the time allotted for observation is short, the data collected in the observation may be insufficient to allow the clinician to draw reliable conclusions about a patient's behavior. While acknowledging the importance of reported observations, professionals and paraprofessionals working in medical settings may not have the time to complete lengthy interviews or questionnaires. Holland and Hinckley (2002) discuss the importance to the diagnostic process of the information gathered from reported observations and describe several methods of gathering this information, such as conversational analysis and streamlined functional communication checklists. This information is particularly important for diagnosis of pragmatic functioning. Boles and Bombard (1998) provide suggestions for accomplishing conversational analysis that is efficient yet generates sufficient data for diagnosis.

Direct Observations

During direct observation, the clinician observes the patient, preferably over several sessions. Repeated observa-

tions are important to maximize the patient's ability to respond and to minimize fatigue, stress, and possible failure. Multiple samples are also essential because qualitative and quantitative aspects of the language abilities of patients with aphasia vary across different communication contexts, contents, tasks, and partners (Murray & Chapey, 2001). In addition, the communicative success of a person with aphasia may also vary despite identical communication conditions (Boyle, Coelho, & Kimbarow, 1991), since "an inconsistent response is one of the most striking results produced by a lesion of the cerebral cortex" (Head, 1920). Therefore the clinician should elicit language in several contexts, such as unstructured, moderately structured, and highly structured contexts, and appraise the effect of sampling methodology on the language elicited (Davidson, Worrall, & Hickson, 2003; Lahey, 1988; Murray & Chapey, 2001; Murray & Clark, 2006).

Unstructured Observation

In unstructured observation, the clinician describes the patient's cognitive, linguistic, and pragmatic behaviors in a natural setting when there is a minimum of control or

interference. The setting should be familiar to the client and provide the opportunity for the individual to interact verbally with others. For example, a clinician working in a home-health setting may spend part of a session early in the treatment program observing the spontaneous communicative interactions among the patient and spouse or other family members during a meal. In this observation the clinician may be able to identify maladaptive behavior strategies (e.g., a spouse who pretends to understand the aphasia jargon produced by his or her partner) that lead to communicative interference or breakdown. The clinician may also observe positive strategies (e.g. an individual with aphasia who requests repetitions, or a spouse who accompanies his or her speech with gesture) that the patient or spouse currently use to facilitate communication interaction (Kagan et al., 2004; LeDorze & Brassard, 1995). In a medical setting a clinician might observe how the patient communicates with the reception area staff, again observing maladaptive or facilitative strategies used by both the staff and the patient.

Moderately Structured Observation

At times, the clinician may take a moderately active role in structuring observations and use predetermined questions or tasks to observe comprehension of and to elicit production of spontaneous communicative interaction (speech and language) (Croteau et al., 2004). For example, a client may be asked to retell a story, describe pictures, or answer direct requests, such as, “How do you change a tire?” or “How do you make scrambled eggs?” The clinician and patient may also role play specific situations such as (a) ordering in a restaurant and paying the bill, (b) relating the date and time of a doctor’s appointment, or (c) answering the telephone and relaying a message (Chapey, 1994; Murray & Chapey, 2001). When possible, descriptive, narrative, procedural, and conversational types of discourse should be elicited since several studies have documented that type of discourse may significantly affect quantitative and qualitative aspects of a patient’s language (Armstrong, 2000; Cherney, Shadden, & Coelho, 1998; Li et al., 1996; Penn, 1999; Shadden et al., 1991). The use of moderately structured observations allows the clinician to collect and observe a larger and more varied sample of communicative behavior than otherwise might be possible in an unstructured observation. In addition, this observation style fosters exploration of specific aspects of spontaneous language production and comprehension that may not have emerged during an unstructured observation (Chapey, 1994; Holland & Hinckley, 2002; Lahey, 1988; Murray & Chapey, 2001).

Highly Structured Observation

The language and communication assessment also includes highly structured observations based on results of bedside and screening assessment tools, comprehensive aphasia

batteries, and/or tests of specific language functions. The American Speech-Language-Hearing Association publishes a list of speech-language assessments that can be accessed by ASHA members (Directory of Speech-Language Pathology Assessment Instruments, 2006).

Screening Tests. Screening tests provide an efficient means to determine the presence or absence of aphasia and to develop ideas for further assessment and initial treatment procedures (Al-Khawaja, Wade, & Collin, 1996; Salter et al., 2006). However, since they are short in length and sample a limited amount of language and communicative behavior, they do not provide a detailed description of the patient’s language ability. Screening tests are most useful in three situations: in the early post-acute stages of recovery when patients may be too ill to complete a lengthy aphasia evaluation; in certain clinical settings where the length of stay in the facility is brief; or when the cost containment necessitates fast clinical information without extensive testing.

Spreeen and Risser (2003) describe three screening procedures relevant to aphasia diagnosis: the bedside clinical examination, published screening instruments, and standardized tests that are limited to a specific aspect of language function. **Bedside tests** are rooted in classic neurology evaluation where interaction between the patient and examiner provides diagnostic data, and ranges from unstructured conversations to structured task sets (Spreeen & Risser, 2003). Spreeen and Risser (2003), Davis (2000), and Brookshire (2003) agree that an experienced clinician is able to make maximal use of patient responses and obtain a satisfactory aphasia screening under almost any set of clinical circumstances. Brookshire (2003) cautions however, that “...an unsystematic approach may lead the examiner to miss important signs, and may invalidate comparisons of the patient’s performance with that of other patients or with the same patient on subsequent visits.” (p. 165).

There are several frequently used aphasia **screening instruments** (Table 4-3), such as the Aphasia Language Performance Scales (Keenan & Brassell, 1975). This instrument consists of four scales (i.e., Listening, Talking, Reading, and Writing), each of which has 10 items of increasing difficulty. The screening requires minimal administration and scoring time and is suitable for patients regardless of aphasia severity or type. A Spanish version is also currently available. The Frenchay Aphasia Screening Test (Enderby & Crow, 1996; Enderby, Wood, & Wade, 2006; Enderby et al., 1987) was designed for use by individuals who are not trained speech-language pathologists, to screen for language disturbances in persons with aphasia. There are four sections to this test (i.e., Comprehension, Expression, Reading, and Writing). The test is short and easy to administer, and provides excellent value (Salter et al., 2006). Nkase-Thompson et al. (2005) introduced the Mississippi Aphasia Screening Test (MAST) as a screening

test designed to detect changes in language abilities over time. It was developed by a team of neuropsychologists, physiatrists, and speech-language pathologists, and has nine subtests designed to measure receptive and expressive language abilities. The Multimodal Communication Screening Task for Persons with Aphasia (Garrett & Lasker, 2005) is a cognitive-linguistic and behavioral assessment protocol for communicators with aphasia who may benefit from Augmentative or Alternative Communication Systems (AAC). This tool consists of eight tasks presented in picture format and designed to communicate a specific message. Responses are rated for accuracy in conveying the message, number of cues provided, number of attempts, and the examiners rating of message adequacy. Scores are summarized to determine whether the patient is an independent or partner-dependent communicator.

Shortened versions of several comprehensive tests of aphasia are also available to be used for screening purposes. These include the Minnesota Test for Differential Diagnosis of Aphasia (Powell, Bailey, & Clark, 1980) and the Porch Index of Communicative Ability (PICA; DiSimoni, Keith, & Darley, 1980). DiSimoni, Keith, and Darley report that shortened PICA scores accurately predict full PICA scores. However, Holtzapple and colleagues (1989) suggest using the shortened version of the PICA with caution as it may not always provide the same results. The third edition of the Boston Diagnostic Aphasia Examination (Goodglass, Kaplan, & Baresi, 2001) contains a short form that is valid for a constrained assessment session. The WAB-E (Kertesz, 2006) also contains a shortened version meant to be administered at the bedside.

Tests for specific aspects of language functioning have also been shortened to serve as screening tools. For example, The Token Test (Spellacy & Spreen, 1969) and the Boston Naming Test (Fastenau, Denburg, & Mauer, 1998) both have short forms. The reliability and validity of the shortened versions, as

compared to the original tests, have been demonstrated and these tests should prove useful as screening instruments.

Several scales exist to screen, very briefly, for aphasia and other physical and neuropsychological sequelae that may accompany stroke (NIH Stroke Scales, 2003; Stroke Scales, 2006). These scales are primarily intended for use by physicians at the first sign of stroke in an individual. Some include only one or two items to assess speech, language, and mental status (i.e., Miami Emergency Neurologic Deficit (MEND) Prehospital Checklist (Miami Emergency Neurologic Deficit (MEND) Prehospital Checklist, 2001)), while others have several items to examine speech and language (NIH Stroke Scale, 2003).

Comprehensive Aphasia Tests. In many instances clinicians rely on comprehensive aphasia batteries to provide the major portion of their highly structured observations. These tests are designed to obtain a diverse sampling of performance at different levels of task difficulty (Spreen & Risser, 2003) and to evaluate language input and output modalities along a continuum of complexity (Brookshire, 2003). Many comprehensive aphasia batteries are available, each of which differs in terminology, internal organization, and the number of modalities tested, and each is associated with particular administration and interpretation of strengths and weaknesses (Lezak, Howieson, & Loring, 2004). Five tests that are commonly used in North America are the Minnesota Test for the Differential Diagnosis of Aphasia (MTDDA; Schuell, 1965), the Boston Diagnostic Aphasia Examination (BDAE; Goodglass et al., 2001), the Western Aphasia Battery (WAB; Kertesz, 1982; 2006), the Aphasia Diagnostic Profiles (ADP; Helm-Estabrooks, 1992), and the Porch Index of Communicative Ability (PICA; Porch, 1967, 1981).

One of the oldest and most comprehensive test batteries for aphasia is the MTDDA (Schuell, 1965). It consists of

46 subtests that are designed to assess a patient's strengths and weaknesses in speaking, listening, reading, and writing. A plus/minus scoring is used for most subtests. In addition, a severity rating scale from 0 to 6 can be used to quantify performance in the four assessed language modalities. The test provides a classification system based on Schuell's view that aphasia is a unidimensional, multi-modality impairment. This system categorizes an individual's performance according to whether the patient presents with aphasia alone, or whether he or she presents with aphasia plus sensory and/or motor deficits. For example, a patient may have a diagnosis of simple aphasia, aphasia with sensorimotor involvement, or aphasia with visual impairment. The test manual provides guidelines for the prediction of recovery based on Schuell's extensive clinical experience.

The third edition of the BDAE-3 (Goodglass et al., 2001) provides a comprehensive exploration of a range of communicative abilities. The results of the BDAE are used to classify patient's language profiles into one of the localization-based classifications of aphasia: Broca's, Wernicke's, anomic, conduction, transcortical motor, transcortical sensory, and global aphasia syndromes. The BDAE contains 34 subtests that assess conversational and narrative speech, auditory comprehension, oral expression, repetition, reading, and writing. The test provides for detailed scoring of conversational and narrative speech using a five-level aphasia severity rating scale, and several seven-point rating scales that comprise a profile of speech characteristics: melodic line, phrase length, articulatory agility, grammatical form, paraphasia in running speech, repetition, word-finding, and auditory comprehension. Raw scores on the subtests vary from a plus/minus scoring procedure, to rating scales, to frequency counts. These scores are converted to percentiles and registered on the Subject Summary Profile. The pattern of scores can be compared to exemplar profiles to help determine aphasia classification. The BDAE-3 consists of an Extended Standard Form for in-depth study of aphasia symptoms, including grammar and syntax, and a Short Form that takes only 30 to 45 minutes to complete. The Boston Naming Test and the Visuospatial Quantitative Battery are included as part of the BDAE-3. They are designed to assess visual confrontation naming (BNT) and visuospatial skills sensitive to parietal-lobe lesion. New to this edition is a videotape in which the authors demonstrate assessment and scoring procedures with individuals with aphasia.

Like the BDAE-3, the WAB (and WAB-Enhanced (WAB-E)) (Kertesz, 1982; 2006) is designed to diagnose localization-based aphasic syndromes. However, unlike the BDAE, the WAB identifies syndromes on the basis of specific test scores, and provides summary scores that allow documentation of progress. The oral language abilities portion of the WAB contains 10 subtests that assess spontaneous speech (i.e., content and fluency), auditory comprehension, repetition, and naming. The seven subtests of visual language and

the other subtest portions examine reading, writing, praxis, and construction abilities. Three summary scores can be calculated from WAB performances: (a) an Aphasia Quotient (AQ), which is derived from performance on the oral language subtests; (b) a Language Quotient (LQ), which is derived from performance on all language subtests (i.e., oral language abilities subtests as well as reading and writing subtests) (Shewan & Kertesz, 1984), and (c) a Cortical Quotient (CQ), which is derived from performance on all subtests.

The WAB-E (Kertesz, 2006) contains 32 tasks within eight subtests, and measures spontaneous speech (content and fluency), auditory comprehension, repetition, and naming, as well as reading and writing. Supplemental tests measure drawing, calculation, block design, and praxis. In addition, two new supplemental tasks (reading and writing of irregular words and nonwords) were included to aid in distinguishing between surface, deep, and visual dyslexia. The WAB-E provides six criterion quotient scores: Aphasia Quotient, Cortical Quotient, Auditory Comprehension Quotient, Oral Expression Quotient, Reading Quotient, and Writing Quotient. The WAB-E has revised administration instructions for each subtest and expanded scoring guidelines, and can be purchased with or without the manipulatives required for administration. In addition, the test battery contains a Bedside WAB-E that can be administered in approximately 15 minutes to assess briefly a patient's level of functioning.

The ADP (Helm-Estabrooks, 1992) provides for documentation of the nature and severity of aphasia, the communicative value of a patient's responses, and information concerning the general social-emotional status of a patient. The test contains nine subtests that assess speaking, listening, reading, writing, and gesture modalities (the reading and writing portions are short and therefore may require follow-up testing in some patients with aphasia). The ADP is designed to emphasize conversational interaction with the patient. The scoring methods vary across subtests, from a four-point scale and plus/minus scoring, to calculation of the number of correct information units and phrase length for verbal fluency tasks. Subtest raw scores are converted to standard scores and percentiles and used to create composite scores for five profiles: Aphasia Classification Profile, Aphasia Severity Profile, Alternative Communication Profile, Error Profile, and Behavioral Profile. Like the WAB, subtest and summary standard scores are used to determine aphasia type in terms of the Boston classification of aphasia. In addition to these nonfluent and fluent types of aphasia classifications, the ADP includes a borderline fluent aphasia type. Clinicians can also plot confidence ranges (i.e., standard error of measurement intervals) for each subtest and summary standard scores that can be used to determine patient progress over time.

The PICA (Porch, 1967; 1981) is a standardized test designed to provide a reliable measure of deficit severity and

TABLE 4-4

Multidimensional Scoring System of the Porch Index of Communicative Ability

Score	Level	Description
16	Complex	Accurate, responsive, complex, immediate, elaborative response to test item
15	Complete	Accurate, responsive, complete, immediate response to test item
14	Distorted	Accurate, responsive, complete response to test item, but with reduced facility of production
13	Complete-delayed	Accurate, responsive, complete response to test item that is significantly slow or delayed
12	Incomplete	Accurate, responsive response to test item that is lacking in completeness
11	Incomplete-delayed	Accurate, responsive, incomplete response to test item that is significantly slowed or delayed
10	Corrected	Accurate response to test item self-correcting a previous error without request or after a prolonged delay
9	Repetition	Accurate response to test item after a repetition of the instructions by request or after a prolonged delay
8	Cued	Accurate response to test item stimulated by a cue, additional information, or another test item
7	Related	Inaccurate response to test item that is clearly related to or suggestive of an accurate response
6	Error	Inaccurate response to test item
5	Intelligible	Intelligible response that is not associated with the test item; for example, perseverative or automatic responses or an expressed indication of inability to respond
4	Unintelligible	Unintelligible or incomprehensible response that can be differentiated from other responses
3	Minimal	Unintelligible response that cannot be differentiated from other responses
2	Attention	Patient attends to test item but gives no response
1	No response	Patient exhibits no awareness of test item

(From Porch, B. (1971). Multidimensional scoring in aphasia testing. *Journal of Speech and Hearing Research*, 14, 776–792.)

recovery progress. It contains 18 subtests that assess verbal, gestural, and graphic modalities through the use of 10 common objects. It does not, however, contain any tasks that assess spontaneous production of connected speech in discourse tasks. Performance on items in each subtest is scored using an elaborate 16-point multidimensional scoring system that encodes five dimensions of behavior: completeness, accuracy, promptness, responsiveness, and efficiency (see Table 4-4). The numbers assigned to a patient's responses are averaged to provide individual subtest scores, overall performance scores, and scores for each of six modalities: pantomime, reading, auditory, visual, writing, and copying. In the 1981 revision, Porch added diacritical markings to the scoring system to provide a greater degree of specific and sensitive response characterization. For example, an intelligible response that was rated a 5 would be augmented by a diacritical "p" if it was a preservative response. The PICA scoring system is highly informative; however, it requires a recommended 40 hours of formal training for skillful use (Martin, 1977; McNeil, Prescott, & Chang, 1975).

The batteries described above are among the most frequently used by clinicians. In addition, several other comprehensive aphasia tests are available. The Comprehensive Aphasia Test (CAT; Swinburn, Porter, & Howard, 2004) contains a cognitive screen, language battery, and disability questionnaire, and can be used to assess performance across

a range of tasks. The Neurosensory Center Comprehensive Examination for Aphasia (Spreen & Benton, 1977; Spreen & Strauss, 1998) assesses language comprehension, language production, reading, and writing in 20 subtests. Examining for Aphasia (Eisenson, 1994) assesses oral and written receptive and expressive language functions, agnosia (visual, auditory, and tactile), and simple mathematic skills.

For patients whose first language is not English or who do not speak English, aphasia batteries are available in other languages (Kennedy & Chiou, 2005), such as the Aachen Aphasia Test (Huber, Poeck, & Willmes, 1984; Huber et al., 1983; Kusunoki, 1985; Miller, Willmes, & DeBleser, 2000). Aphasia batteries originally written in English have been translated to other languages; two examples are the BDAE (Laine et al., 1993; Mazaux & Orgogozo, 1981) and the WAB (Sugishita, 1988). In addition, a few aphasia batteries such as the Multilingual Aphasia Examination (Benton et al., 1994; Rey & Benton, 1991), and the Bilingual Aphasia Tests (Paradis & Libben, 1987; 1993) assess various language abilities of patients who are bilingual or multilingual. These tests provide different language versions (e.g., Spanish, Arabic, Chinese, Swedish) that appear functionally and culturally equivalent in content and not simply direct translations of stimulus items from one version to the next.

Two other comprehensive batteries, the Boston Assessment of Severe Aphasia (BASA: Helm-Estabrooks

et al., 1989) and the Assessment of Communication Effectiveness in Severe Aphasia (Cunningham et al., 1995) have been developed for patients with severe language problems. Because these batteries are designed to measure the language abilities of patients who are severely aphasic, their test procedures differ from those of traditional aphasia tests. For example, the BASA probes for spared language abilities across a variety of tasks and modalities including auditory, visual, and gestural expression and comprehension, as well as visuospatial and praxis tasks. The scoring system on this measure includes the identification of affect and perseveration, as well as partial verbal and gestural responses. Consequently, clinicians can acquire more explicit information regarding the communication strengths and weaknesses of their patients who have severe aphasia than can typically be obtained using one of the traditional aphasia batteries.

Tests of Specific Language Functions. Clinicians may need to supplement or substitute comprehensive aphasia batteries with tests of specific language functions to allow more in-depth quantification and/or qualification of abilities in a specific language modality than can be obtained from a general assessment battery, or to include a greater range of item difficulty. This testing may be particularly important when a person with aphasia scores at either a basal (very low) or ceiling (very high) level on an aphasia battery. In either of these cases little information is obtained with respect to areas of relative strength or weakness in a patient's communicative abilities. Such information is valuable for treatment diagnosis as well as treatment planning. Table 4-5 contains a list of some of the tests available for measuring auditory comprehension, verbal expression, reading comprehension, writing, and gestural abilities of patients with aphasia.

For many of these tests, normative data are provided in the test manual so that the performance of a person with aphasia may be compared with those of brain-damaged or non-brain-damaged peers. For other tests, clinicians must look to the empirical literature to find the appropriate normative data. For example, several studies have been conducted to extend the normative sample of the Boston Naming Test (Goodglass et al., 2001) to individuals who (a) live in institutionalized or community settings (Neils et al., 1995), (b) represent a wide age range (Henderson et al., 1998; Tombaugh & Hubley, 1997; Welch et al., 1996), and (c) represent diverse educational, racial, and socioeconomic backgrounds (Henderson et al., 1998; Kohnert, Hernandez, & Bates, 1998; Neils et al., 1995; Tombaugh & Hubley, 1997). Likewise, expanded normative data for verbal fluency tests such as the Controlled Oral Word Association Test (Benton et al., 1994) and the Thurstone Word Fluency Test (Thurstone & Thurstone, 1962) are also available in the research literature (Heaton, Grant, & Matthews, 1992; Ivnik et al., 1996; Kempler et al., 1998). Further expansion of norms for many published language tests is needed since

the demographic characteristics of the population of individuals with aphasia who live in North America is slowly changing over time (Neils-Strunjas, 1998).

Nonstandard Observation

Nonstandardized observations are useful in diagnosing the presence and severity of aphasia. Indeed, some tests of aphasia and some measures of specific language function rely primarily on nonstandard observations. These observations can be moderately or highly structured and typically do not have published norms (Lahey, 1988). They may be cited as tasks in empirical research studies or in doctoral dissertations or master's theses. These tasks can easily be adopted for assessment purposes and often lend valuable insight into the language, communication, or cognitive abilities and impairments of individuals with aphasia.

One example of a nonstandard observation is the Shewan Spontaneous Language Analysis (Shewan, 1988a, 1988b). The SSLA is a comprehensive and in-depth method for analyzing samples of spontaneous connected speech in picture description tasks. The SSLA contains several scoring dimensions, such as time of utterances, melody, and error analysis. Another example is divergent semantic naming tasks (Chapey, 1983; Murray & Chapey, 2001). For example, a clinician might ask a client to "Name as many objects as you can that can be folded," or "Name as many objects as you can that will break if they are dropped," or "Name as many ways as you can think of to use a hammer." The client's responses can be scored on several dimensions: fluency (the number of responses), flexibility (the variety of responses), originality, or elaboration. These tasks, while useful in diagnosis, do not have published norms for comparison.

Luria (Christensen, 1975) approached aphasia diagnosis through nonstandard observation across a variety of modalities and functions. He developed a series of bedside tasks, and recorded and rated a patient's responses according to level of performance. For example, the functions of reading and writing were examined through analysis of responses on letter identification and production tasks, reading words, reading phrases, and copying simple and complex forms. Performance pattern was related to site of lesion. Christensen (1975) formalized the tasks for use in clinical settings.

Qualitative assessment approaches the assessment process from a discovery perspective, using authentic, functional, and descriptive measures (Tetnowski & Franklin, 2003). Tetnowski and Franklin reviewed several principles of qualitative analysis: collect holistic data, focus on data in authentic settings, engage in a rich description of the communication phenomenon, approach assessment with an open stance to data collection, and collect data from the perspective of the individual being evaluated. Damico and colleagues (1999) illustrated these principles in qualitative analysis of communication skills in persons with aphasia.

TABLE 4-5

Tests of Specific Language Functions That May Be Used to Augment or Replace Comprehensive Aphasia Batteries

Language Function	Instrument	Source
Auditory comprehension	Auditory Comprehension Test for Sentences	Shewan (1979)

	Pantomime Recognition Test	Benton et al. (1993)
	Test of Apraxia	van Heutgen et al. (1999)
	Test of Oral and Limb Apraxia	Helm-Estabrooks (1991)
	15 item battery of movement to imitation	Haaland & Flaherty (1984)

Nonstandardized observation must be reliable to be of greatest value in a clinical setting (Cordes, 1994; Tetzlowski & Franklin, 2003). Cordes described the theoretic foundation for observation and four common methods of measuring reliability: correlation based on classical test theory, interjudge percent agreement calculations, analysis of data from more than one observer, and generalizability theory, which is a method of estimating reliability from sources of error. Regardless of the method selected for measuring reliability in nonstandardized observation, the success of the measurement depends largely on the careful description of the behavior to be observed and the assurance that results were not influenced by error, which is inherent in human judgment (Dollaghan & Campbell, 1992).

Psychometric Considerations

Clinicians should be knowledgeable about the basic psychometric properties of aphasia batteries or tests used to assess an individual with a neurogenic or cognitive communication disorder. Specifically, each test or procedure used should be evaluated in terms of its validity, reliability, and standardization (Carmines & Zeller, 1979). In addition, when selecting a test clinicians should also consider the social and ethical consequences of using the test in terms of costs and benefits as well as possible side effects as a result of using the test, and consequences that might arise as a result of using the data from the test. Messick (1980) labeled the consideration of psychometric properties of a test as the **evidential bias** of test interpretation, and consideration of social and ethical consequences as the **consequential bias**. Skenes and McCauley (1985) reviewed nine tests for use with persons with aphasia and found several to be lacking in one or more categories of psychometric factors. Clinicians are cautioned to carefully review test manuals prior to administration to be assured that the test selected is psychometrically rigorous and addresses the goals of the evaluation (McCauley & Swisher, 1984).

Validity

Three categories of validity are important in language sciences: content, construct, and criterion-related validity. Each of the categories has several subtypes of validity that allow a fine-grained analysis of a test procedure (Messick, 1980). **Content validity** involves determining whether the test contains items that adequately represent the full domain of behaviors that should be measured. In aphasia assessment a test should contain language and communication behaviors that are perceived as being theoretically and functionally germane for successful communication (Carmines & Zeller, 1979; Spreen & Risser, 2003). A fine-grained analysis of content validity might include examination of the range and diversity of the content. **Construct validity** refers to determination of the extent to which a test relates to other measures of the same construct. In the case of aphasia assessment those constructs would be aphasia characteristics or language abilities. Spreen and Risser (2003) suggest that few aphasia tests have known validity; thus, to demonstrate construct validity test administrators may use factor-analytic statistical techniques. These techniques demonstrate whether test items contribute to one or more major factors that represent language or communication function. **Criterion-related validity** refers to the hypothesis about the relationship between a test and the criterion to which it is to be compared (Messick, 1980). In aphasia assessment, criterion validity refers to the accuracy with which a test can determine whether or not a patient meets the criterion for a diagnosis of aphasia. Concurrent and predictive validity are two types of criterion-related validity. Aphasia tests with good concurrent validity should be able to discriminate between the presence or absence of aphasia in an individual. Ideally an aphasia test should be able to discriminate not only between individuals with aphasia and non-brain-damaged individuals, but also between individuals with aphasia and other neurogenic communication disorders, such as

right hemisphere disorder or dementia (Spreen & Risser, 2003; Strauss, Sherman, & Spreen, 2006). A test with good predictive validity should be suitable for measurement of change over time. A single aphasia test may not be appropriate for both concurrent and predictive validity purposes.

Unfortunately, aphasia batteries have been questioned on the basis of all forms of validity. Spreen and Risser (2003), and Strauss, Sherman, and Spreen (2006) note that although an aphasia test may have strong criterion-related validity, analysis often does not indicate whether trivial test items are responsible for discriminating performance of individuals with aphasia from non-brain-damaged individuals. The content and construct validity of some aphasia tests are also suspect because they include no clear operational definition of what is being assessed and/or fail to stipulate the specific model of language on which test construction was based (Byng et al., 1990; Chahey, 1986; 1994; David, 1990; David & Skilbeck, 1984; Kay et al., 1990; Martin, 1977; Murray & Chahey, 2001; Weniger, 1990). For example, the conceptual schemata underlying aphasia tests have often ignored the complexity factor in language (Chahey, 1986; 1994; Murray & Chahey, 2001). Tests have not reflected the fact that the communication of meaning is the essence of language (Goodman, 1971), and results do not supply enough information about the content, context, intent, structure, relevance, and meaningfulness of utterances (Chahey, 1994). Furthermore, most aphasia batteries do not provide a description of the patient's language impairment in relation to recently advanced cognitive neuropsychologic models of language (Ellis & Young, 1988; Hillis, 2002a; Patterson, Coltheart, & Marshall, 1985; Raymer & Rothi, 2000) and consequently fail to yield information concerning the nature of the underlying disorder. As Byng et al. (1990) suggest, "most standardized tests neither clarify what is wrong with the patient, nor specify what treatment should be provided" (p. 67). Lastly, many tasks in aphasia batteries assess composite abilities or more than one linguistic and/or cognitive ability at a time. For example, instructing a patient to "Put the pen on top of the book, then give it to me" (WAB item) engages linguistic processing abilities as well as attention, memory, initiation, and limb praxis abilities. Because linguistic and cognitive skills are both composite abilities and because they are highly interrelated processes, testing one particular aspect of language (e.g., confrontation written naming) without directly or indirectly involving associated processes (e.g., visuoperception or graphomotor constructional abilities) involves at best sophisticated clinical skill and acumen to provide an accurate diagnosis.

Reliability

Reliability refers to the consistency, stability, and accuracy of a test's scores during repeated administration under similar testing conditions (Anastasi & Urbani, 1996; Murray & Chahey,

2001). Spreen and Risser (2003) suggest that three types of reliability are most relevant for aphasia tests: the **internal consistency of the test**, **test-retest stability**, and **interrater reliability**. Aphasia test manuals should report correlation coefficients of at least 0.80 for these measures of reliability. The standard error of measurement for the test should also be reported. Although measuring any phenomenon is always associated with some degree of chance error, a test should contain detailed administration and scoring instructions as well as examples of correct and incorrect responses in order to minimize intra- and inter-examiner measurement error that can affect test reliability as well as validity.

Because of the extensive physiologic changes that typically occur during the early, acute phases of recovery, the reliability of aphasia tests can be poor (Murray & Chahey, 2001). To improve reliability, Spreen and Risser (2003) suggest that "... reliability is best demonstrated with normal, healthy subjects, since the measurement error in patient populations and the likelihood of change in performance due to changes in the patient's condition are high." Many aphasia tests demonstrate reliability using patients who have chronic aphasia rather than patients with acute aphasia, because language and communication deficits related to aphasia are considered to be stable. Considering only time post-onset of aphasia, these individuals are likely to show less variability and thus better reliability than individuals with acute aphasia. Clinicians should carefully examine the standardization sample on which reliability data are reported and examine the reliability of both overall test scores and individual scores (Cordes, 1994; Meline, 2005).

Standardization

Test administration procedures should be standardized (Cronbach, 1990; Spreen & Risser, 2003) to minimize measurement error and to allow valid and reliable comparison of patient performance to published norms. Standardization procedures reflect both test structure and administration instructions. The test structure should allow for minor variations in administration that routinely occur (i.e., variations related to individual clinical settings) but indicate deviations that may result in incorrect interpretation of test results. Test administration and scoring instructions must be clearly stated. Three areas where clarity of administration and scoring instructions are particularly important are (a) clarifying the range of scoring options left to the judgment of the clinician (i.e., use of an equivalent vocabulary term); (b) determining whether repetition of instruction is permitted; and (c) limiting stimulus and response format to that specified in the test (i.e., not allowing extra time for a response, or giving cues to elicit a response). Permitting variations in procedures may provide valuable diagnostic information; however, they render comparison to standardization norms inappropriate (Spreen & Risser, 2003).

To establish norms for comparison, standardized tests are administered to a large number of individuals who represent a cross-section of the population to whom the test will be administered in clinical practice. In addition, many test authors revise their tests in an attempt to improve sampling procedures and to expand normative data to a greater variety of reference groups (e.g., increased age range, or improved minority representation in the normative sample). When selecting a test for use with individuals with aphasia, clinicians are advised to examine carefully the characteristics of the standardization sample (i.e., age, education, time post-onset), the details of administration instructions, the parameters of scoring principles, reliability and validity data, and information about test revision (Jackson & Tompkins, 1991; Strauss, Spreen, & Hunter, 2000).

Predictive Considerations

In addition to meeting psychometric criteria, tests designed for use with persons with aphasia should allow for measurement of recovery or progress in treatment. Several researchers have noted that standardized tests are clearly unsuitable measures of language change or recovery (David, 1990; Kay et al., 1990). For example, the subtests of most aphasia batteries include too few items to provide a sensitive and reliable measure of a particular language modality or dimension. Likewise, real change made by a patient in a specific area of language functioning may not be represented in the overall test score. It is possible that a treatment protocol for a patient might result in real and meaningful change in the patient's language performance in daily communication activities; however, the potential lack of corresponding change in test scores would obscure a determination of treatment effectiveness. During the course of treatment an individual is expected to relearn language behavior or develop compensatory behaviors to replace the deficit. Traditional language tests measure current levels of functioning but do not reflect learning that occurred over time (Spreen & Risser, 2003). Furthermore, standardized language tests typically do not allow cueing or probing to "test the limits" of performance or examine learning styles.

Ethnocultural Considerations

It is well regarded that society is becoming increasingly diverse. As such there is an increasing number of patients on speech-language pathologists' caseloads for whom English is not the first or primary language, and Eurocentric culture is not the primary culture. Evaluating these individuals for the presence of a neurogenic communication disorder presents a challenge to clinicians who are not bilingual or multilingual (Baker, 2000). Spreen and Risser (2003) suggest that evaluation should include testing in all premorbidly spoken languages of a patient and ideally be conducted by a clinician who is fluent in those languages. Evaluation of ability in one

language only may lead to errors in diagnosis, such as failing to detect symptoms that appear in one language but not the other, or assessment bias introduced by using a translator to administer a test. Clearly it may not always be possible for a clinician to evaluate a patient in all languages in which that patient may be fluent; however, it is incumbent upon the clinician to be at least aware of the multilingual nature of a client and to plan as sensitive and thorough an assessment session as possible. Additionally, attitudes on the part of the patient toward the testing process, the clinical setting, or a question-and-answer format may be threats to successful assessment (Baker, 2000).

Culture is "a system of shared beliefs, values, customs, behaviors, and artifacts that members of a group use to cope with their world and one another, and that are transmitted from one generation to another through learning" (Bates & Plog, 1990). Appreciating cultural differences and using culturally competent assessment practices is important to a successful assessment interaction (Mahendra et al., 2005). They describe one framework for achieving cultural competence used by the National Faculty Center at the University of Arizona (National Faculty Center, 2006) that incorporates three stages: awareness, application, and advocacy. As one moves through these stages in one's professional development, one becomes better able to plan and implement an assessment session that is appropriate to the disorder as well as being sensitive to the cultural and linguistic traits of a client.

Ethnocultural considerations have a distinctive role in test selection for a client whose culture or language differs from that of the clinician. Spreen and Risser (2003) suggest that geographic, cultural, and regional considerations should guide test selection for individuals whose first language is not English. Although adaptations of a test may be available (i.e., a Spanish version of the WAB), it is preferable to use tests developed in the country consistent with the premorbid language of the patient (Paradis, 2004). For example, the Aachen Aphasia Test (Huber et al., 1983) would likely be more appropriate for individuals whose native language is German than a German translation of a test written in English (Baker, 2000). However, a client may be from a different geographic region than that in which the test was developed, and thus produce errors that are related to a cultural or linguistic difference rather than a communication disorder. Regional differences, particularly in vocabulary, may induce artificial errors (Barker-Collo, 2001). For example, the Psycholinguistic Assessments of Language Processing in Aphasia (Kay, Lesser, & Coltheart, 1992) contains several items (such as *pram*) that while recognized in the English language per se, may be unfamiliar to English-speaking individuals living in the United States. Kennedy & Chiou (2005) described 33 assessment tools in languages other than English that are available for use with individuals with communication disorders. They reported that their

enthusiasm for the number of available assessment tools was tempered by the lack of adherence to psychometric test-construction principles in many of these tools.

Recently, investigators have begun to examine more closely relationships among test procedures in African-American individuals with aphasia. Ulatowska et al. (2001) examined performance by African-Americans who were neurologically unimpaired and who had aphasia. They found that using fable and proverb interpretation tasks improved the quality of assessment because those communication items fostered greater communication interaction than standardized tests or functional communication measures. Ulatowska et al. (2001) suggested that the stimuli supported familiar text and discourse styles in the participants' cultures and thus encouraged a quick yet sensitive assessment of natural language. Results from Molrine and Pierce (2002) provided support for this conclusion. Molrine and Pierce administered the Minnesota Test for the Differential Diagnosis of Aphasia (Schuell, 1965), the Western Aphasia Battery (Kertesz, 1982), and the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983) to 48 individuals who were black or Caucasian and compared group scores. Across all the subtests of the three batteries, only three subtests showed a significant difference between the two groups. Those three subtests required less structured responses and emphasized variety, quantity, and relevance of information. Molrine and Pierce reported that the three test batteries (MTDDA, WAB, and BDAE) are unlikely to yield performance that is influenced by group membership, while the less structured discourse tasks may show performance differences.

Studies of demographic, cultural, and linguistic influences on test performance in individuals without neurologic impairment and with aphasia have also appeared for persons living outside the United States. For example, Kohnert, Hernandez, and Bates (1998) and Pineda et al., (2000) examined cultural and linguistic influences in Spanish versions of the Boston Naming Test and the BDAE. Mansur and colleagues (2005) and Radanovic and Mansur (2002) studied similar influences in Portuguese. While the studies report individual differences according to the dependent variables examined, lessons to clinicians are similar about the importance of considering ethnocultural influences on the assessment process and diagnostic product.

Ethnocultural considerations apply not only to aphasia and language tests administered by clinicians but also to those tests regularly administered by other team members (Garcia & Desrochers, 1997; Tower, 2004). Chapey and Lu (1998) suggested that such important differences in language and the value that a given culture places upon different tasks and priorities are critical considerations for both assessment and intervention. In addition, values such as the duration of residency in the United States, English proficiency, and the value that a given culture places upon different language and cognitive abilities, test stimuli, and tasks all

influence an individual's performance (Ardilla, 1995; Jacobs et al., 1997; Kempler et al., 1998; Payne-Johnson, 1992). Consequently, clinicians must be aware of how salient and suitable stimuli and procedures are to individuals from particular cultural groups. Likewise, assessment findings will be more accurate and valid if the normative group for a given aphasia test is representative of the ethnocultural or linguistic group to which a person with aphasia belongs (Spree & Risser, 2003).

Body Functions and Structure, Activity, and Participation Considerations

The World Health Organization's framework for health and disability (*Towards a Common Language for Functioning, Disability and Health*, 2002) influences how aphasia is conceptualized and consequently assessed and treated (Simmons-Mackie, 2004; Threats, 2004; Threats & Worrall, 2004). In the ICF, functioning and disability are associated with an individual's health condition (disease or disorder); however, health condition is not the only consideration in assessment. In aphasia or other neurogenic communication disorders, an individual's performance in his or her usual environment will be influenced not only by the degree and nature of impairment in body structure or function and in language, but also by limitations in personal activities and restrictions to participation in society. Therefore, the ICF involves consideration of contextual factors that influence performance, such as social and physical-environmental factors (e.g., social attitudes of individuals in the patient's community, or architectural design of the patient's home) and personal factors (e.g., age, education, or co-existing physical or mental health conditions) that may interact with impairment, activity, and participation. Within ICF, clinicians appraise each of the factors that influence performance since there is not a one-to-one correspondence among these factors and levels of the ICF (Frattali, 1992, 1998a; Ross & Wertz, 1999; 2005; Threats & Worrall, 2004). Estimating the nature and extent of activity and participation assets and limitations, or predicting functional outcome and social reintegration solely on the basis of body functioning and structure is difficult at best (*Towards a Common Language for Functioning, Disability and Health*, 2002).

Body Functions and Structure

Impairment in body functions and/or structure refers to a loss or anomaly in anatomical, physiologic, or psychological structure or function. Examples of conditions at the impairment level of the ICF include aphasia, hemiparesis, hemianopsia, and dysphagia.

Activity

Within the activity level of ICF, aphasia may impose limitations on the four language modalities of speaking, listening,

reading, and writing, as well as tasks necessary for daily living. Such limitations in language-related activities of daily living refer to any communication difficulties that arise in everyday contexts (e.g., using the telephone, writing checks, or reading the newspaper). Therefore, assessment at the activity level can involve the use of comprehensive aphasia tests and tests of specific language functions (e.g., naming or productive syntax ability) as well as functional status measures to assess the extent and type of language with which a person with aphasia may present (Baines, Heeringa, & Martin, 1999; Frattali, 1998b). Additionally, analysis of spontaneous language and communication within the context of activities of daily living (ADLs) and personally meaningful activities is an essential component of assessment (Armstrong, 2000).

The emphasis on functional communication requires clinicians to summarize patient data, often on scales such as the Functional Independence Measure (The FIM System, 2006; Granger et al., 1993). The Functional Independence Measure (FIM) is a tool for measuring an individual's functional ability across motor, cognitive, and self-care domains and is part of The FIM System®. FIM uses a seven-point rating scale (1, which equals "Total Assist," to 7, which equals "Complete Independence (Timely, Safely).") The FIM was originally designed to assist in setting reimbursement rates in response to medical cost-containment efforts and to document a patient's performance on a minimum set of skills at intake and discharge (Ottenbacher et al., 1996) and continues to be frequently used, although it is now part of a subscription system (The FIM System, 2006).

A serious drawback to the FIM is the limited number of items used to summarize language abilities. Consequently the brevity of description of communication skills on this rudimentary scale makes it an instrument of questionable reliability, validity, and sensitivity for assessment of persons with aphasia (Bunch & Dvorch, 1994; Gallagher, 1998; Murray & Chapey, 2001; Ravaud, Delcey, & Yelnik, 1999). In fact, Ottenbacher et al., (1996) found the poorest rating reliability for the comprehension item. Although other scales such as the Functional Assessment Measure (Hall, 1997; Wright, 2000), Frenchay Activities Index (Holbrook & Skilbeck, 1983) and the Functional Communication Measure (Functional Communication Measure, 1995) contain more communication-related information, they also are limited in terms of content, sensitivity and/or validity (Golper, 1996; Odell et al., 1997).

Rather than rely on these scales to summarize communication-related activity limitations, clinicians may adopt other longer but more precise functional language inventories. Several commonly used inventories are the Communicative Effectiveness Index (Lomas et al., 1989), the Functional Assessment of Communication Skills for Adults (Ferketic et al., 1995), the Communicative Activities of Daily Living-2 (Holland, Frattali, & Fromm, 1999), the

Amsterdam-Nijmegen Everyday Language Test (Blomert et al., 1994), or the Assessment of Language-Related Functional Activities (Baines et al., 1999).

Participation in Society

Sustained life participation in personally, culturally, and intrinsically valued tasks and goals enhances individual well-being for all human beings (Cantor & Sanderson, 1999). Such participation and concomitant well-being depend in part upon social, personal, and tangible resources that increase or decrease an individual's likelihood of participating in various tasks. These resources should be assessed and when necessary, supported or augmented to facilitate and motivate "continued participation (even) in the face of threat or frustration" (Cantor & Sanderson, 1999) in order to keep individuals "vigilant as they find new ways to participate in life" (p. 230) and thereby gain renewed health and well-being.

Activity and participation often appear together in assessment tasks and cover a full range of life areas (ICF, 2001). They can be examined in terms of performance (a person's activities in his or her current environment) and capacity (a person's ability to act in a uniform environment). Participation restrictions refer to obstacles that limit an individual from fulfilling his or her social, occupational, or personal role or goals. They reflect the difference between an individual's observed and expected performance. For example, persons with aphasia may be unable to return to work, may become socially isolated, and may undergo role changes (i.e., from provider to dependent). These changes may be the result of aphasia or functional communication problems, or because of transportation and access barriers in the community.

To assess participation and any restrictions to participation, clinicians may use measures of psychosocial status or wellness measures. Two psychosocial scales with a linguistic basis are the Stroke Aphasia Depression Questionnaire (SADQ; Sutcliffe & Lincoln, 1998) and the Geriatric Depression Scale (GDS; Yesavage et al., 1983). Visual-analogue mood scales were created to circumvent linguistic requirements in evaluating psychosocial status and detecting depression symptoms. These scales are 100-mm lines anchored by faces representing mood states; clients mark on the lines to indicate their current mood states. Two scales often used with persons with aphasia are the Visual Analogue Dysphoric Scale (VADS; Stern & Bachman, 1991) and the Visual Analogue Mood Scale (VAMS; Stern et al., 1997). Another measure, the Visual Analogue Self-Esteem Scale (VASES; Brumfitt & Sheeran, 1999), assesses psychosocial status from the perspective of self-esteem.

Another approach to assessing activity and participation levels and/or restrictions is through the use of wellness measures. Two examples of such scales are the Sickness Impact

Profile (Bergner et al., 1981) and the Duke-UNC Health Profile (Parkerson, Gehlbach, & Wagner, 1981). Doyle and colleagues (2003) developed the Burden of Stroke Scale (BOSS) to measure communication difficulty and psychological distress in persons following a stroke. The BOSS is a health-status assessment instrument and measures patient-reported functioning and well-being.

Hypothesis Formation

The information obtained during data collection must be organized, systematized, and condensed in a meaningful way (Murray & Chapey, 2001; Nickels, 2005). In this decision-making component of assessment, the clinician sifts through all the information obtained, delicately balancing and blending the data to arrive at a penetrating understanding of a patient's total behavior. Hypothesis formation is a sophisticated clinical judgment applied to the information collected (Lahey, 1988). It is an evaluation of the type, frequency, and pattern of behaviors produced by the patient as well as an exploration of the interrelatedness of various behaviors observed throughout the assessment period. A synthesis of diagnostic findings will aid not only in determining the suitability of the patient for treatment but also in indicating priorities and specific plans for a program of intervention.

Hypothesis formation is also part of the process of evidence-based practice (EBP). One of the steps in EBP is creation of a clinical question to be answered with evidence. A good clinical question should be patient-oriented and practical, and guide an evidence search (Shlonsky & Gibbs, 2004). The question should lead to constructive action that will benefit the patient and his or her family. Three forms of evidence are important to gather to formulate an hypothesis, gather information, and answer the clinical question: published data that represent the best evidence gathered from research; information about assessment values and expectations gleaned from the patient and his or her family; and a clinician's individual experience (Evidence-based practice in communication disorders [Position Statement], 2005; Shlonsky & Gibbs, 2004). Among the hypotheses that may be formed during the assessment process are those about aphasia classification, aphasia severity, and the locus of deficit derived from a model of language processing.

Aphasia Classification

Many classification systems have been developed to characterize adults with aphasia (Basso, 2003; Kertesz, 1979). Some clinicians use one of the dichotomous classifications systems (e.g., fluent vs. nonfluent aphasia, or receptive vs. expressive aphasia), while others use one of the anatomically based classification systems (e.g., Broca's, Wernicke's, or conduction aphasia). Still others use the classification system developed by Schuell and colleagues (Schuell, Jenkins, &

Jimenez-Pabon, 1964) to organize and label the results of their assessment. However, there is still no universally acceptable classification system (Holland, Fromm, & Swindell, 1986).

The validity of aphasia classification systems has been called into question for several reasons (Byng et al., 1990; Caplan, 1993; Crary, Wertz, & Deal, 1992; Gordon, 1998; McNeil & Kimelman, 2001; Schwartz, 1984; Varney, 1998; Wertz, Deal, & Robinson, 1984): (1) the language profile of many patients cannot be fit into one of the categories (estimates range from 25% to as many as 70% of patients with aphasia who cannot be successfully classified); (2) patients in these categories cannot be said to be homogeneously impaired; (3) certain aphasia classifications such as receptive/expressive or sensory/motor are misleading since most if not all patients with aphasia display some degree of impairment in both language comprehension and production abilities; (4) a patient can evolve from one classification to another during the course of recovery; (5) the inclusionary criteria for the different aphasia types frequently overlap (e.g., all aphasia types include anomia as a symptom); (6) classification of aphasia type may vary as a function of the aphasia battery used (e.g., BDAE vs. WAB results); (7) discrepancies in interjudge reliability can possibly stem from a lack of agreement about how to assign and weight specific responses; (8) categories convey little information concerning the nature of the underlying language impairment (e.g., which particular level [semantic vs. phonologic] of language processing is impaired); and (9) syndrome classification in itself does not provide the basis for any comprehensive treatment program. Despite these concerns, the use of aphasia classifications remains a common and often useful means of describing language deficits in both clinical and research settings. For example, for some patients, a particular aphasia type may succinctly describe their language profile, and consequently the label may, at times, be useful to include in a medical chart note, clinical report, or research paper. Aphasia types are a clinical "shorthand" system of identifying patient characteristics among clinicians (Bartlett & Pashek, 1994), for scientific inquiry and organizing thinking about aphasia; however, their limitations must be kept in mind.

Severity Classification

Determining the severity of the language impairment in a person with aphasia may guide the clinician in selecting appropriate testing materials. For example, for patients with severe language impairments, clinicians may wish to avoid a frustrating assessment experience for themselves and their patients by selecting shorter tests for the initial assessment or only one test or procedure. Ross and Wertz (1999) reported that severity ratings on two standardized impairment measures, the WAB and PICA, and a standard measure of disability, the CADL, were strongly correlated. Scores on

these measures were also strongly correlated to measures of connected speech. The measures are not replacements for one another in terms of content; however, Ross and Wertz (1999) suggested that perhaps administering more than one measure to determine severity of aphasia may be redundant.

In addition to standardized tests other instruments that may be useful in determining aphasia severity are clinical judgment supported by observation, severity rating scales, or a severity score, such as that included on the BDAE. Regardless of the measure used to determine or index overall aphasia severity, clinicians will want to be certain that the measure has been examined with respect to validity and reliability. For example, Lezak et al., (2004) noted that the severity estimate derived from a standardized battery, even the CADL, may underestimate a patient's ability to communicate in everyday situations. Several personal and environmental factors (ICF, 2001) such as contextual cues, routines, familiarity with vocabulary, and well-known communication partner styles, may contribute to underestimation. These factors are unique qualities to everyday interaction and are difficult to replicate in a standardized examination. Aphasia severity rating may also provide a useful guide for assigning patients to language treatment groups (Beeson & Holland, 1994) or selecting treatment goals.

Models of Language Processing: Cognitive Neuropsychological, and Psycholinguistic Information Processing

Rather than summarizing assessment results with two or three test or procedure scores clinicians may use cognitive neuropsychological, psycholinguistic or information processing models to guide assessment and describe clinical findings (Byng et al., 1990; Caplan, 1993; Hillis, 1993, 2002a, 2005; Kay, Lesser, & Coltheart, 1996). Davis (2000) differentiated core aspects of these models in terms of their origin, domain, and principal method of evaluation (p. 70). For example, the origin of cognitive neuropsychological models is the field of cognitive psychology; the domain is mental representation and processes in cognition; and the principle method of assessment is case studies of brain-damaged persons. In these models a particular language behavior (e.g., picture naming or sentence production) is conceptualized as a sequence of operations (e.g., for picture naming: analyze visuoperceptual or auditory input, access semantic stores, access phonologic output lexicon). Figure 4-4 is a cognitive neuropsychological model of the language processing system proposed by Kay, Lesser, and Coltheart (1996). The clinician's task in employing models is to determine the integrity of each of the language operations or components within each language modality in order to localize the level or levels at which the language behavior breaks down. In addition, a model-based approach allows clinicians to assess the types of errors made and the manner in

which a patient completes each language task. For example, according to information-processing approaches, clinicians analyze the underlying processing mechanisms that may be impaired and thus causing surface-level symptoms, in order to understand the nature of the language deficit. Examples of these processes are memory, attention, and executive functions. Using a model of language approach acknowledges that similar behaviors shown by a person with aphasia (i.e., anomia) may result from different underlying processing problems. For example, one patient may have difficulty with written naming because of a breakdown at the semantic level whereas another patient may also be unable to write the name of a target item, but due to a different cause—an inability to access information from the orthographic output lexicon.

Summary

The assessment process supports the need for clinicians to go beyond administering aphasia batteries and labeling aphasia type and severity to describe and summarize the actual cognitive, linguistic (content and form), and pragmatic strengths and weaknesses of each person with aphasia and to hypothesize about contributing factors (Murray & Chapey, 2001; Murray & Clark, 2006). These types of information are essential in clarifying the language and communication breakdown and in guiding the determination of treatment goals and activities. The information can also yield descriptive summaries that indicate the level at which language performance (a) is completely accurate, (b) begins to break down, and (c) breaks down completely. Additionally, such summaries can identify factors that facilitate or impede the patient's language use, help clinicians determine initial goals of therapy, and guide reassessment to monitor progress. The assessment process that results in descriptive language summaries that are accurately written, well-organized, easy to understand, and free of professional jargon, slang, and vague terminology are an asset to hypothesis formation and patient management.

Hypothesis Testing and Reporting

The results of hypothesis formation, and, specifically, the treatment goals that are established, should be considered tentative and flexible enough to change as new evidence emerges (Lahey, 1988; Murray & Chapey, 2001; Whitworth et al., 2005). Hypothesis testing continues throughout a patient's treatment program and enables the clinician to continue to secure additional data about language abilities and impairments in order to determine the validity, accuracy, and appropriateness of the hypotheses that were formulated. Separation of assessment and intervention activities allows for the initial presentation of information in an organized manner in order to begin treatment. However, assessment should be an ongoing part of treatment and occur at every phase of rehabilitation (Murray & Chapey, 2001).

Figure 4–4. A Cognitive Neuropsychological Model of Assessment of Naming^a

^aKay, J., Lesser, R., & Coltheart, M. (1996). Psycholinguistic Assessments of Language Processing in Aphasia (PALPA): An introduction. *Aphasiology*, 10, 159–215. Reprinted with Permission.

At various points during the assessment process—the initial assessment session and other evaluation and/or treatment sessions—a clinician must report the results of the hypothesis testing to other individuals on the assessment team, as well as the patient, family, and significant others. Assessment findings are usually presented when all of the data have been assembled (e.g., unstructured and structured observations, case history, and reports from other team members). The findings may be conveyed verbally at family and/or staff conferences, as well as in the form of a short, concise written report. Frequently, visual illustrations (e.g., a diagram of the brain to assist in describing anatomic areas that have been affected by the patient's stroke or brain injury) help patients, caregivers, and other professionals comprehend the information provided (Shipley & McAfee, 2004). When presenting information it is important to avoid overloading the patient and family with too much informa-

tion at one time. Clinicians should be prepared to repeat and/or paraphrase information across several sessions to assure that the patient and family understand the assessment results (Avent et al., 2005; Luterman, 1996).

A widely used written format for reporting information in a patient's file is the **SOAP note**. SOAP notes are part of the Problem Oriented Medical Records system of reporting and orienting information in a client's file according to specific problems or deficits a patient demonstrates. In this type of reporting format the "S" stands for *subjective*. Comments in this section are the clinician's subjective comments, non-measurable observations about the patient or the session, historical information, any other information that is pertinent to the session, or an aspect of the assessment session. "O" stands for *objective* and this section contains data from the assessment activities. This section presents the findings from the assessment session, without interpretation. The

Reporting Assessment results: two examples of a SOAP note

(S) Mr. S was attentive to all tasks and cooperative throughout the session. He demonstrated and commented about frustration with word-finding difficulties.

(O) The test of adolescent/adult word finding was administered. Mr. S achieved the following scores:

Subtest	% correct
Picture naming: nouns	28%
Sentence-completion naming	19%
Description naming	8%
Picture naming: verbs	5%
Category naming	19%
Total naming	17%
Comprehension	90%
Average item response time	12 secs

(A) Mr. S presented with severe (below the first percentile rank) word-finding difficulty across a variety of word types (i.e., nouns and verbs) and word-finding tasks. Additionally, Mr. S. required substantial time to produce the names of the test items.

(P) Bi-weekly, 1-hour therapy sessions to be scheduled. The focus of therapy should be to increase the accuracy and speech of Mr. S's word-finding abilities at the isolated word level and using a cueing hierarchy approach.

(S) 72 yr female sustained LCVA 15 days ago. ST at hosp; referred for Tx upon dc. Pt's daughter reported good progress c word retrieval. Pt. coop during eval and reported frustration with word retrieval difficulties.

(O) 50% accuracy for confrontation naming. BNT 30/60. Y/N response 100% in questions with concrete and familiar elements. Cognition, reading and writing WFL.

(A) Dx: mod-sev anomic aphasia.

(P) Speech therapy 3x/week x 5 weeks to address following goals: 1: ↑ word-retrieval success in structured tasks and conf naming to 80%. 2: ↑ word-retrieval success in conv speech to 50%. Excellent prognosis considering the patient's cognitive status, motivation and stimulability.

Figure 4–5. Two examples of SOAP notes

“A” section of a SOAP note stands for *assessment* and contains the clinician's interpretation of the assessment data and findings, as well as the session performance. The fourth section is “P”, which stands for *plan*. In this section the clinician writes the direction—or plan—for future assessment or treatment. A sample of a SOAP note appears in Figure 4–5. SOAP notes, or other clinical or chart notes, are usually written in as succinct a manner as possible. As Golper (1996) noted, “brief notes get read and long narratives do not” (p. 69).

It is important that data are included in a report of assessment sessions as they lay the foundation for the diagnosis. Equally as important is a statement of functional communication, which is derived from the data as well as the patient's

overall performance during the session. The WHO ICF provides a useful tool for framing this statement, as does the Life Participation Approach to Aphasia (Chapey et al., 2001; Elman, 2005). A statement of functional communication skills, particularly including interaction with family members and significant others, is particularly useful in setting and prioritizing treatment goals.

GOALS OF ASSESSMENT

Goal 1: Determination of the Presence of Aphasia

One goal of the assessment process is to determine whether a patient presents with aphasia, or a related neurogenic

language disorder (e.g., right hemisphere disorder or dementia), or whether his or her language and communication skills are within normal limits when compared to peers. Frequently the presence or absence of aphasia can be determined relatively quickly during the initial observation or interaction with the patient. For example, when the language impairment is severe or moderate the presence of aphasia is obvious and a diagnosis can be made quickly. In this case the remainder of the session can be devoted to specifying the nature and extent of the disorder. In contrast, when aphasia symptoms are mild, it may be more difficult to confirm the presence of language or communication impairment. That is, language problems may not be immediately apparent when conversational time is limited and when the responses during conversation are conventional, expected, or routine. In such cases, despite the presence of aphasia as identified by the patient, family, or physician, a person with aphasia may be so mildly impaired that he or she achieves perfect or near-perfect scores on traditional test batteries. In this case, assessment must continue on many levels (e.g., ICF) and include information about cognitive, linguistic, and communicative skills to provide a comprehensive and detailed description of language and communication strengths and weaknesses.

Determining the presence of aphasia may be challenging for many reasons. For example, test norms may not accurately reflect a patient's peer group in terms of age, language, cultural background, linguistic preference, or educational background (Garcia & Desrochers, 1997; Neils-Strunjas, 1998; Spreen & Risser, 2003). The limited range of tasks on some aphasia test batteries may not detect subtle differences in language abilities. For example, Wertz and colleagues (1984) found that using the Western Aphasia Battery, five out of 45 patients were diagnosed with normal language skills; however, using the Boston Diagnostic Aphasia Examination, all 45 patients were diagnosed with aphasia. Language disorders may only appear at complex levels (e.g., employment-related discourse) and/or be a result of impairment in executive functioning skills, such as immediate memory (Davis, 2000). Therefore, at times, the final decision regarding the presence of aphasia in individuals who are mildly impaired may be tentative and must be based on carefully documented observation and clinical judgment (Chapey, 1986).

In addition to determining the presence of aphasia it is often the clinician's responsibility to differentiate between language impairment in aphasia and language impairment that results from a different etiology. Careful analysis of the case history will aid in confirming whether the language symptoms reflect the presence of aphasia or related neurogenic communication disorders of right hemisphere syndrome, dementia, primary progressive aphasia, traumatic brain injury, a neurologic deficit (e.g., schizophrenia), a pharmacologic disorder, a metabolic disorder, or an emo-

tional disorder (e.g., depression). The language impairments associated with these disorders have different underlying sources of disturbance and follow different clinical courses. Consequently they demand different treatment approaches. However, it is important to note that having aphasia does not exempt an individual from also presenting with one or more of the above conditions. Careful observation and differential diagnosis will aid in determining the contribution of any disorders to current language functioning within the communication environment and personal environment of the individual (ICF, 2001; LaPointe, 2005).

Right Hemisphere Syndrome

The communication problems that appear in individuals with right hemisphere syndrome (RHD) are not exclusively language-based. Blake (2005) divided deficits associated with RHD into three general categories: communication, attention/perception, and cognition. Although diagnosis of RHD from the perspective of etiology may be easily evident, diagnosis of the behavior deficit is not often easy for several reasons: there may be overlap among deficits in an individual patient; cognitive deficits may interfere with language performance; no clear definition of RHD exists (Blake, 2005; Blake et al., 2003; Myers, 2001); no clear boundaries separate normal and abnormal behavior for the pragmatic and cognitive deficits often observed in persons with RHD (Blake, 2005); and patients with RHD represent a heterogeneous population in terms of extent and type of deficits (Murray & Chapey, 2001; Myers, 2005). Several test batteries that are appropriate for use with persons with RHD are listed in Table 4-6.

Communication Disorders

The communicative deficits that are common among patients with RHD do not resemble those of patients with aphasia, and become most apparent in prolonged conversation and other open-ended or sophisticated communication tasks (Bartels-Tobin & Hinckley, 2005; Brookshire, 2003;

TABLE 4-6

Tests for Right Hemisphere Syndrome

Right Hemisphere Language Battery -2	Bryan (1994)
The Mini Inventory of Right Brain Injury -2	Pimentel & Knight (2000)
Rehabilitation Institute of Chicago Clinical Management of Right Hemisphere Dysfunction, 2nd ed.	Halper et al. (1996)

Brownell et al., 1995; Marini et al., 2005; Myers, 1999; Tompkins, 1995). As communicative tasks or contexts become increasingly abstract or complex patients with RHD are likely to manifest some or all of the following comprehension and production deficits: (a) difficulty organizing and summarizing information in an efficient, meaningful way; (b) a tendency to produce impulsive answers that are tangential and/or provide unnecessary detail; (c) difficulty distinguishing between information that is relevant and irrelevant; (d) an inability to generate and interpret inference; (e) problems in assimilating and using contextual cues; (f) difficulty conveying information in a cohesive and coherent manner; (g) a tendency to overpersonalize external events; (h) a tendency to lend a literal or superficial interpretation to figurative language (e.g., idioms, metaphors, indirect requests); (i) a reduced sensitivity to communicative context and partners, and to the pragmatic or extralinguistic aspects of communication (e.g., turn-taking, topic maintenance, topic shifting); (j) difficulty organizing and maintaining discourse structure (e.g., macrostructure such as main ideas or themes); (k) an inability to comprehend successfully or to produce cohesive ties in discourse; (l) difficulty comprehending or producing prosody in conversational context; and (m) reduced appreciation or altered expression of emotion. Many researchers hypothesize that the variety of perceptual, affective, and/or cognitive deficits that patients with RHD may experience underlie or at least contribute to their higher level of communication disorders (Blake, 2005; Blonder et al., 2005; Myers, 1999; Tompkins et al., 1994).

Attention/Perception Disorders

A number of deficits in attention and/or perception can appear in a person with RHD. These deficits may manifest themselves in several ways, including contributing to a communication deficit. Among the symptoms a person with RHD may experience are (a) anosognosia (denial of illness); (b) inability to focus on internal or external stimuli due to reduced attentional capacity or inability to effectively allocate attentional resources; (c) visuospatial neglect (left hemispatial neglect); (d) visuoperception deficits; (e) prosopagnosia (inability to recognize familiar faces); (f) topographic orientation deficit (inability to relate to the surrounding space); (g) visuoconstruction deficits; (h) verbal or nonverbal memory deficit; (i) executive functioning deficits; and (j) similar auditory perceptual problems (e.g., auditory agnosia, amusia, sound-localization deficits, impaired discrimination of prosody, and music perception difficulty). These perceptual problems are associated with difficulties in appreciating the external context in which the stimulus is embedded and with problems integrating the stimulus with the internal associations. Recent research suggests that the deficits underlying these symptoms may not be straightforward. For example, persons with RHD may not have access

to certain types of contextual information, even under reduced processing conditions, and therefore may not be able to use that information successfully to comprehend complex linguistic content (Cherney, 2002; Leonard & Baum, 2005). Although many of the problems and agnosias observed in persons with RHD are primarily associated with bilateral lesions, some of them may occur following unilateral right hemisphere brain damage.

Cognitive Deficit

Approximately half of the patients with RHD admitted to rehabilitation centers have cognitive deficits (Blake et al., 2002); however, the pattern of deficits observed is not well-explained, for several reasons. Cognitive abilities are inter-related and cannot often be tested independently (McDonald, 2000a; Monetta & Joannette, 2003). In the general population as well as in the population of persons with RHD there is a range of cognitive abilities, and the manner in which cognitive deficits manifest themselves to interfere with communication varies with the type and severity of RHD. Potentially all cognitive domains (e.g., memory and attention) may be disrupted in RHD; however, it is unlikely that all persons with RHD will display deficits in all areas (Murdoch, 2006). In conducting a thorough evaluation of the cognitive deficits in patients with RHD, as well as the deficits' contribution to communication difficulties, clinicians should use assessment procedures (e.g., RHD battery or memory testing), close observation of behavior, and consultation with family members and significant others to compare current and premorbid levels of functioning.

Dementia

Course of the Disease

Dementia is a condition of acquired, progressive degeneration of intellectual abilities affecting several cognitive domains such as language, memory, visuospatial skills, emotion or personality, and executive functions such as reasoning or abstraction (Disease Definition, Natural History, and Epidemiology, 2006). The diagnosis requires impairment in short- and long-term memory, abstract thinking, judgment, and higher cortical function and intellect, which cause significant social and occupational impairment, and which are not related to delirium. Symptomatology varies from subtle changes during the early stages of the dementing illness that may not be noticeable during daily activities, to profound changes during the later stages that may render the patient unable to function socially or occupationally. Dementia may result from a variety of reversible and irreversible disorders (Kaufer & Cummings, 1997). Table 4-7 lists examples of etiologies of reversible and irreversible dementias. Cognitive symptoms associated with reversible dementias can be remediated by treating the underlying medical condition. The

TABLE 4-7

Examples of Reversible and Irreversible Causes of Dementia**Reversible Causes that Can Resemble Dementia**

Depression (pseudodementia)
 Drug use (e.g., anticholinergic side effects)
 Infection (e.g., meningitis, encephalitis)
 Hearing loss
 Neoplasm
 Normal pressure hydrocephalus
 Mental and/or sensory deprivation
 Renal failure (dialysis dementia)
 Thyroid disease
 Toxin exposure (e.g., lead poisoning)
 Vitamin deficiency (e.g., pellagra, Wernicke-Korsakoff syndrome)

Irreversible Causes

Alzheimer's disease
 Creutzfeld-Jakob disease
 Human immunodeficiency virus encephalopathy
 Huntington's disease
 Multi-infarct dementia
 Multiple sclerosis
 Parkinson's disease
 Pick's disease
 Progressive supranuclear palsy
 Traumatic brain injury (e.g., dementia pugilistica)
 Vascular dementia

prevalence of reversible dementias is much lower than previously thought (Clarfield, 2003). A meta-analysis by Clarfield (2003) showed that potentially reversible dementias comprised only 9% of all dementias, and less than 1% of dementia cases were actually reversed. Nonetheless, it is very important that reversible causes of dementia be ruled out prior to diagnosing a patient with irreversible dementia. In contrast, researchers have yet to identify treatments that will reduce or eliminate the cognitive symptoms associated with irreversible dementing diseases. The most commonly occurring dementias are irreversible: Alzheimer's disease (56% of all dementias) and vascular dementia (20%).

Site of Lesion

Dementia may also be categorized on the basis of neuroanatomic location of the causative lesion (Bourgeois, 2005; Brookshire, 2003; Lezak et al., 2004; Ripich, 1995). In the cortical dementias the pathophysiology affects primarily the cortical brain tissue; examples are Alzheimer's disease, Pick's disease, and frontotemporal dementia. Subcortical dementias are those in which the pathology primarily affects

subcortical structures such as the thalamus and basal ganglia; examples are Parkinson's disease, Huntington's disease, and progressive supranuclear palsy. When both cortical and subcortical brain tissue is affected by the disease process, the result is a mixed dementia. An example of a mixed dementia is dementia with Lewy bodies. Vascular dementias arise as a result of thrombotic or embolic occlusions that cause focal neurologic symptoms. Three subgroups are multi-infarct dementia, lacunar state (multiple small infarcts in the subcortex, midbrain, or brain stem), and Binswanger's disease. Some differences exist among the symptom profiles associated with each of these dementia classifications. For example, in terms of communication profiles, patients with cortical dementia may demonstrate logorrhea, empty speech, verbal paraphasias, impaired comprehension, relatively preserved repetition, and topic digression; in contrast, patients with subcortical dementia tend to have decreased output on verbal fluency tests (divergent thinking), agraphia, and motor-speech disturbances such as slow rate, hypophonia, and articulation and intonation difficulties.

Stage of Dementia

Yet another way of understanding dementia and its accompanying behavioral symptoms is in terms of staging over time. Dementia progresses through three stages: early, middle, and late. Despite some differences in symptomatology among patients with varying dementia etiologies (Snowden, 1999), there are similarities in behavior as the dementing disease progresses over time (Bayles & Kaszniak, 1987; Cohan, 1997; Hart & Semple, 1990). Typically, in the early stages of dementia, patients are forgetful and disoriented for time but generally not for place or person. Both their short- and long-term memory abilities are typically already affected. In terms of language abilities, patients may still appear to be successful communicators, especially during casual conversations; however, they may sometimes digress from the topic and ramble at length during conversation. During these stages, patients with dementia may also display periodic word-finding problems and difficulty interpreting higher-level language forms such as humor or sarcasm.

During the middle stages of dementia, patients become further disoriented and have difficulty with both time and place information. Memory abilities become further impaired and patients can no longer manage personal finances, employment, or medication. Conversational problems are now prominent, with patients having difficulty adhering to conversational rules such as turn-taking, topic maintenance, and topic shifting. Language output becomes vague, empty, perseverative, and often irrelevant. Patients will frequently produce semantic paraphasias and may misuse syntactic forms that affect the meaning of an utterance. Problems with auditory and reading comprehension also become prominent during this stage of dementia.

In the later stages of dementia, the patient becomes disoriented for time, place, and person, and is now dependent for most activities of daily living. Language output may be completely void of meaning, and many patients eventually become mute; language comprehension abilities are similarly devastated (Bayles et al., 2000).

Recent research is exploring the notion that there are subtypes of dementia (e.g., Kertesz, 2005) and continuing the process of differential diagnosis among dementia, aphasia, and other progressive disorders. While these disorders are different, a review of the linguistic and cognitive changes that occur in dementia indicates that there are some similarities between patients with aphasia and those with dementia, particularly patients with anomia and patients in early stages of dementia (Nicholas et al., 1985). However, several linguistic and cognitive features may help distinguish individuals with aphasia from individuals with dementia. For example, errors in language form (i.e., morphology and syntax) are less common in the language output of patients with dementia, whereas perseveration of ideas is less common in the language output of patients with aphasia (Bayles & Kaszniak, 1987). In terms of cognitive symptoms, Bayles and colleagues (1989) reported that patients with mild and moderate dementia performed significantly more poorly on delayed recall compared with their immediate recall performance; in contrast, no such disparity was seen between the delayed and immediate recall performances of patients with aphasia. Patients with dementia also displayed much greater difficulty on memory tests of delayed spatial and verbal recognition than did patients with aphasia. Three assessment measures designed for patients with dementia are the Arizona Battery for Communication Disorders in Dementia (Bayles & Tomoeda, 1993), the Alzheimer's Quick Test (Wiig et al., 2004), and the Functional Linguistic Communication Inventory (Bayles & Tomoeda, 1994).

Traumatic Brain Injury

Traumatic brain injury (TBI) is the result of an external force applied to the head. Brain-tissue damage in a TBI may be discrete and focal; typically, however, injury is diffuse and includes cortical and subcortical structures in multiple lobes of the brain. Patients who sustain discrete lesions may display language impairments that are similar to those that appear in individuals with aphasia following a stroke. Patients with diffuse damage may display cognitive-communicative deficits, perceptual deficits, and disorders of executive functioning. Traumatic brain injury can range from mild to severe, as determined by neurologic findings (e.g., length of loss of consciousness) and by behavioral deficits in one or more of the following areas: attention, perception and recognition, short- or long-term memory, working

memory, problem-solving, conceptual organization, abstract reasoning, self-monitoring, and learning as well as comprehension and production of speech and language (Adamovich, 2005; Brookshire, 2003; Davis, 2000; McCullagh & Feinstein, 2005; Murdoch & Theodoros, 2001; Stierwalt, 2002).

Generally, patients who survive their TBI are less likely to present with frank aphasia; instead, they show cognitive-communicative problems that affect multiple aspects of functioning. However, clinicians should plan assessments that examine behavior resulting from both focal and diffuse brain lesions. Few specific assessment tools exist exclusively for patients with TBI (e.g., the Brief Test of Head Injury (Helm-Estabrooks & Hotz, 1991); the Scales of Cognitive Ability for Traumatic Brain Injury (Adamovich & Henderson, 1992)); however, many tests designed to assess language or cognitive function are well suited for use with individuals who sustain a TBI. Sohlberg & Mateer (2001) identified several tests that may be useful in assessing cognitive-communicative behavior in four performance categories: attention; memory/new learning; executive functions; and behavior, adjustment, and outcome measures. Hartley (1995) identified tests in ten categories: attention; memory; visuospatial perception and construction; motor functioning; intelligence; executive functioning; auditory comprehension; verbal learning; oral expression; and verbal integration and reasoning with language (Hartley, 1995, pp. 82–85). Murray and Clark (2006) listed tests in six categories: (1) attention; (2) neglect; (3) nonverbal memory; (4) verbal memory; (5) verbal and nonverbal memory; and (6) executive function (Murray & Clark, 2006, pp. 194–195). Recent evidence reviews have discussed procedures and tools for standardized and nonstandardized assessment of persons with TBI (Coelho et al., 2005; Turkstra, Coelho, & Ylvisaker, 2005; Turkstra et al., 2005). Practice guidelines for standardized assessment as well as tables listing commonly used tests, including detailed reviews, psychometric properties, and expert opinion, can be found in Turkstra, Coelho and Ylvisaker (2005); Turkstra et al., (2005) and Turkstra et al. (2003).

In contrast to the difficulties with content and form frequently observed in patients with aphasia, individuals with cognitive-communicative impairments as a result of TBI display difficulties in pragmatic aspects of language. Examples of these deficits include difficulty organizing verbal and written output so that it is coherent, cohesive, and concise; problems selecting and maintaining appropriate conversational topics; and the frequent production of irrelevant, tangential, or confabulatory verbal and written output (Coelho, 2002; Coelho et al., 2005; Davis, 2000; Hartley, 1995; McDonald, 2000b; Sohlberg & Mateer, 2001). Other higher-level language difficulties seen in patients with TBI, such as problems attending to, comprehending, and/or retaining complex or abstract information (e.g., commands,

stories, or other linguistic material) are usually secondary to cognitive impairments of attention, memory, or executive functions (Whyte et al., 2000; Youse & Coelho, 2005). Although both patients with aphasia and patients with TBI may have word-retrieval problems, there are often some qualitative differences between the types of errors produced by these two patient populations (Boles, 1997; Holland, 1982; Holland et al., 1986). Specifically, in addition to the circumlocutions, semantic paraphasias, and reduced word fluency that are typical of both groups, patients with TBI may make naming errors that are related to their personal situation or to the nature of the stimulus, that are errors of confabulation, or that are a product of visual misperception.

Individuals with cognitive-communicative disorders following TBI vary considerably in behavior, and this must be taken into consideration when planning assessment. Sohlberg and Mateer (2001) suggest that eight variables contribute to variability in behavior: (1) nature of brain injury; (2) patient's preinjury history; (3) current demands on the patient's life; (4) environmental supports; (5) premorbid personality; (6) emotional response to injury; (7) coping skills; and (8) patient and family expectations (Sohlberg & Mateer, 2001, p. 89). Paterson and Scott-Findlay (2002) suggest that interviewing individuals with cognitive-communicative disorders following TBI may be difficult if language and cognitive impairments interfere with effective recall and reflection. Given the complex nature of communicative and cognitive deficits in a person following a TBI, clinicians are challenged to create assessment protocols that will reflect typical and traditional assessment practices as well as the individual variability of patients and their families (Hanks, Ricker, & Millis, 2004; Larkins, Worrall, & Hickson, 2000).

Primary Progressive Aphasia

Primary progressive aphasia (PPA) is a clinical syndrome in which patients suffer progressive language deterioration despite unidentifiable stroke, tumor, infection, or metabolic disease, and by the presence of relative preservation of cognition and independence in activities of daily living, at least in the early years of the disease process (Mesulam et al., 2003; Mesulam & Weintraub, 1992; Weintraub, Rubin, & Mesulam, 1990). In addition, Weintraub and colleagues (1990) suggest that patients should present with at least a 2-year history of isolated and progressive language impairment before being diagnosed with PPA. Currently, there is some debate about whether PPA is a separate clinical entity, or a precursor or variant of more generalized dementias such as Alzheimer's or Pick's disease (Clark et al., 2005; Kertesz et al., 2003; Kertesz et al., 1994; Knibb & Hodges, 2005). Subgroups of PPA have been identified on the basis of clinical features such as phonologic disorders and language deficits (Grossman & Ash, 2004; LeRhun, Richard, &

Pasquier, 2005). Grossman and colleagues (2004) suggested that converging evidence supports distinct subgroups of nonfluent PPA and semantic dementia, but not other subgroups.

Although distinguishing PPA from the language impairments caused by progressive dementing diseases remains controversial, differentiating PPA from traditional aphasia can be made on the bases of etiology (i.e., unknown or diffuse versus focal brain damage) and course of the disorder (i.e., progressive versus relatively static presentation of symptoms). The language symptoms of patients with PPA may be quite variable. Aphasia types such as anomia, Broca's aphasia, conduction aphasia, pure word deafness, nonfluent aphasia, mixed transcortical aphasia, and global aphasia have been reported in persons with PPA (Duffy & Petersen, 1992; Grossman & Ash, 2004; Rogers & Alarcon, 1998; Westbury & Bub, 1997). Despite this variability, the incidence of nonfluent PPA is reported more frequently in the literature than fluent PPA. For patients with nonfluent PPA, specific language symptoms appear to be similar to those associated with traditional aphasia and most frequently include word-finding deficits (the most common initial symptom as well), a semantic interference effect (Vandenberghe et al., 2005), repetition difficulties, and auditory comprehension problems (Westbury & Bub, 1997). Interestingly, in their review of 112 published cases of PPA, Westbury and Bub noted that both reading and writing modalities tended to remain relatively strong for years after the onset of the disorder. Hillis, Oh, and Ken (2004) and Hillis, Tuffiash, and Caramazza (2002) also reported relatively preserved writing abilities and a double differentiating pattern in naming deterioration in patients with PPA. Patients with nonfluent PPA showed greater deterioration on production of verbs than nouns, while patients with fluent PPA showed greater deterioration on nouns.

Psychiatric Disorders

Several psychiatric disorders can negatively affect an individual's communication abilities (Frank, 1998). Of these, schizophrenia generally receives the most attention in the speech and language pathology literature. Schizophrenia is a relatively common, chronic psychotic disorder that most frequently manifests in late adolescence or early adulthood. However, a form of schizophrenia with onset of symptoms in the second half of life has also been reported (Keefe & Harvey, 1994). This disorder is associated with both positive (i.e., the presence of abnormal behavior) and negative (i.e., the absence of normal behavior) symptoms. Positive symptoms include thought disorder, delusions, and hallucinations; negative symptoms include flat affect, apathy, and social withdrawal. Individuals with schizophrenia also present with a variety of neuropsychological problems including memory and attention deficits, and executive function

impairments such as anosognosia (i.e., lack of awareness of deficits), perseveration, and difficulties with planning and problem solving (Elliott et al., 1998).

Communication impairment in individuals with schizophrenia may include word-finding difficulties, language output characterized by reduced content, disturbed affective prosody, perseveration, irrelevance, divergent thinking skills, cohesion, and organizational problems (DiSimoni, Darley, & Aronson, 1977; Goren, Tucker, & Ginsberg, 1996; Murdoch, 2006; Nemoto, Mizuno, & Kashima, 2005). Productive morphosyntactic abilities and basic auditory and reading comprehension abilities are typically spared. Although the communication problems of patients with aphasia are generally sufficiently different from those of patients with schizophrenia, difficulty distinguishing between the two may arise in some cases, such as patients with aphasia who presented with premorbid psychotic disorders.

Goal 2: Identification of Complicating Conditions

Many individuals with aphasia and related neurogenic communication disorders also manifest other physiologic or psychosocial deficits that may contribute to, precipitate, or maintain a language problem, or interfere with treatment planning. The diagnosis of a language and communication disorder must be viewed within the context of these complicating conditions. An efficient method of identifying these conditions is through a comprehensive case history and thorough interview of the patient, his or her caregivers, and other individuals who are important in the patient's life (i.e., co-workers and friends).

Case History and Interviews

To identify the precipitating and maintaining factors that affect language and communication deficits, the clinician should complete a thorough and systematic review of a patient's demographic, medical, and behavioral information including a detailed history in several areas: educational, medical, family, mental health, and occupation, as well as past, present, and future communication environments and goals. This information can be gathered by reviewing the patient's medical chart and by asking the patient, family, and significant others to complete pre-interviews or referral forms. It is preferable, but not always possible, for a clinician to obtain a significant amount of information regarding the patient's history before the initial patient contact. Prior knowledge will enable the clinician to formulate an opinion concerning the possible areas that need greater specificity during testing and plan accordingly.

One method for gathering information prior to the initial assessment session is through the use of a patient-history questionnaire. Most textbooks on diagnosis in speech-

language pathology or neurogenic communication disorders contain examples of case-history forms or pre-interview questionnaires (Shipley & McAfee, 2004). Individual work settings often develop a form that reflects the needs of the institution (e.g., acute-care facility or rehabilitation hospital). Using the patient history, clinicians can often save time, provide a systematic method for obtaining additional information, and provide a focus and direction for subsequent interviews. An example of a case history appears in Appendix 4-1.

During subsequent interviews and treatment sessions, specific areas that seem unclear from the case history or initial interview, or that need greater specificity, can be explored. Interviews provide an opportunity to verify and clarify information obtained on the referral forms, and to pursue data that may be pertinent to the nature of the patient's communication problem but that were not included on the form. For example, the clinician may attempt to determine the degree to which the verbal and nonverbal behaviors of individuals in the patient's environment facilitate or impede language recovery. Other areas that may be described are the relationships between and among persons in the environment, the social role change of the client and family subsequent to aphasia, patient and family understanding of and attitudes toward aphasia, needs and expectations concerning treatment and treatment outcome, and the realistic or unrealistic nature of these expectations. Families can quickly experience information overload during interview sessions so it is better to uncover information at a pace to match families' needs rather than to "over-help" by presenting an abundance of information at one time (Avent, 2005).

In addition, information can be gained by interviewing or reviewing the reports of other assessment and/or intervention team members who have evaluated some aspect of the patient's physical, psychological, emotional, social, or occupational functioning. Such a team may be composed of the attending physician and nursing staff, a neurologist, a physiatrist, a geriatrician, an occupational therapist, a physical therapist, a neuropsychologist, a social worker, a therapeutic recreational specialist, a dietitian, a rehabilitation counselor, and family members. It is crucial to have good communication among team members, particularly in those clinical settings in which others such as the neuropsychologist or occupational therapist may share the responsibility of determining the cognitive and linguistic abilities of patients with aphasia.

Complicating Conditions

During testing of the patient with aphasia, the clinician should be alert for signs of dysfunction in areas that do not appear to be generally equivalent in severity with overall language or cognitive performance. This is done to determine

whether any complicating conditions may interfere with treatment and recovery. Detailed assessment of these areas should be completed prior to the in-depth evaluation of language abilities, as soon as the clinician becomes aware of their presence. Testing included in this category would be procedures designed to discern auditory and visual sensitivity, auditory and visual agnosia, behaviors frequently associated with right hemisphere functions, motoric impairments, medical conditions, and post-stroke psychobehavioral disorders such as clinical depression.

Auditory and Visual Sensitivity

Assessment of auditory sensitivity should include hearing screening at WHO ICF (ICF, 2001) levels of impairment and activity/participation (Guidelines for audiologic screening, 1997). Screening procedures include a case history regarding hearing difficulties or pain in the ear, visual inspection of the outer ear, otoscopic inspection as appropriate, pure-tone hearing screening, and screening tympanometry. While not all these procedures may be available or appropriate in specific circumstances, at the least the clinician should have access to information concerning a patient's threshold for the awareness of sound (impairment level) and reported difficulties in hearing. If an audiologist is part of the assessment team the data that should minimally be available to the clinician are (a) threshold for awareness of sound, (b) pure tone air and bone thresholds, and (c) speech discrimination scores.

Although aphasia is not a problem of auditory sensitivity, hearing loss can negatively affect a patient's auditory comprehension abilities. The necessity of testing hearing sensitivity is made even more obvious by the fact that many patients with aphasia are older and therefore at high risk for hearing disorders (Gates et al., 1990; Yueh et al., 2003). However, testing the hearing acuity of some patients may be difficult if they are severely language-impaired and therefore unable to understand test instructions or to grasp the nature of the response requirements (Wilson, Fowler, & Shanks, 1981; Kelly, 2006). Accordingly, collaboration between the clinician and the audiologist is necessary to assure a valid assessment of hearing abilities. Additionally, for those patients with aphasia who wear hearing aids or rely upon other assistive listening devices, it is important for the clinician to check whether these devices are in working order (e.g., no buildup of cerumen, functional batteries) prior to the language evaluation.

It is equally important to determine that the patient's visual acuity and visual fields are functionally intact so as not to significantly impede assessment and treatment procedures. Examples of disorders that might impede visual acuity are cataracts and myopia, and an example of a visual-field dysfunction is right homonymous hemianopia. Assuring adequate vision is particularly important for clinicians work-

ing with older patients with aphasia since at least one-third of the elderly have some degree of vision loss (Quillen, 1999). When a visual defect is suspected, the patient should be referred to an ophthalmologist for testing. For patients with aphasia who have been identified as having visual acuity problems, clinicians should ensure that any assistive devices (e.g., glasses, contact lenses, magnifying glass) are available and in appropriate condition (e.g., clean, most recent prescription) when completing the language assessment. For patients with aphasia who have identified visual-field cuts, the clinician can arrange visual stimuli in a vertical presentation to avoid eliciting visual-based versus language-based errors.

Auditory and Visual Agnosia

Occasionally, patients with aphasia, particularly those who have suffered bilateral brain damage, may present with auditory or visual agnosia (Bauer & Demery, 2003; Burns, 2004; Cummings & Trimble, 2002; Stringer, 1996). Patients with auditory agnosia have difficulties recognizing auditory stimuli even though they may recognize the same stimuli in other modalities and even though they have adequate hearing sensitivity (Bauer & Demery, 2003; Bauer & Zawacki, 1997). Patients with aphasia may demonstrate one or more of the following types of auditory agnosia (Bauer & Demery, 2003; Burns, 2004; Vignolo, 2005): (a) amusia, or the inability to recognize music rhythms, or forms; (b) auditory sound agnosia, or the inability to recognize nonverbal sounds; and (c) pure word deafness, or the inability to recognize and repeat spoken language with a relatively preserved ability to recognize nonverbal sounds.

Visual agnosia refers to impairment in the recognition of visual stimuli despite adequate visual sensitivity (Farah, 2004). Several types of visual agnosia can occur with aphasia (Burns, 2004; DeRenzi, 1997; Farah, 2004; Stringer, 1996): (a) prosopagnosia, or a difficulty in recognizing familiar faces; (b) autopagnosia, or difficulty in recognizing body parts; or (c) visual object agnosia, or a difficulty in recognizing actual or pictured objects. In diagnosing auditory or visual agnosia, it is important to exclude sensory deficits in the affected modality, comprehension deficits, expressive disturbances, and unfamiliarity with the test stimuli (Stringer, 1996).

Right Hemisphere Function

Patients with aphasia may demonstrate nonverbal impairments that are more frequently associated with right hemisphere brain damage and that may directly or indirectly interfere with the therapeutic process. For example, some patients with aphasia present with an apraxia, such as constructional apraxia or difficulties copying or composing drawings of two- or three-dimensional figures (Georgopoulos, 2004; Rothi & Heilman, 1997). Such patients might construct

drawings that are oversimplified and reduced in size but that improve with repetition. Therefore, several aphasia batteries (e.g., WAB, PICA) include subtests that examine for the presence of constructional impairments and other apraxias.

Patients with aphasia may also display inattention or neglect to the right side of space. Although neglect is more frequently associated with right hemisphere brain damage, recent research indicates that it is also quite common following left hemisphere brain damage, with incidence rates of between 15% to 65% (Karnath, Milner, & Vallar, 2002; Pedersen et al., 1997). Therefore, during assessment, clinicians may use published tests such as the Behavioral Inattention Test (Wilson, Cockburn & Halligan, 1987), or may develop cancellation, line bisection, copying, and other pencil-and-paper tasks to identify neglect in their aphasic patients. In addition, since neglect may affect any modality, testing should be in other modalities as well.

Motoric Impairments

It is not uncommon for patients with aphasia to present with a variety of motoric impairments that may directly or indirectly affect their functional communicative abilities. Specifically, motoric deficits may impair the speed and accuracy of a patient's motor speech, gestural, and graphomotor abilities. Three frequently co-occurring motoric impairments are apraxia, dysarthria, and hemiparesis.

Apraxia. Apraxia generally refers to impairment in the capacity to position muscles and to plan and sequence muscle movements for volitional purposes (Darley et al., 1975; Duffy, 2005). This motoric performance problem cannot be attributed to muscular weakness, slowness, or incoordination as these same muscles may be used without difficulty in reflexive or automatic motor acts. Likewise, patients who have difficulties performing skilled and purposeful motor acts because of cognitive or motivational problems would not be considered apraxic. Two common forms of apraxia that may co-occur with aphasia and that may negatively impact a patient's communication abilities are apraxia of speech and limb apraxia.

In patients with apraxia of speech, the apraxia involves the speech musculature, resulting in difficulty with the volitional production of phonemes and phoneme sequences (Ballard, Granier, & Robin, 2000; McNeil, Doyle, & Wambaugh, 2000; Ogar et al., 2005; Ogar et al., 2006; Peach, 2004). Consequently, these patients demonstrate articulatory breakdown in the form of variable and inconsistent articulatory substitutions, distortions, omissions, repetitions, or additions. These patients also present with prosodic alterations including abnormal stress patterns, slow speech rate, and pauses that are inappropriate or of increased duration. Some of the speech symptom variability

in apraxia of speech is related to the context in which the utterance is produced, such as word or utterance length, word frequency, the phonetic complexity of the word or utterance, and the nature of the task being performed (e.g., repetition vs. spontaneous production). Since this disorder is frequently associated with damage to premotor cortex or insular regions of the left hemisphere (Dronkers, 1996; Duffy, 2005; Ogar et al., 2006), it is commonly associated with aphasia.

Considering the potential interference of apraxia of speech and its frequent coexistence with aphasia, many aphasia batteries (e.g., BDAE) include subtests to examine for the presence of apraxia of speech. In addition, clinicians may also choose to further examine the motor speech abilities of their patients with aphasia using standardized tests such as the Apraxia Battery for Adults- 2 (Dabul, 2000) or the Comprehensive Apraxia Test (DiSimoni, 1989), or a procedure such as Tasks for Assessing Motor Speech Planning or Programming Capacity (Duffy, 2005).

Limb Apraxia. Limb apraxia refers to an inability to execute acquired and volitional movements of the fingers, wrist, elbow, or shoulder that is unrelated to motoric, sensory, or cognitive deficits (Heilman, Watson, & Rothi, 2006; Maher & Rothi, 2001; Neiman et al., 2000; Ochipa, Rothi, & Leslie, 2000; Rose & Douglas, 2003). Limb apraxia is another frequent correlate of aphasia but may often remain undiagnosed, particularly in patients with hemiparesis who must attempt to perform skilled movements with their non-dominant arm (i.e., their difficulty is attributed to using their nonpreferred arm versus an apraxic disorder). Generally, patients with limb apraxia have more difficulty performing distal versus proximal movements, and transitive (i.e., involving a tool or instrument) versus intransitive movements. Patients with this disorder may make the following types of errors (Rothi et al., 1988): (a) content errors, in which they perform the wrong movement or action (e.g., when asked to show how they brush their teeth, they show how to comb their hair); and (b) production errors, in which the spatial or temporal organization of the movement or action is incorrect (e.g., pantomiming brushing one's teeth by holding the toothbrush vertically versus horizontally).

The assessment of ideomotor praxis should occur prior to administering any language or cognitive tests (Helm-Estabrooks & Albert, 1991). Failure to do so may result in patients with limb apraxia being mistakenly diagnosed with comprehension or other neuropsychological deficits (e.g., memory, attention) because they have difficulty completing commands that require purposeful movements, and also possibly because of problems providing a reliable pointing or yes/no head movement response. Clinicians may assess the presence or absence of limb apraxia by developing a battery of tasks that represent a range of difficulty and complexity (Belanger, Duffy, & Coelho, 1996; Rothi, Raymer, &

TABLE 4-8

Items of Paired-Word Intelligibility Test Listed by Phonetic Contrast

Category of Feature	Pair 1	Pair 2	Pair 3
Initial voicing	bee-pea	do-two	goo-coo
Final voicing	add-at	buzz-bus	need-neat
Vowel duration	eat-it	gas-guess	pop-pup
Stop vs. fricative	see-tea	sew-toe	do-zoo
Glottal vs. null	high-eye	hit-it	has-as
Fricative vs. affricate	shoe-chew	shop-chop	ship-chip
Stop vs. nasal	dough-no	bee-me	buy-my
Alveolar vs. palatal	see-she	sew-show	sip-ship
Tongue height	eat-at	soup-soap	eat-eight
Tongue advancement	hat-hot	tea-two	day-dough
Stop place	pan-can	dough-go	bow-go
Diphthong	buy-boy	high-how	aisle-oil
r/l	ray-lay	rip-lip	raw-law
w/r	way-ray	row-woe	won-run
Liquid vs. vowel	string-stirring	spring-spurring	bring-burring
Cluster with one intrusive vowel	blow-below	plight-polite	claps-collapse

(From Kent, R. D., Weismer, J. F., Kent, J. C., & Rosenbek, J. (1989). Toward phonetic intelligibility testing in dysarthria. *Journal of Speech and Hearing Disorders*, 54 (4), 493.)

Heilman, 1997) or by using one of the commercially available apraxia tests such as the Test of Oral and Limb Apraxia (Helm-Estabrooks, 1991) or the Apraxia Battery for Adults- 2 (Dabul, 2000).

Dysarthria. Dysarthria refers to a group of neurologic motor speech disorders that result from impaired control or changes in the tone (i.e., weakness, slowness, imprecision, and/or incoordination) of the speech musculature (Darley et al., 1975; Duffy, 2005; Freed, 2000). Patients with dysarthria have difficulty with one or more of the basic subsystems of motor speech production, including respiration, phonation, resonance, articulation, and prosody. Motor speech symptoms of individual patients tend to be relatively consistent across speaking contexts. However, motor speech symptoms may vary considerably among patients with this disorder due to different etiologies and different muscular involvement. Persistent dysarthria is most likely to be present in patients with aphasia who have suffered bilateral brain damage, since the speech musculature is innervated bilaterally (Duffy, 2005).

Clinicians may use a variety of published tools to quantify and qualify dysarthric speech disturbances, including the Assessment of Intelligibility of Dysarthric Speech (Yorkston, Beukelman, & Traynor, 1984), the Frenchay Dysarthria Assessment (Enderby, 1983), and the Dysarthria Examination Battery (Drummond, 1993). Another assessment option is the word-intelligibility test developed by Kent et al. (1989).

This test is “designed to examine 19 acoustic-phonetic contrasts that are likely to (a) be sensitive to dysarthric impairment, and (b) contribute significantly to speech intelligibility” (p. 482). Table 4-8 lists items of paired-word intelligibility from Kent et al. (1989). Importantly, Kent and colleagues provide a discussion of the therapeutic implications of their test.

Hemiparesis. Many patients with aphasia may present with hemiparesis or muscular weakness of the right side of their body. If the motoric impairment is so severe that the entire side of the body is paralyzed, the term hemiplegia may be used. Weakness of the right hand or a reliance on their non-dominant, left hand may compromise the speed and precision of many patients’ writing, typing, drawing, and/or gesturing.

Medical Conditions

Individuals with aphasia may also have a variety of medical conditions that may interfere with assessment and treatment of aphasia. These conditions are not the etiology of aphasia but may contribute to an individual’s ability to respond to assessment activities. Examples of such conditions are a vitamin or mineral deficiency, learning disability, high or low blood pressure leading to additional strokes or to loss of consciousness, high cholesterol level, and diabetes. Information about the presence of these disorders should be

discussed as part of the history and interview with the patient and family member. Clinicians should be aware of treatment for these disorders and be mindful of any symptoms that may appear as assessment and treatment sessions continue.

Post-Stroke Psychobehavioral Disorders

Many patients suffer from post-stroke psychobehavioral disorders including depression, anxiety, catastrophic reactions, mania, psychosis, adjustment disorder, and behavioral problems such as aggressiveness and sexual inappropriateness (Bishop & Pet, 1995; Craig & Cummings, 1995; Frank, 1998). These psychobehavioral disorders may be the result of one or more of the following (Gupta, Pansari, & Shetty, 2002; Koenig, 1997; Whyte, 2002): a premorbid mood disorder, medications (e.g., depression is a common side effect of certain antihypertensives), brain damage, or a psychological reaction to the stress associated with acquiring communication, as well as other possible cognitive and physical impairments. Such psychobehavioral disorders are viewed as serious medical problems that can compromise the overall assessment and rehabilitative process, including speech and language evaluation and treatment (Patterson, 2002; Swindell & Hammons, 1991).

Because it is the most commonly observed mood disorder subsequent to brain damage, research has focused primarily on issues relating to depression in aphasia. Post-stroke depression (PSD) is a broadly descriptive term (Spencer, Tompkins, & Schultz, 1997) applied to persons who experience depression following left or right hemisphere stroke. PSD occurring in persons with aphasia following left hemisphere stroke has been described as situational depression (Lyon, 1998), mood disorder (Code, Hemsley, & Herrmann, 1999; Craig & Cummings, 1995), part of the grief response (Tanner, Gerstenberger, & Keller, 1989), and reactive (Goldstein, 1948; Währborg, 1991). Hermann and Wallesch (1993) identified three stages of PSD that occur as the rehabilitation process unfolds: primary depression resulting from structural neural change; secondary depression from neuropsychological sequelae of stroke; and tertiary depression arising from maladaptive coping strategies for long-term social change. The variation in these descriptions alludes to the importance of careful assessment and description of depression in persons with aphasia, and appropriate referral to a mental-health professional.

Client self-report, clinical observation, and report by a caregiver are three methods of noting the presence of depression symptoms in patients with aphasia (Swindell & Hammons, 1991; Währborg, 1991). Self-report using a behavior rating scale or through interview is appropriate for clients with mild aphasia who have language and cognitive abilities sufficient to complete the tasks. As aphasia severity increases self-report becomes unreliable and depression

symptoms must be identified through clinical observation or report by a caregiver.

Rating Scales. Rating scales are used to judge a client's mood state. Some scales have a heavy linguistic basis, while others present information in pictorial format to avoid the diagnostic dilemma created by using a linguistically based diagnostic task with a person who has moderate to severe aphasia.

Two scales with a linguistic basis are the Stroke Aphasia Depression Questionnaire (Sutcliffe & Lincoln, 1998) and the Geriatric Depression Scale (Yesavage & Brink, 2006; Yesavage et al., 1983). The Stroke Aphasia Depression Questionnaire (SADQ) uses predominantly caregiver-report and, if needed, client report, and was validated with persons with mild and severe aphasia. An advantage of the SADQ is that it was designed for use with persons with aphasia and can be completed by a caregiver; however, it has a heavy linguistic bias. The Geriatric Depression Scale (GDS) uses client self-report. Both the long and short forms of the GDS are internally consistent, sensitive, and predictive instruments, and are used to detect depression (Agrell & Dehlin, 1989). The major disadvantage to the GDS is also its heavy reliance on the linguistic abilities of the client.

Visual-analogue mood scales were created to circumvent linguistic requirements in detecting depression symptoms. These scales are 100-mm lines anchored by faces representing mood states, and clients mark on the lines to indicate their current mood states. Two scales used with persons with aphasia are the Visual Analogue Dysphoric Scale (Stern & Bachman, 1991) and the Visual Analogue Mood Scale (Stern et al., 1997). The Visual Analogue Dysphoric Scale (VADS) is anchored by two poles, happy and sad, and is a valid indicator of mood state in clients with aphasia, even those with severe auditory comprehension deficits (Stern & Bachman, 1991). The Visual Analogue Mood Scale (VAMS) has eight scales, each anchored with a neutral face and a mood face (sad, happy, tense, afraid, confused, tired, energetic, and angry). The VAMS has normative data and cutoff scores to indicate pathologic mood state, and studies have validated the VAMS for use with many types of clients, including persons with aphasia. The Aphasic Depression Rating Scale (Benaim et al., 2004) was created in part from items on the Visual Analogue Mood Scale to examine depression in persons with severe aphasia or those in a hospital setting.

In contrast, the Visual Analogue Self-Esteem Scale (Brumfitt & Sheeran, 1999) assesses mood state from the perspective of self-esteem. Self-esteem is a global characteristic rather than a specific attribute (e.g., sadness) that is related to but not synonymous with depression, and is thought to be consistent over time in contrast to specific attributes that may easily change. The Visual Analogue Self-Esteem Scale has 10 items, each of which contains two pictures and a corresponding descriptor (e.g., pessimistic and

optimistic). Clients use a five-point scale to represent their views of themselves.

The Challenge of Identifying Depression Symptoms.

Several challenges present themselves when describing depression symptoms in persons with aphasia. The most notable, described by Starkstein and Robinson (1988, p.1) is the "... fundamental paradox of studying a problem (i.e. emotional disorder) when the basic method for assessing the problem (i.e. language) is disturbed." Depression in persons with aphasia may be underestimated in the literature on post-stroke depression because most studies exclude participants with severely impaired linguistic skills.

Client-related factors also pose challenges to identifying depression symptoms. Clients who have compromised cognitive abilities may be unable to reflect on their current mood states, or judge their levels of functioning or outlooks on life, as required by some assessment methods. The presence of neurobehavioral sequelae of stroke such as anosognosia, dysprosodia, apathy, or amnesia can confound, mask, or lead to misdiagnosis of depression (Stern, 1999). Age-related factors, such as sensory changes that may limit the ability to read or hear questions, dementia, memory loss, pseudodementia, and increased use of medication may alter responsivity. Changes in body image or presence of physical disability may also confound the diagnosis of depression after stroke (Dunkle, 1984). Changes in the family or environmental support structure may induce social isolation, functional dependence, or fatigue, further complicating the identification of depression symptoms, particularly in elderly clients with aphasia (King, 1996).

The presence and course of depression symptoms is difficult to predict. No consistent relationship has been observed between PSD and lesion site or size, or type of aphasia. PSD is likely to be both a psychological reaction to life-changing events and a neurochemical result of cortical or subcortical lesion.

Goal 3. Analysis of Cognitive Ability

Cognition is a generic term for any process whereby an organism becomes aware of or obtains knowledge of an object (English & English, 1958). It "refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used" (Neisser, 1967, p. 4). It is a group of processes that we use in a coordinated and integrated manner in order to achieve knowledge and command of our world. That is, cognition is our means of processing and handling information.

Mental Operations

A multitude of specific processes contribute to our overall cognitive proficiency. According to Chapey (1994) these

processes of cognition can be operationally defined as the five mental operations of the Guilford Structure of Intellect model (Guilford, 1967, 1988) — namely, recognition/understanding/comprehension (including perception and attention), memory, and thinking (convergent, divergent, and evaluative).

Recognition/Understanding

Recognition/understanding/comprehension involves knowing, awareness, immediate discovery or rediscovery, recognition of information in various forms, perception, attention, and comprehension or understanding. Recognition involves acknowledgment that something has been seen or perceived previously (Guilford, 1967). Several attentional behaviors have been identified and can be assessed, including (a) sustained attention, or the ability to maintain attention and therefore produce consistent performance over a long period; (b) focused or selective attention, or the ability to focus on and prioritize part of our external or internal environment in the presence of competing stimuli; and (c) divided attention, or the ability to attend to and complete more than one task, or to attend and process multiple stimuli simultaneously (Lezak et al., 2004; Murray, 2002; Spreen & Strauss, 1998). Several neuropsychological tests serve to assess perception (Lezak et al., 2004). The area of comprehension has been well researched in terms of assessment procedures and tools (see Goals 4 and 5).

Memory

Memory is the power, act, or process of fixing newly gained information in storage as well as retaining and retrieving this new information at a later time (Guilford, 1967; Klatzky, 1980; Squire, 1987). Memory is both short-term or working memory and long-term. Short-term memory is a capacity-limited arena, and is usually thought to hold seven items plus or minus two (Clark et al., 2005; Miller, 1956). Information is processed in short-term memory and temporarily stored (Baddeley, 1986). This memory structure is hypothesized to contain buffers (e.g., phonologic loop, visuospatial sketchpad) that briefly hold incoming information, as well as an executive component that controls what information is processed and stored. Memory is also long-term, and the repository of factual and relational information stored over one's lifetime.

Impairments of both working memory and long-term memory have been observed in patients with aphasia (Murray, Ramage, & Hopper, 2001). In fact, Allport (1986) proposed that "the dysphasias...are a class of memory disorder" (p. 32). Patients with aphasia demonstrate working memory deficits when completing verbal as well as visuospatial and other nonverbal memory tasks (Tompkins et al., 1994). Additionally, some evidence suggests that there is a relation between patients' working memory and language

abilities (Caspar et al., 1998; Tompkins et al., 1994). Wright and Shisler (2005) reviewed several theories of working memory and described how elements of those theories may pertain to aphasia. They concluded that assessing and treating working memory in persons with aphasia is an important area of future research, as current results relating aphasia and working memory, while promising, are inconclusive.

Long-term memory contains Guilford's entire Structure of Intellect (SOI) cube: operations, contents, and products (Chapey, 2001). Information is hypothesized to be stored in different sites or in a different manner depending on the type of memory, rather than in a unitary storage system. Research has identified long-term memory deficits among patients with both verbal and nonverbal information (Beeson et al., 1993; Burgio & Basso, 1997; Ween, Verfaellie, & Alexander, 1996). Although minimal research has been completed to examine the relation between long-term memory deficits and language abilities in aphasia, there is some evidence from other patient populations (e.g., patients having undergone temporal lobectomy) that impairments to certain long-term memory stores may negatively affect vocabulary acquisition skills as well as pragmatic language abilities (Gabrieli, Cohen, & Corkin, 1988; Wilson & Wearing, 1995).

Thinking

There are three types of thinking: convergent thinking, divergent thinking, and evaluative thinking. **Convergent thinking** is the generation of logical conclusions from given information, in which emphasis is on achieving the conventionally best outcomes. Usually, the information given fully determines the outcome (Guilford & Hoepfner, 1971). Convergent production leads to logical deductions or compelling inferences and requires the generation of logical necessities.

Divergent thinking involves the generation of logical alternatives from a set of given information, in which emphasis is on variety, quantity, and relevance of output from one source. Divergent thinking fosters generation of logical possibilities, with the ready flow of ideas, the flexibility to change the direction of one's responses (Guilford, 1967), and suggestion of ideas in situations where a proliferation of ideas on a specific topic is required. Such behavior necessitates the use of a broad search of memory storage, and the production of multiple possible solutions to a problem. It is the ability to extend previous experience and knowledge or to widen existing concepts (Cropley, 1967). Divergent behavior is directed toward new responses — new in the sense that the thinker was not aware of the response before beginning the particular line of thought (Gowan, Demos, & Torrence, 1967). Divergent questions are open-ended and do not have a single correct answer. Responses are scored according to the number of ideas produced (flu-

ency), and the variety of ideas suggested (flexibility). They can also be scored according to the originality, frequency, or unusualness of the response, and/or the elaboration or the ability to specify numerous details in planning an event or making a decision (Guilford, 1967). Purdy (2006) examined cognitive flexibility in persons with aphasia and showed that individuals with greater cognitive flexibility are more likely to be successful using compensatory strategies during functional communication tasks than individuals with less flexibility.

According to Guilford (1967), **evaluative thinking** or judgment involves the ability of the individual to use knowledge to make appraisals or comparisons or to formulate evaluations in terms of known specifications or criteria, such as correctness, completeness, identity, relevance, adequacy, utility, safety, consistency, logical feasibility, practical feasibility, or social custom.

Executive-Function Abilities

Various researchers use the term "executive functions" to refer to a collection of cognitive abilities (or composite abilities) that enable us to successfully complete independent, deliberate, and novel behaviors (Dugbartey et al., 1999; Murray, 2002; Purdy, 2002; Ylvisaker & Feeney, 1998). These behaviors allow us to generate, choose, plan, and monitor responses that are goal-directed and adaptive (Borkowski & Burke, 1996; Denckla, 1996; Ylvisaker & Feeney, 1998). Such functions include (a) self-awareness of one's strengths and weaknesses and level of task difficulty (which involves recognition/understanding); (b) inhibition of incompatible responses; and (c) reasoning, problem-solving, strategic thinking, and decision-making. Within the Guilford model, problem-solving, decision-making, and learning are composite abilities that involve many or all of these executive functions. The specific aspects of functioning that are used depend on the problem presented, the decision to be made, the reasoning required, and/or the information to be learned.

Individuals with aphasia may have executive-function difficulties such as problem-solving and decision-making deficits (Chapey, 2001; Purdy, 2002; Ramsberger, 2005; Tatemichi et al., 1994) and preservation or failure to inhibit or shift a response (Albert & Sandson, 1986; Glosser & Goodglass, 1990; Purdy, 2006). Some individuals with aphasia also present with executive-function difficulties thought to be characteristic of sequelae of right hemisphere brain damage, such as lack of awareness or anosognosia (Marshall et al., 1998; Paquier, 2005; Stone, Halligan, & Greenwood, 1993).

Contents of the Guilford SOI Model

According to Guilford (1967, 1988), in the Structure of Intellect model there are five broad, substantive, basic types

of information or content that the organism discriminates: visual, auditory, symbolic, semantic, and behavioral (in the original model visual and auditory contents were subsumed under the term “figural”). The two that are most relevant to language are semantic content and behavioral content. Semantic content pertains to “information in the form of conceptions or mental constructs to which words are often applied.” Therefore, it involves thinking and verbal communication; however, it need not necessarily be dependent on words (Guilford & Hoepfner, 1971). Behavioral content pertains to the psychological aspects of human interactions or to information that is essentially nonfigural and nonverbal: the attitudes, needs, desires, moods, intentions, perceptions, and thoughts of others and of ourselves. This content pertains to the cues that the human organism obtains about the attention, perception, thinking, feeling, emotions, and intentions of others that come indirectly through nonverbal means.

Products of the Guilford SOI Model

There are six products in the Guilford model. According to Guilford and Hoepfner (1971), products are the manner in which things are associated in the mind and the depth to which they are related. Products are considered on a continuum from simple to complex, or concrete to abstract (Chapey, 2001). The continuum of products begins with units, which combine to enter into *classes*. *Classes* then enter into *relations*, which enter into *systems*, which enter into *transformations*, which ultimately enter into *implications*, the most complex product in the model.

Guilford and Hoepfner (1971) describe the products in the following manner. *Units* are relatively “segregated or circumscribed items” or “chunks” of information having “thing” character. They are items to which nouns are often applied. *Classes* are “conceptions underlying sets of items of information grouped by virtue of their common properties” and involve common properties within sets. *Relations* are meaningful connections “between items of information based upon variables or points of contact that apply to them.” *Systems* are organized patterns of information or “complexes of interrelated or interacting parts.” *Transformations* are changes of various kinds (such as redefinitions, shifts, transitions, or modifications) in existing information. *Implications* are “circumstantial connections between items of information, as by virtue of contiguity, or any condition that promotes “belongingness.” Implications involve information expected, anticipated, suggested, or predicted by other information.

Assessment of Cognition

Since cognition is the process by which language is learned and used, each of the cognitive processes identified in the SOI model should be assessed (Wade, 2005). Specifically, the

ability to produce semantic and behavioral units, classes (concepts), systems, relations, transformations, and implications under all mental operations (recognition/understanding, memory, thinking, and executive functions) are explored. Tests developed by Guilford and colleagues can be used for this purpose (Chapey, 2001). Many other published tests also tap these abilities (Lezak et al., 2004; Spreen & Strauss, 1998). In addition, recognition/understanding and convergent thinking are assessed on many standard tests of aphasia.

Assessing Attention

The status of the attention abilities in a person with aphasia is evaluated in both unstructured and structured contexts in an attempt to provide information about if and how such problems interfere with activities of daily living (Coslett, 2000). In unstructured observations, the clinician can determine whether the individual appears alert and able to maintain attention over a specific length of time. Patient ability to resist distraction by either external or internal stimuli is also noted. These and other aspects of attention may also be assessed using published tests such as those listed in Table 4-9 and in Lezak et al. (2004), Murray and Clark (2006), and van Zomeren and Spikman (2005). For example, the Test of Everyday Attention (Robertson et al., 1994) contains real-life materials and tasks that target a variety of attentional processes: sustained attention, focused attention, divided attention, and attentional switching skills. The Wisconsin Card Sorting Test (Grant & Berg, 1993) tests abstract behavior and the ability to “shift set.” Clinicians may also use rating scales such as the one developed by Ponsford and Kinsella (1991), which are completed by both the clinician and the patient (Fig. 4-6).

Assessing Memory

Unstructured observations may provide some information about patient memory abilities such as whether or not the individual is oriented to place, time, and person. For structured assessment, many commercially available tests of memory are accessible. However, relatively few tests are appropriate for persons with aphasia, since most of the tests rely heavily upon processing of linguistic stimuli, verbal responses, or both (Table 4-9). The Rivermead Behavioral Memory Test (RBMT; Wilson, Cockburn, & Baddeley, 2003) represents an exception and includes subtests such as remembering an appointment or a short route. Cockburn and colleagues (1990) demonstrated that most RBMT subtests can be validly administered to patients with aphasia, since performance of only a few subtests are significantly affected by language impairment. Other appropriate structured evaluations include the Visual Memory Span subtest of the Wechsler Memory Scale-3 (Wechsler, 1997b) to assess working memory abilities (particularly the Backward

	Wisconsin Card Sorting Test	Grant & Berg (1993)

Tapping portion), and the Rey Complex Figure Test (Meyers & Meyers, 1995) to examine long-term visuospatial recall. Although performance is usually quantified in terms of the number and length of items remembered or the length of time items can be retained, responses may also be analyzed to identify patterns of impairment (such as remembering only the beginning or end of the material or the production of random errors).

Assessing Thinking

Common methods of assessing convergent thinking skills are confrontation naming tasks, matching tasks, sentence-completion tasks, and question-and-answer tasks that obligate a specific response. These tasks appear in comprehensive aphasia test batteries (e.g., WAB), tests of specific function (e.g., TAWF), and in tasks created by clinicians. Several measures also exist to assess divergent thinking skills. These

measures have in common the lack of a predetermined response. Examples of tests that assess divergent thinking skills are word-fluency tasks (e.g., FAS test), creativity tests (Torrance, 1966), tasks requiring a patient to suggest creative uses for common objects (e.g., how many uses can be created for a hammer), or narrative storytelling tasks (e.g., spontaneous speech elicited from the “Cookie Theft” picture in the BDAE). Evaluative thinking can be assessed by asking a patient to predict the outcome of an event (e.g., a television situation comedy or a story), judge the appropriateness of a correct and an incorrect response to a situation (e.g., what to do if one finds a wallet), or self-reflect on previous behavior.

Assessing Executive Functions

The assessment of executive functions also includes observations as well as the administration of psychometrically rigorous tests (see Table 4–9). For example, the Test of Problem Solving (TOPS; Bowers et al., 1991) may be used to explore processes such as explaining inferences, determining causes, answering negative questions, determining solutions, and avoiding problems (note that norms for TOPS are only provided for children). Sohlberg and colleagues’ (Braswell et al., 1993) Profile of Executive Control System involves both observation of the individual performing daily tasks as well as a patient interview. Other examples are the Test of Nonverbal Intelligence-3 (Brown, Sherbenou, & Johnson, 1997) and the Williams Inhibition Test (Williams, 2006).

Goal 4: Analysis of Ability to Comprehend Language Content

Language content is the meaning, topic, or subject matter of individual words, individual utterances, and/or conversation (Lahey, 1988; McCauley, 2001). Content also refers to the characterization or conceptualization of topics according to how they relate or are similar to one another in different messages. A topic is the particular idea expressed in a message, such as comments about a specific object (e.g., a pipe); a particular action (e.g., eating lunch); or a specific relation (e.g., the relation between Harry and his wand, or a patient and his shoes) (Lahey, 1988). It is important to note that the meaning of words and concepts may change over time and across cultures, and may depend on the social and experiential context in which they are used.

The ability to comprehend the content of language is always impaired in aphasia (e.g., Webb & Love, 1983) but may not always be evident in connected-speech tasks because of the influence of context (Whitworth et al., 2005). Patients with mild aphasia may successfully use contextual cues and predictable communicative sequences (e.g., greeting) and produce responses that appear to demonstrate comprehension, yet are not derived from full comprehension of

language content. A deficit in content comprehension involves assigning meaning to incoming auditory or written messages and/or to understanding words as they relate to objects, persons, actions, ideas, and experiences. For many patients with aphasia, this impairment is confounded by deficiencies in cognitive abilities such as perception (e.g., visual or auditory discrimination), memory, and thinking. Assessment, therefore, centers on analyzing not only the patient’s comprehension of language content but also on perceptual and cognitive abilities that may interfere with comprehension. Comprehension of content should be assessed in both the auditory and reading modalities, and at multiple levels of performance: single words, connected speech (short and long utterances), and gestural communication. These assessments are necessary since in many patients auditory comprehension is better than reading comprehension, some patients display better reading skills than auditory comprehension skills, and for others comprehension at one performance level is better than at other levels (see Appendix 4-2).

Comprehension of Content in Isolated Words

Receptive vocabulary is assessed by asking patients with aphasia to point to real or pictured objects, actions, attributes, and relationships, and categories of objects, actions, numbers, and letters (e.g., “Point to car,” “Point to drinking,” “Show me yellow”). Knowledge of language categories is assessed by requiring the patient to point to objects, pictures, or words that belong to a specific class or group of words (e.g., “Show me the words that are the names of fruit”), and to identify rhyme words, synonyms, and antonyms. Most aphasia batteries include subtests to examine word-level comprehension of objects, actions, and so forth. However, few of them include subtests to examine understanding of word relationships and categories. Therefore, clinicians must rely upon probe tasks to assess this aspect of word comprehension (see Appendix 4-2). Another option is to use tests such as the Pyramids and Palm Trees test (Howard & Patterson, 1992). During administration of this instrument, patients are asked to match pictures on the basis of a semantic association (e.g., for the target “pyramid,” the response choices are “palm tree” and “pine tree”). The six versions of this test allow the clinician to determine whether the patient has a general semantic deficit or a modality-specific problem.

Assessment of content may be difficult to ascertain as the patient may rely on strategies other than meaning comprehension to respond (Raymer & Rothi, 2000). For example, a patient may attend to a superficial feature and use a sophisticated guessing strategy to produce the correct response. Generally, pointing tasks to assess comprehension can be made more difficult by increasing the number of items or words from which the patient must select the target (e.g.,

increase from two to six distractor items), by increasing the similarity of the target and distractor items (e.g., for the target word “car,” printed distractors could be changed from “lemon,” “glass,” and “toe,” to “cab,” “bus,” and “bar”), or both. The influence of other variables such as word frequency or familiarity, length, and imageability on a patient’s understanding can also be examined.

Comprehension of Content in Connected Language

Comprehension of labels for objects, actions, attributes, and relationships and categories of objects, actions, and relationships should be assessed in connected language at both the sentence and discourse levels. At the sentence level, the clinician evaluates the patient’s ability to point to common objects by description (e.g., “Read this sentence and point to the object that it describes”) or by function (e.g., “Point to something that cuts”), and/or the patient’s ability to follow directions or commands (e.g., “Write your address and then underline the name of your street”). Testing also includes assessment of the patient’s ability to understand concrete and abstract sentences. For example, in evaluating concrete sentences, the clinician might ask, “Is this a cup?” Items that evaluate more abstract comprehension abilities typically assess the patient’s understanding of complex relationships, such as comparative (e.g., “Are grapefruits larger than lemons?”), spatial (e.g., “Is California west of Arizona?”), temporal (e.g., “Does November come before October?”), inferential (e.g., “The man cut the steak. Did the man use a knife?”), cause-and-effect (“Can smoke cause a fire?”), or synonymy (e.g., “Does sob mean the same as cry?”) (Wiig & Semel, 1984). Additional examples appear in Appendix 4-2. In addition to manipulating vocabulary characteristics (e.g., word frequency or imageability), clinicians alter variables such as sentence length and/or relational complexity to increase or decrease the difficulty of sentence-level comprehension tasks.

During highly structured assessment of both language content and form, response requirements are carefully controlled to be sure that success or failure is dependent on the stimulus characteristics and not on an inability to respond. For example, requiring a patient to gesture a response (e.g., “Pretend to use a hammer”) may be complicated by a co-existing limb apraxia. Therefore, this patient may be required to respond by pointing to a word or picture, or by saying or pointing to a one-word answer such as yes/no, true/false, or right/wrong. Abilities and impairments can then be confidently ascribed to the specific input parameter that is being systematically controlled.

Comprehension of discourse-length spoken or written material is also to be assessed since there may be a difference between sentence-level and discourse-level comprehension abilities (Armstrong, 2000; Brownell & Friedman, 2000; Larfeuil & LeDorze, 1997; Nicholas, MacLennan, &

Brookshire, 1986). Most aphasia batteries include subtests designed to assess auditory and reading comprehension abilities at the discourse level. However, research has revealed that patients with aphasia were able to answer more than half of the reading items from several popular aphasia batteries correctly (e.g., BDAE, WAB) at a significantly greater rate than by chance. This suggests that their responses show relatively low passage dependency and instead are based on some other comprehension strategy. Consequently, when clinicians use these materials they may be assessing reading comprehension levels of information other than those which were planned. In comparison to the reading subtests of aphasia batteries, the Nelson Reading Skills Test (Hanna, Schell, & Schreiner, 1977) was found to have more acceptable passage dependency. That is, patients with aphasia and adults with no brain damage had to read the paragraphs to answer the test questions correctly (Nicholas & Brookshire, 1987) rather than rely on other, unknown strategies to respond. Another assessment option, the Discourse Comprehension Test (Brookshire & Nicholas, 1997), is designed to examine understanding of information that varies in terms of salience (main ideas vs. detailed information), as well as directness (explicitly stated information vs. implied information). Therefore, it can be administered as either a test of listening or reading comprehension.

Lastly, the aphasic patient’s ability to understand meaning in unstructured, spontaneous language is determined. This is done by noting the type and amount of content that appears to be understood, as demonstrated by appropriate responses to conversation. For example, if a patient hears the statements “No, this belongs to the nurse. Is this hers?” and “This is mine. Please give it to me” and responds appropriately, the clinician may begin to hypothesize that the patient comprehends the relationship of possession. However, it is important to be cautious when basing judgments about discourse-level abilities on the basis of general conversational speech since patients with aphasia frequently nod or gesture appropriately as a response to social or prosodic cues and may not be comprehending the language content.

Gesture

Clinicians also assess the ability to comprehend gestures or pantomime since, for some patients with severe aphasia, gestures may represent a patent modality for comprehension (Daniloff et al., 1986; Daniloff et al., 1982; Marshall, 2006; Power & Code, 2006; Rose, 2006; Varney, 1982). In particular, patients with severe auditory comprehension impairments but relatively minimal or mild reading impairments have been found to display better gestural recognition abilities than those patients with severe auditory and reading comprehension impairments (Goodwin, 2002). This finding has led some researchers to suggest

that reading-comprehension abilities may be a better indicator of the ability to communicate effectively via gestures than of overall aphasia severity (Daniloff et al., 1982; Rose & Douglas, 2003). In contrast, other studies have found a relationship between praxis and pantomime-recognition impairments (Bell, 1994; Wang & Goodglass, 1992). With respect to gestural codes, iconic gestures (e.g., pantomiming the function of objects), and AmerInd signs (i.e., a modification of American Indian hand talk) are easier for naive viewers to discern than American Sign Language (ASL) and consequently may be more suitable for use in assessing and treating aphasia (Campbell & Jackson, 1995; Daniloff et al., 1986; Power & Code, 2006).

Gestural recognition abilities are not typically tested as part of most aphasia batteries. Therefore, clinicians may use a subtest of an aphasia battery, one of the nonstandardized tasks described in the literature (Bell, 1994; Daniloff et al., 1982; Rothi et al., 1997), or a probe task developed by themselves. Generally, gestural comprehension is assessed with videotaped or live presentation of gestures, and the patient points to the correct picture in a multiple-choice format. In addition to assessing gesture comprehension abilities in isolation, clinicians may also examine the effect of providing gestural information in concert with auditory information (Marshall, 2005; Records, 1994; Rose, 2006). That is, clinicians can determine whether gestural information aids auditory comprehension.

Influential Variables

A variety of variables may positively or negatively influence aphasic patients' abilities to comprehend language content as well as language form (see Goal 5 for further information about assessing comprehension of language form). Research indicates that comprehension of both content and form are inversely proportional to the level of intellectual complexity (Shewan & Canter, 1971; Siegel, 1959), length (Shewan & Canter, 1971; Weidner & Lasky, 1976), and degree of semantic similarity among response choices (Baker, Blumstein, & Goodglass, 1981; Duffy & Watkins, 1984; Howland & Pierce, 2004). In contrast, there is believed to be a positive relationship between comprehension abilities and other stimulus variables, such as:

- word frequency (Gerratt & Jones, 1987; Marshall et al., 2001; Nickels & Howard, 1995; Pashek & Tompkins, 2002; Schuell, Jenkins, & Landis, 1961),
- age of acquisition (Hirsch & Ellis, 1994),
- imageability (Cole-Virtue & Nickels, 2004; Kay et al., 1990; Luzzatti et al., 2001),
- emotional content (Boller et al., 1979),
- salience (i.e., main ideas vs. details),
- directness (i.e., stated vs. implied) (Cole-Virtue & Nickels, 2004; Ernest-Baron, Brookshire, & Nicholas,

1987; Laiacona et al., 2000; Nicholas & Brookshire, 1986, 1995a; Nickels & Howard, 1995),

- sentence constraint (Faust & Kravetz, 1998; Puskaric & Pierce, 1997),
- redundancy (Gardner, Albert, & Weintraub, 1975; Huntley, Pindzola, & Weidner, 1986; Stachowiak et al., 1977),
- context (Cannito, Vogel, & Pierce, 1989; Hough et al., 1997; Howland & Pierce, 2004; Nickels & Howard, 1995), and
- personal significance of the material.

Additionally, for some patients with aphasia, the grammatical class or part of speech (e.g., verbs vs. nouns) can influence their comprehension abilities (Berndt, Handiges et al., 2002; Carramazza & Hillis, 1991; Daniloff et al., 1982). However, the effect of these variables is neither consistent nor predictable. Recent research is attempting to tease apart the individual effects of variables (e.g., Berndt, Haendiges et al., 2002), and beginning to suggest that other factors (e.g., age of acquisition) are of greater importance (Hirsch & Ellis, 1994).

Several factors (listed below) related to the presentation of the verbal stimuli also contribute to a patient's success or failure in comprehension (Blumstein et al., 1985; Gardner et al., 1975; Hough et al., 1997; Kimelman & McNeil, 1989; Lasky, Weidner, & Johnson, 1976; Murray, Holland, & Beeson, 1997; Records, 1994; Toppin & Brookshire, 1978). Consequently, the degree to which a patient's comprehension is facilitated or impeded by tone of voice, intensity, stress, attentional demands (e.g., focused vs. divided attention tasks), concomitant gestures or pictorial cues, presentation rate, pauses at intervals, prolongation of words, and imposed response delays can be determined.

Goal 5: Analysis of the Ability to Comprehend Language Form

Language form includes syntax, a system of rules used to order words and relate them to one another in order to express ideas, and morphology, a system of rules used to construct words (Nelson, 1998). In aphasia, impairments in the ability to understand syntax or grammatical morphology are common. Consequently, assessment involves an analysis of the patient's ability to understand language form at both the word and sentence levels (see Appendix 4-3).

Comprehension of Form Words and Morphology

Form words can be of two types: substantive or open-class words (e.g., verbs, nouns, adjectives, adverbs) and relational or closed-class words (e.g., prepositions, conjunctions, and articles) (Allen & Badecker, 2001; Saffran, Berndt, & Schwartz, 1989). Because most aphasia batteries focus primarily on examining comprehension of nouns, clinicians

may devise tests of their own or borrow from nonstandardized measures to conduct a broad-based assessment of comprehension of form words. The ability to comprehend the meaning of both substantive and relational words can be assessed through the use of picture-verification tasks in which the patient with aphasia sees a picture, hears or reads a word or phrase, and points to the best picture for that word or phrase. For example, a picture-verification task to evaluate comprehension of prepositions might include stimuli such as “Point to (a) The cup is on the table; (b) The cup is under the table; or (c) The cup is near the table.” Because of interest in the patient’s ability to comprehend prepositions, the clinician may first ensure that the patient can accurately recognize the substantive words within the test stimuli (e.g., “cup,” “table”) (see Appendix 4-3). In each instance, responses are analyzed to determine the type and frequency of words the patient is able to understand, the length of the stimulus that can be understood, and the latency or length of time needed to comprehend the material and respond.

In attempts to understand further the nature of form words, researchers are examining aspects of them and how they are compromised in persons with aphasia. For example, some studies have examined the relationship between the phonologic and morphologic forms (Braber et al., 2005; Miceli, Capasso, & Caramazza, 2004) and found inconsistent results regarding the influence of phonologic form on morphologic form. Saffran et al. (1989) developed a procedure for quantitative analysis of narrative speech to examine morphologic and syntactic structure, and reported that aspects of grammatical morphology may dissociate in agrammatism. Kim and Thompson (2000) and Shapiro, Shelton, and Caramazza (2000) suggested that one dimension of lexical organization is by word-form class (nouns or verbs, and verb-argument structure).

Morphology involves the rules used to form words into other words (Caplan, 1993). More specifically, in English, word formation is accomplished via affixing derivational or inflectional morphemes. Addition of a derivational morpheme changes a word into a different form word (e.g., “pain” into “painful”), whereas addition of an inflectional morpheme signifies a certain syntactic relationship (e.g., subject-verb agreement of “read” for “She reads.”). Deficits comprehending both types of morphology are observed in patients with aphasia (Badecker & Caramazza, 1987; Braber et al., 2005). However, few assessment tools have been developed to examine such abilities. Two exceptions are the commercially available Psycholinguistic Assessments of Language Processing in Aphasia (Kay et al., 1992), and, in the research literature, a test developed by Caplan and Bub (1990). Caplan and Bub’s test includes subtests to assess recognition and comprehension of morphologically complex words. The recognition subtest contains real, affixed words (e.g., “runs”) and nonwords (e.g., “runned”), and patients with aphasia make a lexical decision regarding

whether the item heard or read was a real or made-up word. In the comprehension subtest, patients complete a word-picture matching task and a similarity judgment task.

Comprehension of Syntactic Constructions

Processing syntactic structures involves the knowledge of how one orders words within an utterance and how to construct various sentence types, such as active, passive, negative, and negative-passive. To comprehend syntactic information, patients with aphasia need adequate knowledge of syntactic rules (i.e., the ability to parse the structures that organize phrase elements into hierarchically translatable constituents such as subject NP, or object NP). They also need to be able to process quickly a transient auditory signal (if it is a listening situation) and to retain a memory representation of the signal to assure that sentential elements are not missed or misinterpreted (Berndt, 1998; Caplan, 1993; Schwartz, Fink, & Saffran, 1995). Disruption to this temporal aspect of syntactic processing will likely result in slow, labored reading abilities, although in reading there may be multiple opportunities to extract syntactic information from the written material.

Patients with aphasia may have difficulty comprehending the syntactic structure of spoken or written language that range from minimal difficulty, to very selective deficits (i.e., problems interpreting only certain sentence types such as cleft-object sentences), to profound impairments (i.e., patients must rely on semantic and pragmatic knowledge to comprehend sentences) (Chatterjee & Maher, 2000; Dick et al., 2001; Grodzinsky, 2000). Research in recent years has examined syntactic deficits in persons with aphasia from several perspectives: syntactic structure (Friedmann, 2005), availability of word class during syntactic comprehension (Park, McNeil, & Doyle, 2002; ter Keurs, Brown, & Hagoort, 2002), and differences in time post-onset of aphasia (Springer et al., 2000).

In assessing syntactic comprehension abilities and deficits, patients are often asked to respond to basic sentence types. However, aphasia batteries rarely include items that assess a range of syntactic comprehension abilities. Further, other tests have been criticized because they do not allow differentiation between disorders of syntactic comprehension or short-term or working memory limitations (Caplan, 1993; Martin & Miller, 2002). Lacking this distinction, clinicians may make an incorrect diagnosis and potentially plan inappropriate treatment. Three tests assess syntactic deficits in detail: the PALPA (Kay et al., 1992), the Verb and Sentence Test (Bastiaanse et al., 2003), and the Sentence Processing Resource Pack (Marshall et al., 1998). Clinicians may also probe the syntactic processing abilities of their patients with aphasia using commercially available tests such as the Revised Token Test (McNeil & Prescott, 1978), tests from the research literature (Caplan & Bub, 1990; Caplan, Waters, & Hildebrandt, 1997), or probes developed based on these test procedures.

Assessment often takes the form of a picture-sentence verification task in which the patient decides whether a spoken or written phrase or sentence is true or false or if it answers the question “yes” or “no”. For example, the patient might be presented with a picture of a boy pushing a girl. Subsequently, he would point to the printed word “true” or “false” after each of the following sentences: “The boy is pushing the girl”; “The girl is pushing the boy”; “The boy is being pushed by the girl,” and so forth. Caplan and colleagues (1997) also have patients demonstrate or act out sentence stimuli using the objects provided. The stimuli are constructed so that sentences cannot be interpreted solely on the basis of semantic processing or word knowledge, and so that distractor items represent plausible sentence inter-

pretations (Beretta et al., 1999; Berndt, 1998). During analysis of responses, clinicians attend to accuracy of response as well as to error types.

In determining the complexity of structures that the patient can comprehend, clinicians attend to the following syntactic features of a sentence: (a) **canonicity of thematic role order** (canonical order refers to sentences with the structure of subject-verb-object), (b) the **number of verbs** in a sentence, (c) the **verb argument** structure, and (d) the **number of propositions or thematic roles** played by nouns around a given verb. Table 4–10 contains a list of the sentence types (as well as possible foils) in an order of increasing complexity. Patients with aphasia and comprehension deficits (Caplan et al., 1993; 1997) should respond more

TABLE 4–10

Sentence Types that May Be Used to Probe Syntactic Comprehension

Sentence Structure	Number of			Canonicity of Thematic Roles
	Words	Propositions	Thematic Roles	
<i>Active</i> The lion kicked the elephant (Foil: The elephant kicked the lion)	5	1	2	Canonical
<i>Active Conjoined Theme</i> The pig chased the lion and the cow (Foil: The lion chased the pig and the cow)	8	1	2	Canonical
<i>Active with Adjunct</i> The elephant pulled the dog to the horse (Foil: The dog pulled the elephant to the horse)	8	1	3	Canonical
<i>Passive with Adjunct</i> The dog was pulled to the horse by the elephant (Foil: The horse pulled the dog to the elephant)	9	1	3	Noncanonical
<i>Truncated Passive (TP)</i> The pig was touched (Foil: The animal that was depicted as touching the pig was touched)	4	1	2	Noncanonical
<i>Passive (P)</i> The elephant was pushed by the cow (Foil: The cow pushed the elephant)	7	1	2	Noncanonical
<i>Cleft Object (CO)</i> It was the dog that the horse passed (Foil: The dog passed the horse)	8	1	2	Noncanonical
<i>Conjoined (C)</i> The elephant followed the lion and pulled the dog (Foil: The elephant followed the lion that pulled the dog)	9	2	4	Canonical
<i>Object-Subject (OS)</i> The horse kicked the elephant that touched the dog (Foil: The horse kicked the elephant and touched the dog)	9	2	4	Canonical
<i>Subject-Object (SO)</i> The dog that the pig followed touched the horse (Foil: The pig that followed the dog touched the horse)	9	2	4	Noncanonical

(From Caplan, D., Waters, G. S., & Hildebrandt, N. (1997). Determinants of sentence comprehension in aphasic patients in sentence-picture matching tasks. *Journal of Speech, Language, and Hearing Research*, 40, 542–555.)

accurately and more quickly to sentence types at the top versus the bottom of the list of items in this table. A clinician can compare his or her patient's understanding of sentence types of active versus truncated passive, active conjoined versus cleft object, active with adjunct versus passive with adjunct, object-subject versus subject-object, and conjoined versus subject-object. This hierarchy of sentence types serves as a possible framework to identify the approximate level at which a patient is functioning and to describe the syntactic features that the patient with aphasia can comprehend.

Goal 6: Analysis of the Ability to Produce Language Content

Impairments in the ability to produce language content are always part of aphasia (Benson, 1979; Goodglass, 1993). Deficiencies are observed in the appropriate selection or use of vocabulary words relating to objects, events, relationships, and content. The person with aphasia may have difficulty in word finding, labeling, and categorizing, and/or in the spontaneous selection or substitution of one appropriate word for another. Therefore, assessment involves an analysis of the ability to provide the spoken and written label or name of objects, actions, events, attributes, and relationships in response to highly structured tasks as well as during connected and spontaneous language. Importantly, clinicians should not assume that a patient's writing deficits will parallel his or her spoken language deficits. Indeed, writing disturbances may differ both quantitatively and qualitatively from disturbances in spoken language (Varney, 1998).

Production of Content in Highly Structured Tasks

An important component of content assessment involves determining the patient's ability to provide the verbal and written label of objects, actions, events, attributes, and relationships at various levels of task and stimulus difficulty. Clinicians routinely use several common, structured word-finding tasks that vary in terms of difficulty to assess production of content: (a) defining referents, (b) superordinate or category naming, (c) verbal fluency, (d) confrontation naming, (e) automatic closure naming, (f) automatic serial naming, (g) recognition naming, and (h) repetition naming (Murray & Chapey, 2001). For each task, a variety of psycholinguistic variables such as word frequency, picturability, length, imageability, age of acquisition, and concreteness can be varied to enable the clinician to specify the nature and extent of the word-finding impairment (Deloche et al., 1997; Nickels, 1995; Nickels & Howard, 1995; Snodgrass & Vanderwoort, 1980; Wilshire & Coslett, 2000). Most aphasia batteries and tests of spoken or written naming, such as the Test of Adolescent and Adult Word Finding (German, 1990), include subtests that examine several if not all of these types of word-finding abilities (see Table 4–5).

Defining Referents

A patient's ability to define words is assessed by asking the patient questions such as "What does anchor mean?" or "What does robin mean?" Responses are analyzed to determine the type of explanation produced, such as definition by usage, by location, or by classification. The ability to name words that are defined can also be explored further with follow-up questions that solicit either more detailed information, or a response that is in a different category (e.g., "A kind of plant that grows in a garden is _____." as a follow up to "What does garden mean?").

Category Naming

The ability to classify semantically related words and concepts is assessed through tasks that require responses at various levels and types of categories. The patient's ability to categorize in his or her own language can be scored according to (a) **perceptual categories**: classifying on the basis of a relevant sensory quality of a stimulus such as shape, size, or color (e.g., banana, lemon, grapefruit are all yellow); (b) **conceptual or semantic categories**: classifying on the basis of a generalized idea of a class of objects (e.g., banana, lemon, grapefruit are all fruit); and (c) **functional categories**: classifying on the basis of an action or function associated with a class of objects (e.g., banana, lemon, grapefruit are all for eating) (Goldstein, 1948). The clinician may also examine the degree of concreteness or abstractness of a patient's category responses. For example, grouping items on the basis of perceptual categories would be considered a more concrete response than grouping on the basis of semantic or functional category. Further, category naming may be examined according to the semantic level of words (Baker & Goodglass, 1976). Objects can be categorized at the superordinate level (e.g., animal), the basic object level (e.g., dog), or the exemplar level (e.g., Labrador Retriever).

To explore the ability to decipher categories, patients may be asked to (a) provide the verbal or written name of an object category (e.g., "Rose, tulip, and carnation are all a type of _____."), (b) name as many words as possible that belong to a certain category (e.g., "Write down the names of as many animals as you can.") (a divergent semantic task), (c) produce word associations (e.g., "What is the first word that you think of when I say school?"), and (d) sort objects into categories and explain the rationale for their sort (e.g., Goldstein's [1948] sort task).

Verbal Fluency

Verbal fluency tasks are category-naming tasks that obligate divergent thinking within one's semantic space. These tasks require patients to name as many words as they can think of within a certain category (as described above) or starting with

a particular letter such as P, R, F, or C (Benton et al., 1994). For the letter task, patients are instructed not to use proper nouns. A time limit of at least 60 seconds is typically imposed, and the patient is given more than one test trial. Normative data for these types of naming tasks are available in the research literature (Heaton et al., 1992; Spreen & Strauss, 1998).

Confrontation Naming

Verbal and written naming in response to visual presentation is assessed by presenting objects, actions, events, and relationships, or pictures of these items, that vary in frequency, imageability, degree of abstractness, and type of category. For example, in an assessment of content-production ability, oral and written naming of objects, geometric forms, letters, animals, colors, body parts, and actions is almost always evaluated. For patients with right hemiparesis or other motoric impairments that may affect legibility of a written response, it may also be beneficial to assess writing skills with block letters that can be ordered to spell words (e.g., for a picture of a circle, the clinician gives the patient blocks with the letters “I,” “R,” “C,” “E,” “C,” and “L” and asks him or her to spell the name of this picture); to make this task more difficult, distractor letter blocks could be added.

Confrontation naming has been criticized for its potential lack of relationship to daily communication activities (Mayer & Murray, 2003). Although confrontation naming is not always a part of conversational exchange, it is a communicative response that is a frequent and regular part of successful communication between individuals. For example, many communication exchanges contain short questions that further the intent of the exchange (e.g., Q: “Where do you want to go for dinner?” R: “Spinnaker”). To address this reasonable criticism, a clinician might carefully select the target items to include some that are familiar to the patient and frequently used by his or her family. Confrontation naming can also be assessed during connected speech tasks (Allchin & Patterson, 2000; Mayer & Murray, 2003; Patterson & Hinnach, 2005).

Automatic-Closure Naming

The capacity to complete an open-ended sentence or phrase stem such as “The sky is _____” is often a component of assessment. These sentence or phrase stems can be varied in terms of constraint or the degree to which a stem generates a particular response (Fischler & Bloom, 1979; Schwanenflugel & Shoben, 1985). For example, the stimulus “It’s raining cats and _____” would be considered highly constrained because only one response, “dogs,” is appropriate, given the nonliteral interpretation of the sentence. In contrast, the stimulus “He ate the _____” would be minimally constrained because there are numerous plausible responses. For both adults with aphasia and non-brain-damaged adults, automatic-closure naming is facilitated when the sentence or phrase stem is highly constrained or conver-

gent, and there is a limited number, or closed set, of response choices (Breen & Warrington, 1994; McCall et al., 1997; Treisman, 1965).

Automatic Serial Naming

The ability to produce rote or over-learned material may also be appraised. For example, the patient may be asked to count to 20, name the days of the week, write out the letters of the alphabet, and/or recite well-known prayers, nursery rhymes, or poems. It has often been assumed that this ability is intact when other naming abilities are not; however, this is not always the case.

Recognition Naming

When patients are unable to name an item, the correct word can be offered to them to determine whether they are capable of recognizing words they cannot name. For example, for the target stimulus “elephant,” a patient may be required to indicate which of three verbal or written choices is the appropriate label (e.g., “giraffe,” “elephant,” or “telephone”). To increase the difficulty of this task, distractor items can be manipulated to be semantically (e.g., “giraffe”) and/or phonologically or orthographically (e.g., “telephone”) similar to the target. The most recent version of the Boston Naming Test includes this testing component.

Repetition Naming

Repetition or copying of words is assessed to determine whether the patient can repeat or copy words that he or she cannot verbally name or write, respectively (e.g., the clinician says “Now repeat: elephant.”).

Production of Content in Connected Language

The ability to retrieve precise words for objects, events, relationships, and ideas during unstructured, spontaneous language production is important to the communication of meaning. In addition, the ability of a person with aphasia to produce content during highly structured tasks may differ from his or her abilities during less structured communication activities that require greater amounts of verbal or written output and more thinking to prepare the response. Therefore, clinicians analyze samples of their patients’ spoken or written connected language to determine the accuracy, responsiveness, completeness, promptness, and efficiency of the content.

Picture description tasks are often used to elicit spoken and written discourse. The data generated can provide a controlled source for analyzing parameters of language content, form, and use (Armstrong, 2000; Shadden, 1998b). Although several aphasia test batteries include spoken and written picture-description tasks, eliciting larger samples using other connected language tasks should improve the

TABLE 4-11

Concepts Elicited from Normal Speakers Describing the “Cookie Theft” Picture

two	little	mother	in the kitchen (indoors)
children	girl	woman (lady)	general statement about disaster
little	sister	children behind her	
boy	standing	standing by sink	lawn
brother	by boy	washing (doing)	sidewalk
standing	reaching up	dishes	house next door
on stool	asking for	drying	open windows
wobbling (off balance)	cookie	faucet on	curtains
3-legged	has finger to mouth	full blast	
falling over	saying “shhh”	ignoring (daydreaming)	
on the floor	(keeping him quiet)	water	
hurt himself	trying to help (not trying to	overflowing	
reaching up	help)	onto floor	
taking (stealing)	laughing	feet getting wet

on the high shelf			
in the cupboard			
with the open door			
handing to sister			

(From Yorkston, K. & Beukelman, D. (1980). An analysis of connected speech samples of aphasic and normal speakers. *Journal of Speech and Hearing Disorders*, 45, 27–36.)

reliability and validity of assessment results. In addition, to assure adequate test-retest stability for measures of connected language, clinicians may wish to use at least four or five stimuli to collect language samples that are at least 300 to 400 words in length (Armstrong, 2000; Brookshire & Nicholas, 1994). The stimuli should include more than picture-description tasks since these tend to elicit labeling behavior and potentially limit the number and variety of lexical and pragmatic behaviors produced as well as the complexity of morphosyntactic structures generated by patients (Armstrong, 2000; Armstrong, 2002; Davis, 2000; Li et al., 1996; Olness et al., 2002; Shadden, 1998b; Shadden et al., 1991). Other language tasks that may be used to elicit spoken or written language samples include conversational discourse, sequential events illustrated through multiple pictures, story-retelling, video-narration, providing interpretation of fables or stories, or procedural description tasks (e.g., “How do you change a tire?”) (Cherney et al., 1998; Shadden et al., 1991; Ulatowska, Doyel, Freedman-Stern et al., 1983; Ulatowska, Freedman-Stern, Doyel et al., 1983). However, the usefulness of data from these tasks may be moderated by the presence of interfering variables such as motor-speech disorders.

Numerous methods are available to analyze content in connected-language samples (Armstrong, 2000; Shadden, 1998a). For example, one popular scoring system, developed

by Yorkston and Beukelman (1980), requires the clinician to determine the number of content units or “grouping of information that was always expressed as a unit” (p. 30), per unit of time. These researchers provided a list of content units for the “cookie theft” picture-description task of the BDAE (Table 4-11). One limitation of this system, however, is that it only provides responses to this picture. Consequently, Nicholas and Brookshire (1993) expanded on this idea and created a scoring system to analyze content in language samples derived from a variety of stimuli. In their system, rules are provided to help the clinician determine the number of words and “correct information units” (CIUs), or words that are “accurate, relevant and informative relative to the eliciting stimulus” (p. 340). Nicholas and Brookshire recommend that clinicians calculate both words per minute and the percentage of CIUs (i.e., number of CIUs/number of words) to obtain the most information about both the content and efficiency of their patients’ connected language. Nicholas and Brookshire (1995b) also described a rule-based system for scoring the presence, completeness, and accuracy of content pertaining to the main concepts or gist in the connected language of patients with aphasia. In addition, they listed the main concepts consistently identified by non-brain-damaged adults in response to the “cookie theft” picture from the BDAE (Nicholas & Brookshire, 1995b) and to their stimulus “the birthday party

picture" (Nicholas & Brookshire, 1992). These content measures are excellent predictors of how informative patients with aphasia are as perceived by unfamiliar listeners (Doyle et al., 1996). In addition, changes on these measures over time correlate positively with unfamiliar listeners' perceptions of socially relevant changes in the communicative ability of patients with aphasia (Ross & Wertz, 1999). Doyle, Goda, and Spencer (1995) compared the performance of persons with aphasia on structured-discourse tasks and conversation and noted significant differences in contexts. They reported that despite differences, performance on the structured tasks predicted performance in conversation. This observation is helpful in planning an assessment session in that the time-consuming task of conversational analysis may not be required during an early session in order to determine a diagnosis. Instead, structured-discourse tasks can be included in the initial assessment and conversational analysis (Boles & Bombard, 1998) completed at a later date.

Other measures available to analyze production of content in connected language are described as structural or functional in nature. Examples of structural-content analysis measures are word class, grammatical complexity, semantic diversity, and error pattern. Examples of functional-content analysis measures are speech acts (Searle, 1969), transitional elements, cohesion, and coherence.

Production of Content in Gesture

Although gestural abilities are often impaired in aphasia due to linguistic, cognitive, and/or apraxic deficits, many patients, even those with severe and global aphasia, have been able to acquire simple forms of gestural communication (Helm-Estabrooks, Fitzpatrick, & Barresi, 1982; Lott, 1999; Skelly, 1979). With respect to gestural codes, iconic (e.g., demonstrating how to use a toothbrush), symbolic (e.g., showing how to salute), and AmerInd gestures are often more suitable than American Sign Language (ASL) signs as assessment and treatment stimuli because they can be discerned more easily by unfamiliar viewers, and because they have been created or adapted for one-handed gesturing (Campbell & Jackson, 1995; Daniloff et al., 1982; Skelly, 1979).

Most aphasia batteries (e.g., ADP, PICA) include a subtest that examines ability to produce a limited number of iconic gestures, common symbolic gestures, or both. Another option is to assess the gestural-production skills using one of the several nonstandardized procedures described in the research literature (Alexander & Loverso, 1993; Conlon & McNeil, 1989; Rothi, Raymer et al., 1997; Rose, 2006).

Drawing

For some severely impaired patients with aphasia, it may be useful to examine their ability to reproduce or spontaneously produce drawings in order to communicate content

(Lyon & Helm-Estabrooks, 1987; Ward-Loneragan & Nicholas, 1995). However, before communicative drawing is adapted as a viable option, Lyon and Helm-Estabrooks (1987) suggest that the following abilities be considered as prerequisites: (a) an intact visuosystem for the concepts to be drawn, (b) adequate access to the symbols within this visuosystem, (c) adequate motoric and praxic abilities to draw these symbols, and (d) the ability to manipulate or augment drawn output "in a communicatively interactive and problem-solving manner" (p. 62). Therefore, assessment may involve determining the integrity of the patient's abilities in each of these areas via probes such as copying and drawing from memory, and via an evaluation of hand and limb motoric and praxic skills. The Daily Mishaps Test, which requires the patient to draw enacted scenarios that contain one- to three-part scenes, may also be used to evaluate patients' drawing abilities (Helm-Estabrooks & Albert, 1991). Although no formal scoring procedures are provided, clinicians can develop their own or borrow from scoring criteria described in the research literature (Murray, 1998). Sacchett (2002) reviewed approaches to the use of drawing in aphasia, and suggested three principles to include in evaluation and treatment: draw economically rather than perfectly; allow the communication partner to contribute to the drawing; and use interactive drawing within natural contexts.

Cognitive Neuropsychological and Neurolinguistic Approaches to Assessment of Content Production

Clinicians who adhere to a neuropsychological or a neurolinguistic approach to assessment attempt to determine the nature of their aphasic patients' language impairment with respect to models of language (Caplan, 1993; Hillis, 2002a, 2005; Kay et al., 1996; Nadeau, Rothi, & Crosson, 2000). That is, the clinician attempts to localize which particular component(s) of the model are impaired (see Fig. 4-4). In terms of word-finding abilities, for example, patients with aphasia have been found to have breakdowns in the word-retrieval process at the semantic and/or phonologic or graphemic output lexicon levels. These symptoms are most frequently characterized as impairments of access to or egress from memory, rather than loss of these respective linguistic representations (Raymer, 2005; Raymer & Rothi, 2002; Wilshire & Coslett, 2000). Patients with aphasia may also display difficulties at the articulatory/graphic planning stage or with the motor realization of that plan, but these difficulties are often viewed as a motoric (e.g., apraxia of speech, apractic agraphia), rather than a linguistic problem.

The research literature contains many articles that provide guidance for performing a neuropsychological or neurolinguistic assessment of disorders of content production (Rothi et al., 1991; Hillis, 1998). Rothi et al. (1991) and Hillis (1998) described how cognitive neuropsychological

models guided their assessments of word-retrieval deficits across modalities, tasks, and sessions in order to distinguish impaired access/egress from degradation of linguistic knowledge. Rothi et al. (1991), suggested that access/egress word-retrieval deficits are associated with inconsistent errors, and knowledge impairments are associated with consistent errors. Hillis demonstrated how the pattern of performance in a series of word-retrieval tasks can be used to identify the loci of damaged cognitive mechanisms that underlie the deficit. Raymer (2005), Raymer and Rothi (2002), and Murray and Clark (2006) described several tasks that would be helpful in this type of assessment. For example, an evaluation might vary the stimuli according to psycholinguistic factors (e.g., age of acquisition or imageability), explore error analysis (e.g., paraphasias or neologisms), rate the informativeness of responses, or compare oral and written responses.

Three test batteries also are available that adopt a neuropsychological or neurolinguistic approach to the assessment of aphasia: the Psycholinguistic Assessments of Language Processing in Aphasia (PALPA; Kay et al., 1996), the Psycholinguistic Assessment of Aphasia (PAL; Caplan & Bub, 1990), and LeMo (DeBleser et al., 1997). LeMo is a computer-assisted, expert system for assessment of word-processing impairments; however, it is currently only available in a German version. These batteries include a variety of tasks to help the clinician identify the locus or loci of impairments in producing spoken or written language content and form at the word level. However, only the PAL includes subtests to determine language-production skills at the sentence level; none of these batteries examines language skills at the discourse level. In addition, the batteries are not standardized and do not provide comprehensive normative data.

Error Analysis in Production of Language Content

In addition to observing the accuracy and quantity of content in aphasic patients' verbal and written output, clinicians can analyze the nature and pattern of errors made (Goodglass et al., 1997; Kulke & Blanken, 2001; Schwartz & Brecher, 2000; Wilshire, 2002). In terms of types of paraphasias or naming errors, patients with aphasia frequently produce one or more of the following: (a) **phonemic** or literal paraphasia: the response contains substitution, addition, omission, and/or rearrangement of the target word's phonemes (e.g., "skoon" for the target "spoon"); (b) **semantic** paraphasia: the substituted word is semantically related to the target word (e.g., "fork" for the target "spoon"); (c) **random** paraphasia: the substituted word has no apparent semantic relation to the target word (e.g., "tractor" for the target "spoon"); (d) **circumlocution**: the response is a description or definition of the target word (e.g., "it's metallic and is used to eat soup" for the target "spoon"); (e) **neologism**: the response is a non-

sense word (e.g., "clumpter" for the target "spoon"); (f) **indefinite substitution**: the response is a nonspecific word or description (e.g., "a thing for doing stuff" for the target "spoon"); and (g) **no response**.

Several researchers have developed detailed coding systems to describe the word-finding errors of patients with aphasia (Brookshire & Nicholas, 1993; Cuetos, Aguado, & Caramazza, 2000; Kemmerer & Tranel, 2000; Mitchum et al., 1990; Zingeser & Berndt, 1988). For example, Kemmerer and Tranel coded verbs in five categories: verb errors, phrasal errors, nominal errors, adpositional errors, and other errors. Cuetos et al. (2000) coded nouns in six categories: semantic, formal, mixed, unrelated, nonword, and other. Brookshire and Nicholas (1995) described a set of categories to quantify and qualify performance deviations in language output that could not be scored as real words or correct information units (Table 4-12) (see also Nicholas & Brookshire, 1993). These authors used this system to analyze the language of their patients with aphasia and found that they produced a significantly greater proportion of inaccurate words, false starts, and part-words or unintelligible words in comparison to their non-brain-damaged peers. Error analysis may also be a prognostic factor in recovery from stroke-induced aphasia (Davis & Majesky, 2005).

Cohesion Analysis

Cohesion is defined as the relations of meaning that "tie" or "glue" linguistic items together (such as one main clause and all subordinate clausal and nonclausal elements attached or embedded in it), thereby creating meaningful interdependencies among the words in a text or within a discourse sample. Cohesion is achieved linguistically through a variety of cohesive devices that contribute to the overall coherence of the verbal or written output. Various researchers recommend exploring semantic cohesion in the spontaneous connected speech of patients with aphasia (Glosser & Deser, 1990; Glosser, Wiener, & Kaplan, 1988; Liles, 1985; Liles & Coelho, 1998; Lock & Armstrong, 1997). In contrast, Bloom et al., (1996) reported that while coherence was disrupted in their patients with left hemisphere damage, cohesion was not.

Of the numerous types of cohesive devices (Halliday & Hasan, 1976), the following types are most frequently examined in the language of patients with aphasia (Glosser & Deser, 1990; Lemme, Hedberg, & Bottenberg, 1984): (a) **reference**: terms such as personal pronouns (e.g., "he," "us") and demonstrative pronouns (e.g., "these," "here") are used to refer to a previously stated or written, unambiguous antecedent (Armstrong, 2000); (b) **lexical ties**: vocabulary is selected to exemplify previously stated or written information (e.g., repetition of nouns, provision of a synonym or superordinate); (c) **conjunction**: conjunctive devices such as "and" and "then" are included; and (d) **ellipsis**: certain items

TABLE 4-12

Categories of Performance Deviations That May Be Examined in Samples of Connected Language*

Category	Definition	Examples
<i>Nonword</i>		
Part-word or unintelligible production	Word fragments or productions that are intelligible in context	... on a <i>st . . sk</i> . . . stool ... on a <i>frampi</i>
Nonword filler	Utterances such as “uh” or “um”	... on a . . <i>um</i> . . stool . . <i>uh</i> . .
<i>Non-CIU</i>		
Inaccurate	Not accurate with regard to the stimulus, and no attempt to correct	... on a <i>chair</i> (for stool)
False start	False start or abandoned utterance	... on a <i>chair</i> . . no, a stool
Unnecessary exact	Exact repetition of words, unless used purposefully for emphasis or cohesion	... on a . . <i>on a</i> stool
Nonspecific or vague	Nonspecific or vague words lacking an unambiguous referent	... on a <i>thing</i>
Filler	Empty words that do not communicate information about the stimulus	... on a . . <i>you know</i> . . stool
And	All occurrences of the word <i>and</i>	... a boy <i>and</i> a stool
Off-task or irrelevant	Commentary on the task or the speaker's performance	<i>I've seen this one before.</i> <i>I can't say it.</i>

*In the examples, only nonwords and words printed in italics were scored as performance deviations.

(From Brookshire, R.H. & Nicholas, L.E. (1995). Performance deviations in the connected speech of adults with no brain damage and adults with aphasia. *American Journal of Speech-Language Pathology*, 4, 118–123.)

are omitted because they can be presupposed from the previous stated or written text.

During assessment, clinicians may explore the relationship between the clarity of a message and the amount of cohesion it contains (Armstrong, 1987). This is accomplished by identifying the occurrence of these cohesive devices in connected language and determining the degree and accuracy of their use, which may be either appropriate (Coelho et al., 1994), inappropriate (Glosser & Deser, 1990; Liles & Coelho, 1998), complete (the antecedent is easily identified), incomplete (the antecedent was not provided), or inaccurate (an ambiguous antecedent) (Liles, 1985).

Influential Variables

Many variables may facilitate or impede production of language content. Assessment should include analysis of these variables in order to specify the nature and extent of the word-finding impairment. Such analyses yield valuable information not only about patient functioning but also about potential treatment activities and stimuli. Three categories of influential variables are item-related, task-related, and patient-related. Examples of item-related variables that may influence content production are the target words' frequency (Deloche et al., 1996), age of acquisition (Bird, Franklin, & Howard, 2001; Deloche et al., 1997; Hirsch & Ellis, 1994), length (Nickels & Howard, 2004), concreteness (Nickels, 1995), semantic category (Goodglass et al., 1966), grammatical class (Berndt, Haendiges et al., 2002), degree of

certainty (Mills et al., 1979), and operativity (Nickels & Howard, 1995). Examples of task-related influential variables are type of sensory input (Benton, Smith, & Lang, 1972), stimulus novelty (Faber & Aten, 1979), length of trial and intertrial time (Brookshire, 1971; Fridriksson et al., 2005), type of naming task (Berndt et al., 2002), concomitant gesturing (Cunningham & Ward, 2003; Hanlon, Brown, & Gerstman, 1990; Rose & Douglas, 2001), verbal reinforcement (Stoicheff, 1960), attention condition (Murray, 1996), and word-retrieval success rate (Brookshire, 1972; Nickels & Best, 1996). It is important to note that these variables may not only influence the content produced by patients with aphasia during word-level or structured language, but also during connected language. Therefore, during assessment clinicians should introduce conversational topics that vary in terms of abstraction, intellectual complexity, length, and familiarity in order to examine which topics facilitate and which impede the amount of meaningful content, jargon, and/or word-finding errors in their patients' spoken or written language.

Evaluation also includes an analysis of patient-related variables. Examples of these are skills of the communication partner (Hickey & Rondeau, 2005; Linebaugh et al., 2006), and the ability of a patient to use clinician-produced and/or self-generated cues (Freed, Marshall, & Nippold, 1995; Marshall et al., 2002; Pease & Goodglass, 1978). Pease and Goodglass (1978) described a differential effect of cues on production of language content. They demonstrated that cues have potency as aids to word retrieval, but that the

TABLE 4-13

An Example of a Cueing Hierarchy

1. The clinician imposes a delay or the patient requests additional time to produce the word
2. The clinician provides a semantically related word or the patient generates one or more words that are semantically related to the target (e.g., “sugar” or “tea” for the target “coffee”)
3. The clinician provides a phonemic cue (e.g., “/k/ for the target “coffee”) or the patient produces one or more words that are phonetically similar to the target (e.g., “cost,” or “caddy”)
4. The clinician or the patient provides a description of the target word (e.g., “I drink this every morning.” For the target “coffee”).
5. The clinician provides a carrier phrase for the target word (e.g., “A cup of ____.”).

potency varies for individuals with aphasia. Cueing hierarchies, such as that displayed in Table 4-13, can be explored to examine word-finding stimulability and to determine what type of self-correction strategies a patient uses (Linebaugh & Lehner, 1977; Linebaugh, Shisler, & Lehner, 2005; Patterson, 2001).

Goal 7: Analysis of Ability to Produce Language Form

Linguistic form includes morphology, syntax, and phonology. Morphology refers to the set of rules that govern the structure of words and the construction of word forms from the basic elements of meaning (i.e., morphemes). Syntax refers to the rule system for ordering words into sentences. Phonology refers to the sound system as well as the rules used to combine those sounds (Nelson, 1998). Aphasia may result in difficulties producing one or more aspects of form; consequently, each should be assessed during an in-depth language evaluation.

Production of Form Words and Morphology

Morphologic and syntactic impairments in verbal production are common in patients with aphasia. Such deficits are observed in the use of relational words such as articles, prepositions, conjunctions, and personal pronouns (Goodglass, Christiansen, & Gallagher, 1993; Kohn & Melvold, 2000). In addition, morphologic inflections such as the plural /-s/, possessive /-s/, or present progressive /-ing/ are frequently omitted or inappropriately used. In aphasia, the occurrence of morphologic and phonological errors is not necessarily correlated (Miceli et al., 2004). Persons with aphasia who make morphologic errors are likely to produce

phonologic errors, but the reverse is not the case. A hierarchy of difficulty for producing these various morphemes has been found to be a function of grammatical rather than phonologic complexity (Goodglass & Berko, 1960; Haarmann & Kolk, 1992; Miceli et al., 2004). Specifically, patients with aphasia tend to display relatively greater difficulty as they shift from producing determiners to prepositions to pronouns to auxiliary verbs for form words, and as they shift from producing plural to adjective to verb inflections for grammatical morphemes.

Most traditional aphasia batteries do not assess this aspect of language. However, both the PALPA (Kay et al., 1997) and the PAL (Caplan & Bub, 1990) include subtests to assess production of morphology. For example, on the PAL, patients are given a word that they insert into a given sentence (e.g., “courage” must be affixed to fit into the sentence “If a man is brave, we say he is ____.”). Goodglass and Berko’s (1960) sentence-completion test examines a patient’s ability to affix several types of grammatical morphemes. For example, to examine the regular past tense /-ed/ morpheme, the clinician reads the stimuli aloud and the patient then supplies the final word with the target morphologic inflection: “He is using the fly swatter to swat flies. Yesterday, several flies were ____.”

The above tests elicit form words and morphology via relatively structured or constrained, highly structured tasks. In addition, a number of scoring systems described in the aphasia literature may be used to examine these syntactic features in connected-language samples (Menn, Ramsberger, & Helm-Estabrooks, 1994; Saffran et al., 1989; Thompson et al., 1995). For example, Menn and colleagues developed an Index of Grammatical Support to examine the average number of form words and grammatical morphemes that are correctly used in the spoken output of patients with aphasia.

Production of Syntactic Constructions

Persons with aphasia may experience difficulty in combining words into both simple and complex constructions in order to express relationships (Chatterjee & Maher, 2000). More specifically, patients demonstrate restricted use of syntactic forms and therefore produce incomplete syntactic structures, simple syntactic structures, or both (Bird & Franklin, 1996; Cappa et al., 2000; Edwards, 1998). They may also produce few complex syntactic structures or sentence forms and commit more errors when attempting them.

The goal of assessment of production of syntactic construction is to determine the specific syntactic structures that are available to each patient with aphasia. To examine the production of spoken and written sentences in highly structured contexts, clinicians may choose from one of the few structured tests (see Table 4-5) or subtests that are designed to elicit a variety of syntactic forms (e.g., passives,

TABLE 4-14

Examples of Syntactic Constructions

Construction	Examples
Noun phrase	cookies; the boss
Verb	stealing; hurry up
Adjective	big; warm
Prepositional phrase	in the basket
Expanded noun phrase	cookies in the jar
Expanded verb	get up in the morning
Expanded adjective	sick of the office
Expanded prepositional phrase	in bed in the morning
Subject + auxiliary	so is the woman; aren't they? (tag question)
Subject-verb	the man's running
Subject + predicate	he's the president
Verb-object	dry the dishes
Subject-object	the dog . . . chicken
Topic-comment	boy . . . off stool; burglar . . . policeman
Expanded subject-verb	the guy's running to work
Expanded subject + predicate	the woman's angry with her husband
Expanded verb-object	grab the chicken quickly/from the basket
Expanded subject-object	dog . . . chicken in basket
Expanded topic-comment	burglar policeman outside
Subject-verb-object	the dog stole the chicken
Expanded subject-verb-object	the mother's washing dishes in the kitchen
Complex	I hope he gets to work on time
Multicomplex	he picks the corn to see if it's ripe
Aborted utterance	this boy has . . .
Abandoned utterance	the sink is overflowing on to the . . .

datives, relative clauses). For example, on the PAL (Caplan & Bub, 1990), patients are asked to describe a picture with the constraint that they must begin their description with a certain word such as “bicycle” (e.g., the intent is to elicit the passive sentence, “The bicycle is being pushed by the man.”).

Another assessment option is to examine connected, spoken, or written language samples using one of the several syntactic scoring systems described in the aphasia literature (Curtiss et al., 2004; Edwards, 1995; Goodglass, Christiansen, & Gallagher, 1994; Rochon et al., 1998; Saffran et al., 1989; Thompson et al., 1995) (Table 4-14). Although some of these analysis systems were developed to characterize agrammatic language output (e.g., Saffran et al., 1989), other systems were aimed at characterizing structural aspects of fluent or paragrammatic language output (e.g., Edwards, 1995). Most of these scoring systems provide detailed procedures for collecting language samples (typically using picture-description or story retelling tasks), separating samples into utterances or T-units (i.e., an independent main clause and any dependent clauses modifying it), and identifying a variety of syntactic forms and relationships

(e.g., proportion of grammatical sentences, proportion of simple vs. complex grammatical sentences, number and type of sentential constituents). Because the procedures are so explicit, researchers report good inter-rater reliability.

Analysis of Production of Word Forms, Morphology, and Syntactic Construction

Analysis of production responses is typically completed in two broad categories: error analysis, and analysis of frequency and consistency of production. Error analysis typically takes the form of whether the morphologic or syntactic errors are a substitution or omission of target structures. Substitution errors might involve the interchangeability of constituents. For example, the patient might confuse nouns with verbs, or affix the inappropriate morphologic inflection. Substitutions may be further examined to determine whether errors are within-category (e.g., “in” for “with”) or across-category (e.g., “her” for “with”) substitutions (Haarman & Kolk, 1992). Omission errors might, for example, involve production of verbs in their infinitive form (e.g., without person or number agreement or tense endings), or the omission

of a whole group of words such as relational words or auxiliary verbs. Intelligibility analysis is a part of error analysis as it involves determining whether sentences are understandable in spite of omissions and substitutions. Interestingly, in English, word-order violations are relatively uncommon among patients with aphasia (Bates et al., 1988; Menn & Obler, 1990); therefore, identifying word-order violations is not typically a major focus of error analysis.

The frequency and consistency of production of various syntactic structures is evaluated to determine which structures are frequently, infrequently, or never used and which are consistently or inconsistently used correctly. For example, some patients with fluent types of aphasia may produce a variety of syntactic forms but produce complex syntactic forms at a reduced frequency compared with their non-brain-damaged peers (Edwards, 1995; 1998). When patients with aphasia inconsistently use form words, morphologic inflections, or syntactic forms, the clinician tries to identify whether or not there are any influential linguistic or task variables. For example, for some patients with aphasia, a relationship exists between the degree of structure or task constraint (e.g., sentence-completion vs. conversational activities) and the number and type of grammatical errors produced (Hofstede & Kolk, 1994).

Production of Phonology

Phonology refers to the set of sounds in a language as well as the rules used to distribute and sequence those sounds into words (Owens, 2004). Speech and language pathologists typically assess two components of phonology: a segmental component that consists of phonemes and syllables, and a suprasegmental component that includes intonation, stress, and pauses.

Segmental Phonology

Aphasia is frequently accompanied by a segmental phonologic disorder or an impairment in the ability to produce the distinctive sound elements of a word or syllable in the standard manner. In fact, Blumstein (1998) concluded that “nearly all aphasic patients produce phonological errors in their speech output” (p. 162). Often, segmental phonologic disorders are associated with dysarthria or apraxia of speech (Dogil & Mayer, 1998) and consequently with breakdown in terms of phonetic implementation (Aichert & Ziegler, 2004). Both of these disorders are frequent accompaniments of aphasia and have been described above under Goal 2. When either or both of them are present, phonology should be assessed in detail. The data collected should include (a) phonemic errors produced during unstructured spontaneous language and the phonologic context of those errors, (b) errors produced on a standard articulation test, (c) results of stimulability testing or the patient’s ability to modify his or her production of error phonemes following auditory and

visual stimulation, (d) a phonetic inventory, and (e) results of an evaluation of the patient’s peripheral speech mechanism.

Suprasegmental Phonology

The production of suprasegmental components of phonology may also be problematic for some patients with aphasia (den Ouden & Bastiaanse, 2003; Seddoh, 2000). There are many suprasegmental components, but two that are commonly affected in aphasia are intonation and stress

Intonation refers to modulations of the pitch or musical flow of an utterance and is primarily dependent upon laryngeal control (Blumstein, 1998). Ability to produce typical melodic intonation or prosodic quality is assessed to determine whether the patient has problems using pitch variations to indicate grammatical segmentation or complexity (Goodglass, 1968), such as at the end of a phrase or sentence. Difficulties in the production of intonation have been reported, particularly in patients with Broca’s aphasia or anterior left hemisphere lesions (Seddoh, 2004) and may contribute to difficulty in word comprehension.

Stress refers to the force or accentuation of a particular sound or syllable (Blumstein, 1998). In evaluating a patient’s ability to produce appropriate stress patterns a clinician determines whether the patient with aphasia uses stress patterns that are typical of his or her linguistic peer group and predictable within linguistic context, or if he or she manifests incorrect stress placement that results in subsequent reduction or omission of vowels or morphemes that would normally have been stressed. Stress is assessed at both the phrase and sentence level (Goodglass, 1968).

A goal of assessment is to determine the specific suprasegmental phonologic variables that the patient with aphasia can produce, or that he or she can be stimulated to produce. This can be accomplished during moderately structured observations or by administering aphasia batteries (e.g., WAB, BDAE) that contain tasks in which suprasegmental features of spoken output are examined, such as tasks that require the clinician to rate the fluency of connected speech. Additionally, those suprasegmental features that can be used to improve the intelligibility of spontaneous speech or the communication of meaning should be identified and incorporated into therapeutic goals.

Goal 8: Analysis of the Ability to Comprehend and Produce Pragmatic Aspects of Communication Interaction

Communication is the reciprocal act of sending and receiving information, and is profoundly influenced by the context in which it is used and the partners who are involved. That is, both the communication environment and the partners are dynamic components of the communication itself. Therefore, language (including content and form) varies

with each context and partner (Joanette, Ansaldo, & Stemmer, 1999). Indeed, the language produced or comprehended by an individual at any point in time will be an interactive product of contextual variables and the individual's structural linguistic knowledge (Gallagher, 1983). Communicative competence is the successful interaction of comprehension of language content, language form, and pragmatics (Lahey, 1988).

Pragmatics refers to the system of rules that regulate the use of language in context (Bates, 1976). It involves the interactional aspects of communication and the use of language for communication (Prutting & Kirchner, 1983). The emphasis is not on sentence structure but rather on how meaning is communicated—how units of language function in discourse and as authentic communication within social contexts (Holland & Hinckley, 2002). Pragmatics is a knowledge of who can say what to whom, in what way, where, when, why, and by what means (Prutting, 1979). It is the knowledge of how to converse with different partners and in different contexts, as well as the knowledge of the rights, obligations, and expectations underlying the initiation, maintenance, and termination of discourse.

Pragmatic abilities include a communicator's proficiency in constantly adjusting the content, form, and acceptability of his or her message, in switching or shifting sets of reference as in topic changes, and in being sensitive to the influence of the communication partner's social status and communicative abilities and to the physical context in which communication occurs (Penn, 1999). It also refers to the ability to use language for a variety of functions or intents such as requesting, greeting, warning, and protesting (Lucas, 1980). Penn (1999) identified three knowledge areas that comprise pragmatic competence: (1) knowledge—of language and its structure, of the world and its contents, and social knowledge; (2) adaptation—the speed and ease with which reaction to environment occurs; and (3) processing variables—the “real-time” behaviors required to engage in successful interaction, such as attention and memory.

Pragmatic aspects of language often remain an area of relative strength for many patients with aphasia (Wulfeck et al., 1989). Indeed, most patients with aphasia can communicate better than they can speak. However, “pragmatic skills certainly can be affected by focal brain damage” (Holland, 1996). Consequently, clinicians assess pragmatic skills to determine whether these abilities are an area of strength that may be capitalized upon during treatment, or whether they are problematic and need to be remediated during treatment. Specifically, it is important to examine the comprehension and production of several sources of knowledge about pragmatics and patterns of use, such as speech acts and intents, and discourse rules that govern conversational skills such as turn-taking and topic selection, maintenance, and code switching. It is also important to determine how these factors are influenced by various contexts and partners (Murray & Chapey 2001).

The WHO ICF (ICF, 2001) provides a useful framework for assessing pragmatic comprehension and production. In particular, the activity and participation levels of the ICF guide clinicians to look beyond a patient's abilities and deficits in language content and form, and assess the patient's ability to convey meaning and to communicate in a manner that is functional for that individual (Elman & Bernstein-Ellis, 1999; Holland & Thompson, 1998). “Functional” has a different meaning for each individual with aphasia, and can best be assessed using multiple measures such as direct observation, conversational analysis, and discourse analysis, as well as published tools (Holland & Hinckley, 2002).

Communication Environment

Various communication settings and activities may affect the length, morphosyntactic complexity (e.g., anaphoric pronouns), redundancy, fluency, responsiveness (e.g., elaborations of comments), semantic relatedness, and lexical selections (e.g., technical jargon) of the language that is produced or that is understood (Labov, 1970; Lyon, 1992). For example, clinicians frequently observe variations in production and comprehension of spoken and written language when comparing communicative performance in the therapy room to that observed in more natural environments (Egolf & Chester, 1977). Also, Glosser et al. (1988) found that verbal complexity and language errors vary significantly with different contents and contexts of communication. For example, in conditions that restrict visual contact between the speaker and listener (e.g., communicating over the telephone or through an opaque barrier), patients with aphasia, like non-brain-damaged adults, produce fewer communicative gestures and more complex verbalizations. Hofstede and Kolk (1994) also observed changes in the morphosyntactic output of patients with aphasia across different speaking conditions (e.g., conversation, formal interview, picture description). Further, “aphasic patients show appropriate and predictable linguistic changes in response to nonlinguistic social contextual variables” (Glosser et al., 1988, p. 115). Therefore, assessment involves an analysis of whether or not the patient's linguistic behavior changes with various contexts, and if so, how specific contexts facilitate or hinder the number and variety of his or her communicative behaviors.

Communication Partners

Specific communication partners may also affect the form, content, and intent of language that is produced (Gallagher, 1983). Partner characteristics such as age, sex, familiarity, and authoritative status, as well as internal variables such as world knowledge, values, previous experiences, and emotional status, affect communication (Davis, 2000). Frequently the burden of communication between a person with aphasia and his or her communication partners will

shift following aphasia (Linebaugh et al., 2006). Clinicians must analyze such partner variability and note patterns of performance.

Part of successful communication involves having the opportunity to communicate highly personal thoughts and emotions to those who are judged to be important partners, as well as feeling the fulfillment associated with sending and receiving messages (Armstrong, 2005; Denman, 1998; Lubinski, 1995). That is, successful communication gives the individual the feeling of social connectedness to others, the ability to influence other's thoughts and actions, and a means of establishing shared reference (Hengst, 2003). Unfortunately, some patients with aphasia may have few opportunities for successful, meaningful communication due to a lack of sensitivity to the value of interpersonal communication, few reasons to talk, lack of privacy, excessive background noise, no viable communication partner, negative perceptions of their communicative competence, and/or lack of stimulation in general (Kagan, 1995; Lubinski, 1995; McCooey, Toffolo, & Code, 2000; Parr & Byng, 2000; Parr, Byng, & Gilpin, 1997). Therefore, the aphasia assessment should include an evaluation of the communication opportunities afforded the patient and the barriers to such communication using tools such as the Profile of the Communication Environment of the Adult Aphasic (Lubinski, 2001), or Pragmatic Protocol (Prutting & Kirchner, 1987). Part of the assessment is the determination of whether a patient has anyone with whom to talk, the names and relationship to the patient of the frequent and infrequent communicative partners, and how their presence and communication style affect the patient's communicative behavior and the communicative interaction.

Other nonstandardized tools such as the Family Interaction Analysis (Florance, 1981) (Table 4-15) or observational measures of a conversational partner's support and level of participants (Kagan et al., 2004) may also help the clinician identify the psychosocial factors that promote successful communication interaction and those that contribute to a communication-impaired environment. The information gained from these types of analyses may help provide information about the caregivers' and significant others' sensitivity to the patient's communication difficulties, as well as about their successful and unsuccessful strategies for communicating with the patient (Simmons-Mackie & Kagan, 1999). Subsequently, the clinician can help the patient, and significant communication partners, create a positive and rewarding communication environment that contains stimulating activities and a variety of interesting communication partners (Elman, 2005).

Speech Acts and Communicative Intent

Pragmatics is the rule-governed, social use of language and represents the speaker's method of conveying intended

meaning. Speech acts are the instantiations of pragmatics. Austin (1962) and Searle (1969) described speech acts as theoretic units of communication between a speaker and listener that are performed in the course of verbal and written interaction, and carry with them an intention on the part of the speaker. According to Searle (1969), the speech act includes what the message-sender means, what the message means, what the message-sender intends, what the message-receiver intends, what the message-receiver understands, and what the rules are governing the linguistic utterance. In Searle's theory, the proposition is the words or sentences produced, and the illocutionary force of this proposition is the message-sender's intent in producing the utterance.

A number of taxonomies have been developed to describe the variety of intentions that can be used in communicating (Austin, 1962; Dore, 1974; Searle, 1969). Frequently identified intents include (a) **response**: the intention to attend to and respond to another's utterance or question; (b) **request**: the intention to address another for help, whether it be to solicit information, action, or perhaps acknowledgment; (c) **greeting**: the intention to convey a conventional greeting; (d) **protesting**: the intention to object to another person's behavior, or to reject or resist the action, statement, or command of another; (e) **description/comment**: the intention to give a mental image of something seen or heard; (f) **assertion**: the intention to point out to another that some statement or proposition is true; this intent includes a subset called affirmation, which includes instances in which the speaker is agreeing with or confirming a proposition; and (g) **informing**: the intention to report on present and past experiences.

Many of these intents are used in one or more of the following four communication categories proposed by Lomas et al. (1989) (see Table 4-2): (a) basic need: communication skills that are needed to accomplish basic needs such as eating and daily hygiene; (b) health threat: communication skills that are needed to maintain physical well-being or health (e.g., calling for assistance after falling, telephoning 911 for emergency help); (c) life skill: communication skills that support the ability to provide or understand information needed to complete daily activities such as shopping, home maintenance, and driving; and (d) social need: communication skills that are needed to participate in social activities such as playing cards, going to church, or writing a letter to a friend.

Intents may be communicated and comprehended through semantic-syntactic utterances and/or by previous or subsequent utterances. In addition, they may be expressed (and comprehended) through facial expression or accompanying actions, gestures, or tone of voice. What is not said may also communicate intent. Further, one can say one thing and mean another. That is, individuals frequently use their knowledge of the communication environment and their partners to help them decipher between what is said and what is meant.

(From Florance, C. (1981). Methods of communication analysis used in family interaction therapy. *Clinical Aphasiology*, 11, 204-211.)

Patients with aphasia often have a relatively preserved ability to interpret a variety of speech acts and intents, including the ability to respond correctly to indirect requests (Foldi, 1987; Wilcox, Davis, & Leonard, 1978). In terms of production, some patients maintain the ability to produce a variety of speech acts or intents, including requests for clarification, responses to requests for clarification, and greetings (Newhoff et al., 1985; Prinz, 1980; Ulatowska et al., 1992). Despite these preserved pragmatic abilities, however, impairments in other aspects of pragmat-

ics are reported. First, patients with aphasia use a restricted range of speech acts and intents (Armstrong, 2001; Prutting, 1979; Wilcox et al., 1978). For example, Doyle and colleagues (1994) found that patients with aphasia primarily produced responses to direct requests. In contrast, assertions predominated the verbal output of non-brain-damaged adults. Second, different pragmatic impairments are observed among patients with different types of aphasia and different sites of brain damage (Murray & Holland, 1995; Prutting & Kirchner, 1987). Because of these possible

pragmatic limitations, examining patients' abilities to communicate and comprehend various speech acts or intents is an important part of a comprehensive aphasia assessment.

Discourse Skills

The pragmatic nature of communicative interaction appears in discourse in the form of verbal and nonverbal speech acts that initiate or maintain a topic, shift topic, repair or revise a previous speech act, or terminate a topic. These speech acts are intended to establish cooperative discourse participation to achieve a mutual communication goal. Grice (1975) proposed that successful discourse is achieved when (a) the message-sender provides a sufficient amount of information (i.e., not too much and not too little); (b) the messages being shared are truthful; (c) the vocabulary used is relevant to the topic and is cohesively related; and (d) the manner in which messages are shared is concise and avoids ambivalence and obscurity.

Initiation of the speech act (as the message-sender) includes topic selection, introduction, and/or change of topic. This communicative act should contain new, relevant, and what is judged to be sincerely wanted information. The message-sender therefore needs to determine what, if any, information is shared by the various message-receivers. Thus, topical or referential identification involves searching one's long-term memory for information that is judged to be relevant, interesting, and wanted or already known by the partner. For some patients with aphasia, inappropriate initiation has been observed (Avent, Wertz, & Auther, 1998; Patterson & Fahey, 1994). Despite this, persons with aphasia have been reported to be relatively good at being sensitive to their partners' interests and previous knowledge (Penn, 1988).

Maintenance of communication involves turn-taking or the variation of roles as message-sender and message-receiver in order to serve the pragmatic function of sustaining the communicative exchange. The role of the message-receiver is to comprehend the message that is communicated. Comprehension can be indicated by one or a combination of the following: nonverbal responses (e.g., nodding the head, leaning forward), a short and usually affirmative verbal response such as "yes," and visual orientation rather than gaze avoidance (Davis, 1981). To assist the message-sender, the message-receiver must also monitor and evaluate the message and provide feedback concerning the effectiveness and acceptability of the communication exchange.

The message-sender may use gaze and hand posture to signal control of the interaction. To retain his or her role, the message-sender may use gaze-avoidance and a hand gesture that is not maintained or not returned to a resting state through a phonetic clause juncture (Rosenfeld, 1978). When a message-sender wants a reaction or response, he or she signals "with a pause between clauses" or "with a rising or

falling pitch at the end of a phonemic clause" (Davis, 1981, p. 171). The message-receiver also uses gaze to signal control in an interaction. The message-receiver maintains his or her role by visually orienting toward the message-sender.

Nonverbal cues are usually used by partners to signal a wish to maintain or change roles (Rosenfeld, 1978). Because role-switching typically occurs as a result of the message-sender's desire to relinquish the role, the message-receiver needs to formulate a judgment concerning the message-sender's willingness to switch roles. When role-switching occurs in the absence of the speaker's readiness to switch, it may be accompanied by overloudness and a shift of the head away from the speaker.

Successful maintenance of turn and turn-taking behavior results in a mutually satisfying interaction. When one of the communication partners has aphasia the nature of the turn may change, with the partner who does not have aphasia assuming more of the conversational burden than the partner with aphasia. Maintenance and turn-taking must be appropriate for the communication partners and not attempt to adhere to standards appropriate for conversations when neither partner has aphasia.

As the person with aphasia takes turns in a conversation, the turn may be successful; however, the overall communicative event may be altered. For example, although the pause time in turn-taking may be lengthened for a person with aphasia participating in conversation (Lesser & Milroy, 1993; Prutting & Kirchner, 1987), most patients with aphasia continue to display appropriate turn-taking skills, often relying primarily upon the use of nonverbal behaviors such as nodding or eye gaze (Penn, 1988; Schienberg & Holland, 1980).

Repair and revision are an integral part of discourse maintenance and regulation, and reflect a message-sender's sensitivity to a message-receiver's state of comprehension. Moves by both communication partners identify communication sequences that were unsuccessful and apply repair strategies to assure comprehension of the communicative message. Discourse regulatory devices such as requests for clarification are essential to the maintenance of communication (Fey & Leonard, 1983; Schegloff, Jefferson, & Sacks, 1977). The most common form of repair in normal interactions is the self-initiated self-repair, and it typically occurs within the turn in which the communication breakdown has transpired.

Because of the well-documented difficulties persons with aphasia have in conveying accurate and nonambiguous information (a product of their language-content and form deficits), repair and revision strategies are important and frequently used when communicating with patients with aphasia (Ferguson, 1994; Milroy & Perkins, 1992). Furthermore, the linguistic impairments of patients with aphasia may limit their ability to identify communication breakdowns, to repair them, or both. Although some patients with aphasia

retain the ability to initiate and make repairs (Klippi, 1996) this process typically takes longer to resolve than during interactions among non-brain-damaged individuals, and may be accomplished collaboratively rather than solely by one partner (Laasko, 2003). The type of repair used varies in interactions between the person with aphasia and his or her family, and between the person with aphasia and the clinician (Lindsay & Wilkinson, 1999), and among types of discourse activity (Heeschen & Schegloff, 1999). However, some types of repair can be detrimental to communication interactions. For example, the partner may, in a good faith attempt to help the patient with aphasia, use repairs excessively to correct conversational errors, even if these errors have not obscured the meaning of the patient's message (Booth & Perkins, 1999; Murray, 1998). This strategy can foster the perception that the patient with aphasia is not a competent partner as well as change the interactional roles from that of partners to that of a student-teacher or patient-clinician.

Maintenance of communication interaction may also involve a response that sustains a topic. For example, a contingent utterance shares the same topic as the preceding utterance and adds information to the prior communication act. Thus, sequential organization of topics is also a component of communication maintenance (Beeke, Wilkinson, & Maxim, 2001). For example, in procedural and narrative discourse, a sufficient number of steps and episodes, respectively, must be elaborated on or communicated in a logical order (Ulatowska, Doyel et al., 1983) in order to ensure satisfactory exchange of information.

Individuals with aphasia have been shown to demonstrate a variety of difficulties in maintaining communication interactions. Although patients with mild aphasia frequently demonstrate appropriate discourse maintenance skills, patients with more severe language impairments use fewer contingent utterances than do non-brain-damaged adults (Ulatowska et al., 1992). They have also been found to produce somewhat lengthy and digressive or tangential responses (Penn, 1988). In terms of sequential organization, fewer complete episodes and more missing episodes are observed in story retellings by patients with aphasia compared to responses of non-brain-damaged adults (Uryase, Duffy, & Liles, 1991). Although Ulatowska et al. (1983a, 1983b) found that patients with aphasia omitted story episodes and procedural steps, and included some inaccurate information, they also noted that those episodes and steps that were conveyed were those considered essential to the story or procedure. Furthermore, most of these episodes and events were presented in the correct sequence.

In summary, although patients with aphasia show many pragmatic strengths in terms of their ability to communicate successfully in discourse activities, they may also display a variety of impairments that may negatively affect the efficiency and success of their discourse interactions.

Consequently, assessment in adult aphasia involves an analysis of the patient's ability to initiate and maintain discourse in various contexts and with various partners. This is particularly important given the highly individualized role of context in many communicative exchanges.

Assessing Pragmatic Skills and Functional Communication

Although assessing pragmatic abilities and assessing functional communication skills are often viewed as one and the same, there are some notable distinctions between the two assessment approaches (Elman & Bernstein-Ellis, 1999; Lyon, 2000; Manochiopini, Sheard, & Reed, 1992; Worral, 1995). Pragmatic skills encompass the use of the rules that govern social interaction in a language and culture, while functional communication refers to the ability to operate and interact in real-life situations in response to specific communicative demands. Both reflect the summation of an individual's linguistic, pragmatic, and cognitive skills. Table 4-16 lists a variety of tests and observational profiles that can be used to examine pragmatic abilities, functional communication skills, or both.

Pragmatics

Pragmatic abilities are primarily assessed using observational profiles or checklists in which the clinician identifies the presence and appropriateness of various pragmatic behaviors. Typically these observations are based upon discourse samples, since this level of communication interaction illuminates "the complex associations across linguistic, pragmatic, and cognitive processes as well as the potential dissociations (of) either across or within clinical populations" (Chapman, Highley, & Thompson, 1998, p. 56). Although some clinicians and payors view such analysis as time-consuming, Boles and Bombard (1998) found that such behaviors could be reliably analyzed with 5- to 10-minute discourse samples of patients when these behaviors occurred at a rate of approximately three times per minute. Tools for pragmatic analysis, such as direct observation, discourse analysis, and conversational analysis, offer important information in the assessment process and should be included (Armstrong, 2000; Boles & Bombard, 1998; Holland & Hinckley, 2002).

Tools such as the Pragmatic Protocol (Prutting & Kirchner, 1987), the Communication Profile (Gurland & Gerber, 1982), the Revised Edinburgh Functional Communication Profile (Wirz et al., 1990), and the Profile of Communicative Appropriateness (Penn, 1988) can be used to rate a patient's use of specific pragmatic skills. For example, the clinician can use approximately 15 minutes of conversation between the patient with aphasia and a familiar partner to complete the Pragmatic Protocol and to rate the appropriateness of 30 pragmatic parameters covering a

range of speech acts (e.g., requests, comments) and discourse abilities (e.g., topic maintenance, repair/revision skills) across verbal, nonverbal, and paralinguistic domains. When the clinician summarizes Pragmatic Protocol results, he or she compares the overall number of appropriate and inappropriate pragmatic behaviors (i.e., calculates a percentage of appropriate behaviors). These results are interpreted with respect to the number of pragmatic behaviors for which there was no opportunity to observe in the language sample. Such assessment tools clearly provide information that is not obtained from more traditional standardized tests. However, some of the pragmatic tools may have specific psychometric limitations and should be used with caution (Armstrong, 2000; Ball et al., 1991; Hux et al., 1997; Manochiopinig et al., 1992; Penn, 1999; Perkins, Crisp, & Walshaw, 1999).

Functional Communication

Generally two methodologic approaches are used to examine functional communication skills: structured tests, in which performance of test items is evaluated, and observational profiles, based on unstructured or moderately structured communication interactions. Of the structured tests available (see Table 4-16), the Communication Activities of Daily Living-2 (CADL-2; Holland et al., 1999) is probably the best known. The CADL-2 examines a patient's ability to recognize and produce a variety of speech acts and interactions across both spoken and written language modalities. Evaluation of communicative success is based on both verbal and nonverbal responses. The CADL-2 differs from the earlier version of the CADL in that it is slightly shorter (i.e., 50

items that take about 25 minutes to complete versus 68 items that take about 35 minutes to complete), and does not include role-playing items.

Strengths of standardized tests of functional communication include their documented reliability and their use in noting change over time. However, this approach and these tests have been criticized because of the restricted view of the manner in which patients with aphasia spontaneously interact in real-life functional communication situations (Lomas et al., 1989; Manochiopinig et al., 1992) and because administering one of these tests is more time-consuming than completing a rating protocol (Crockford & Lesser, 1994).

A number of observational profiles and rating protocols are available to examine the functional communication abilities of patients with aphasia (see Table 4–16). This group of measures includes the Functional Communication Profile (Sarno, 1969), Communicative Effectiveness Index (Lomas et al., 1989), ASHA Functional Assessment of Communication Skills for Adults (ASHA FACS; Frattali et al., 1995), the Communication Profile: A Functional Skills Survey (Payne, 1994), and the Inpatient Functional Communication Interview (O'Halloran et al., 2004). The ASHA FACS has both qualitative and quantitative scales for scoring a patient's ability to complete a variety of everyday communication activities across four domains: social communication (e.g., “exchanges information on the telephone”), communication of basic needs (e.g., “responds in an emergency”), reading, writing, and number concepts (e.g., “understands simple signs”), and daily planning (e.g., “follows a map”). Unlike several of the other observational profiles, this test has undergone extensive standardization and has good reliability and validity.

Another notable rating scale is Payne's (1994) Communication Profile: A Functional Skills Survey. This protocol uses an interview approach in which the patient rates the relative importance of 26 communication behaviors in his or her daily life related to his or her basic, present health-care and social needs. The normative sample for this instrument includes patients of varying ethnicity, living accommodations, employment history, and income levels, and is therefore culturally sensitive. Several other ratings scales have been created, some of which are widely available and frequently used and others that are available only in research papers. Also, many methods of conversational analysis have been published (Armstrong, 2000; Penn, 1999). Some follow previously published methods of analysis (e.g., Nicholas & Brookshire, 1995a) and others were created anew with respect to a theoretic model (O'Halloran et al., 2004).

Several researchers propose that clinicians should not rely on the results of a single test or observational profile for the assessment of functional communication abilities (Worrall et al., 2002). Within the context of the WHO ICF (ICF, 2001), Worrall et al. (2002) reviewed several measures of functional communication and observed patients with

aphasia in functional communication situations. They suggested that the ICF is a valuable model to guide assessment but may oversimplify the real-life communication needs of individuals with aphasia. They proposed that three types of functional communication should be considered in assessment of persons with aphasia: (a) generic (e.g., speech acts for social greeting), (b) population-specific (e.g., for individuals with a specific impairment or communicating within a specific setting), and (c) individualized (particular needs of an individual). Worrall (1995, p. 53) suggested that “the concept of functional communication is too complex for a single test administration” and developed the Everyday Communicative Needs Assessment (Worrall, 1992). This contains a series of tasks, including an interview, to evaluate a patient's communicative needs (Table 4–17); a questionnaire to assess the individual's social-support system; and observations and ratings of the patient's interactions in his or her natural environment and with his or her daily communicative partners. The Communicative Profiling System, developed by Simmons-Mackie and Damico (1996), is similar and also represents a multi-method approach to examining the conversational abilities of patients with aphasia, and the way these skills are influenced by daily communication partners and environments. Social Network Theory (Blackstone & Berg, 2003) examines functional communication within the structure of an individual's communication needs and abilities, and within an expanding circle of family, acquaintances, and unfamiliar partners; it is built upon the model of communication as joint interaction.

Irwin, Wertz, and Avent (2002) compared results of measures of language impairment (PICA; Porch, 1981), functional communication (Rating of Functional Performance; Wertz et al., 1981), and a measure of pragmatic abilities (Pragmatic Protocol; Prutting & Kirchner, 1987) over the course of a year. They reported that severity of language impairment was related to severity of functional communication and pragmatic performance, but the latter two measures were only related in patients in the acute stage of aphasia, not the chronic stage. This work highlights the utility of using multiple tools on multiple assessment dates to assess different aspects of aphasia to obtain a well-rounded assessment.

It is likely that the number of tools for assessing functional communication will increase and become ever more sophisticated (Hartley, 1995). It is unlikely, however, that any one tool will adequately measure the functional communication skills for all patients with aphasia and other neurogenic communication disorders. For many of the tools developed recently, and those that will be created in the future, research is needed to determine whether they possess the following attributes: “sensitivity to change over time; reliability within and across raters, and over time; sufficient range of performance measured to prevent threshold effects; usefulness across different methods of administration;

TABLE 4-17

Example of an Interview Guide, One Aspect of Worrall's (1992) Everyday Communicative Needs Assessment

1. Finances

- checking and paying bills
- writing checks
- reading bank statements
- balancing accounts/budgeting
- organizing payment of rent/mortgage
- reading literature (e.g., Social Security/Veterans Affairs)
- filling in forms (e.g., Social Security, Veterans Affairs, Medicare)
- using an automatic teller machine

2. Using the Phone

- looking up numbers in phone book
- using Yellow Pages
- dialing emergency numbers
- writing down phone messages
- making appointments/business calls
- making social calls

3. Preparing Food

- reading labels on food packets
- measuring ingredients
- reading sell by/use by dates and calculating food freshness
- following recipes
- making choices at mealtimes
- using the microwave and oven

4. General Household Activities

- following washing and ironing instructions on clothes
- following instruction leaflets for household appliances
- setting washing machine
- directing workmen (e.g., plumber)
- dealing with people who come to door (e.g., meter-reader)
- following written instruction re DIY jobs (e.g., shelves)
- writing note for milkman, home help, etc.
- caring for pets
- following instructions for use of gardening products
- gardening

Coding for reasons:

1. immobility
2. aphasia
3. other stroke-related problems
4. other

(From Worrall, L. (1995). The functional communication perspective. In C. Code & D. J. Muller (Eds.), *The treatment of aphasia: From theory to practice* (pp. 47–69). San Diego, CA: Singular Publishing. Reprinted with permission.)

usefulness during different phases of rehabilitation and relevance to function outside the clinical setting” (Frattali, 1992). Considering the trend for health care to focus on functional outcomes and measures, this task should be one of our highest priorities.

Goal 9: Analysis of Quality of Life in Persons with Aphasia

Quality of life, (QOL) is related to an individual's activity and participation in society, and his or her satisfaction with their physical, emotional and social environment. QOL is defined as “an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns. It is a broad ranging concept affected in a complex way by the person's physical health, psychological state, personal beliefs, social relationships and their relationship to salient features of their environment.” (WHOQOL: Measuring Quality of Life, 1997.) QOL has several dimensions, including physical problems, body image, communication, and interpersonal issues (Code, 2003; LaPointe, 1996; Madden, Oelshlaeger, & Damico, 2002; Rolnick & Hoops, 1969) and is typically measured with a self-report.

Threats (2005) described the complex interrelationship between QOL and ICF. Both instruments were developed by the World Health Organization and show overlap in their perspectives yet serve different purposes. The ICF is intended to be used to report observations of an individual's behavior, including the perspective of the person being evaluated. ICF measures list behaviors in categories, and as the assessment progresses the behaviors should be prioritized as to importance in an individual's life. QOL is a perceptual rating that presents an individual's subjective opinions about his or her status or position in life. Several researchers and clinicians support the use of the WHO ICF in assessment of QOL (e.g., Ross & Wertz, 2005), yet there are points of disagreement (Worrall & Cruice, 2005).

Cruice and colleagues (2003), using the ICF as a framework, sought to determine which aspects of communication predicted participants' QOL. They reported that in addition to emotional and psychosocial well-being, functional communication was a contributor to positive QOL. They proposed the communication-related QOL (CRQOL) model as an enhanced version of QOL that incorporated functional communication. The CRQOL (Cruice et al., 2003) describes the language and communication behaviors that may be associated with the ICF levels as well as personal and environmental factors that may influence communication, and can be used as a guide when assessing QOL in persons with aphasia.

Another QOL assessment measure designed for use with persons with aphasia is the Stroke and Aphasia Quality of Life Scale (SAQOL and SAQOL-39) (Hilari & Byng, 2001; Hilari et al., 2003). The authors adapted this scale from the Stroke-Specific Quality of Life Scale (SS-QOL) (Williams et al., 1999) in part because they believed the SS-QOL and other QOL scales were difficult for some persons with aphasia to use given the linguistic requirements of the scales. The SAQOL measures QOL in four subdomains: physical,

psychosocial, communication, and energy. It was reported to be reliable and valid, but requires additional investigation for successful use in assessment. Finally, the Communication Quality of Life Scale (ASHA CQL) (Paul et al., 1997) provides information about the psychosocial, vocational, and educational effects of a having a communication impairment.

Ross & Wertz (2003) compared responses on three QOL measures: WHOQOL Instrument (WHOQOL, 1997), WHOQOL-BREF (World Health Organization Quality of Life – BREF, 2004), and the Psychosocial Well-Being Index (Lyon et al., 1997). These measures were selected to be consistent with the WHO recommendation of assessing QOL with both general and disease-specific instruments. Ross and Wertz found that three domains—level of independence, social relationships, and environment—were best at distinguishing QOL in persons with and without aphasia. They emphasized two considerations that should guide measurement of QOL in persons with aphasia in the future. First, there is no current single measure that will best capture QOL for all patients with aphasia, and, given the individual variation in patients, finding one best instrument for all patients may be an unrealistic goal. Second, the importance of measuring QOL does not diminish the importance of assessing impairment-based functions, such as comprehension and production of language form and content.

One difficulty associated with QOL measures is that they frequently have heavy reliance on linguistic skills in order for an individual to complete the measure (Cruice et al., 2003). Cruice et al. devised an iconic tool to assess QOL in individuals with aphasia to avoid this problem.

QOL can also be examined in terms of burden on a patient and his or her family. Doyle and colleagues (Doyle et al., 2003; Doyle et al., 2004) developed the Burden of Stroke Scale to quantify physical, cognitive, and psychological aspects of the burden of stroke, as reported by the patient. Responses to a series of questions in several domains provide a clinician with an expansive picture of the effect of stroke on a patient, with or without a communication disorder. Linebaugh et al. (2006) examined burden from the point of view of communication between a person with aphasia and his or her communication partner. They reported that communication burden was indeed reapportioned between a person with aphasia and his or her communication partner, and that factors such as amount of functional communication evinced by the patient influenced the degree of shift.

QOL Reported by Family Members

Cruice and colleagues (2005) examined the relationship between responses about patients' QOL from the patients themselves and proxy respondents. They discovered biases in responding across aspects of the survey tools they used, and called for the development of measures that are accessible to all patients with aphasia. Another example of a QOL

measure developed for completion by a family member as well as the person with a communication disorder is the LaTrobe Communication Questionnaire (Douglas, O'Flaherty, & Snow, 2000). This tool examines communicative behaviors in several conversational domains from the perspectives of the patient and his or her family members. Similar to Cruice et al. (2003), Douglas et al. (2000) found disagreement between rating of patients and of family members. Glueckauf et al. (2003) developed a questionnaire designed to assess functional outcome of treatment in persons with aphasia, as reported by caregivers. Of note with this instrument is that it does not appear to be heavily biased by caregiver strain, which is caused by the daily responsibilities of caring for a person with aphasia and by the compromise to communicative interactions.

Engell and colleagues (2003) examined responses from persons with aphasia and their family members using a pictorial and a written version of the Aachen Life Quality Inventory. The tool examined responses in the physical and psychosocial domains, and the pictorial version used icons (e.g., person on a bench to indicate loneliness, and thumb up or down to indicate opinion) for both the stimulus items and responses. Engell et al. (2003) reported success with this instrument in measuring QOL. Similar to other studies, they found differences between the ratings of patients and family members for many of the items. These results highlight the importance of creatively measuring QOL in individuals with aphasia, particularly those with severe aphasia who likely may be unable to comprehend complex written material or verbally respond in connected speech. In addition, it supports the need to examine psychosocial factors as well as physical factors that influence QOL.

The literature is inconsistent in reporting the reliability and accuracy of informants' rating of communication abilities of their significant other with aphasia. This inconsistency is related both to conditions surrounding the assessment process (e.g., length of questionnaire or method of analysis in the study) as well as observer characteristics (e.g., emotional influence or clarity of observation). The effort to refine instruments and procedures for assessment of QOL by proxy report continues to be of importance, although a single instrument is unlikely to be effective for all patients with aphasia and their families.

Relationship among QOL and ICF Impairment and Activity-Based Measures

A question of interest to clinicians is the degree of relationship of communication disorder among measures of language impairment (such as word-retrieval assessments), measure of activity (such as the CADL-2; Holland et al., 1999), and measures of QOL (such as the CRQOL; Cruice et al., 2003). Ross and Wertz (2002) administered six assessment tools to individuals with chronic aphasia. Two were

measures of impairment (WAB; Kertesz, 1982, and PICA; Porch, 1967), two were measures of communication-activity limitation (CADL-2; Holland et al., 1999, and ASHA FACS; Ferketic et al., 1995), and two were measures of QOL (WHOQOL-BREF, 2004, and Personal Wellness Inventory; Lyon et al., 1997). In contrast to the notion that individuals with aphasia might show different results on the three types of measures, Ross and Wertz found no systematic significant relationships. One interpretation of these results is at face value, and suggests no relationship; however, Ross and Wertz chose to look more closely at several factors that might have influenced results, such as experimental method (e.g., sample size) and nature of the instruments (e.g., range of test items). They concluded that at best, the relationship among these levels of measurement is unclear but the importance of QOL and the contribution of communication skills to QOL deserves continued study.

Sarno (1997) examined the performance changes on three measures in two groups of persons with aphasia. The measures were a language-based tool, Neurosensory Center Comprehensive Examination for Aphasia (Spreen & Benton, 1977; Spreen & Strauss, 1998); an activity-based tool, the Functional Communication Profile (Sarno, 1969); and a quality-of-life measure, The Functional Life Scale (Sarno, Sarno, & Levita, 1973). Participants in this study were divided into younger and older age groups; however, age was not a factor in the results. Sarno et al. (1997) reported that improved QOL in persons with aphasia in the first year post-stroke was related to aphasia rehabilitation services that included language, communication, and psychosocial goals.

In their editorial on QOL, Worrall and Holland (2003) laid out the importance of measuring QOL in persons who live with aphasia, and also suggested that the challenge in the future would be to refine QOL measurements to capture those elements of an individual's life that reflect quality. Worrall and Holland identified areas of consensus in considering QOL in persons with aphasia and areas about which more information is required to creatively assess and ultimately treat QOL in individuals with aphasia. Assessing QOL and participation in society is of ever-increasing importance as individuals adjust and accommodate to life with aphasia (LaPointe, 1996; Ross & Wertz, 2005).

Goal 10: Determination of Candidacy for Prognosis in Therapy

Formulating prognoses for recovery from aphasia is one of the primary tasks of the speech-language pathologist (Tompkins, Jackson, & Shulz, 1990) and is one of the first questions usually asked by patients with aphasia, their caregivers, and family. Although relevant and reliable predictors and optimal methods of measuring prognoses are still limited, some of the prognostic indicators commonly suggested in the literature include **biographical variables** such as age,

gender, education, premorbid intelligence, support systems, usual/necessary activities, and level and type of life participation; **medical variables** such as etiology and duration of aphasia, site and extent of brain lesion, and concomitant physical and mental-health problems; and **language and cognitive variables** such as type and severity of aphasia and language stimulability.

Biographical Variables

Age

Many authors note that age and outcome correlate significantly (Holland & Bartlett, 1985; Marshall, Tompkins, & Phillips, 1982; Sands, Sarno, & Shankwilder, 1969); that is, younger patients with aphasia typically demonstrate greater language recovery than older patients. OGREZeanu and colleagues (1994) showed such a correlation for patients younger than 71 years of age. However, several researchers have failed to identify a meaningful relationship between age and aphasia recovery (Basso, 1992; de Riesthal & Wertz, 2004; Wertz et al., 1981). Basso (1992) suggested that demographic variables such as age and education play a minor role in prognosis, whereas neurologic factors, such as severity of aphasia, play a major role. Consequently, there are most likely many variables such as personal attitude, available support systems, level and type of life participation, learning style, pharmacologic treatment, and general medical health that confound the influence of age on recovery (Berthier, 2005; Crosson et al., 2005; Darley, 1977; Johnson, George, & Hinckley, 1998; Laganaro, DiPietro, & Schnider, 2006). Indeed, Tompkins et al. (1990) note that physiologic characteristics such as activity level or general health indicators and “psychosocial factors like personality, social involvement, or life satisfaction . . . are more predictive of cognitive ability, life adaptation, and morale than is chronological age” (p. 399).

Gender

Some studies show that gender and outcome correlate significantly, favoring males (Holland et al., 1989). Other studies report mixed findings with respect to the influence of gender on prognosis (Sarno, Buonaguro, & Levita, 1985). Basso (1992) found better recovery of spoken language in female as opposed to male patients with aphasia but did not observe this differential recovery in auditory comprehension skills. However, other researchers have failed to observe any significant differences in the recovery of female and male patients (OGREZeanu et al., 1994). Consequently, future research is necessary to shed light on the exact nature of gender as a prognostic indicator in language recovery.

Education and Premorbid Intelligence

Although many clinicians use education level as a prognostic factor in aphasia, Tompkins et al. (1990) point out that years

of formal education do not necessarily correspond to premorbid intellectual ability. Instead, these authors recommend the use of estimates of premorbid intelligence that weigh and enter standard demographic data including age, education, gender, occupational category, and race into specifically developed equations (Barona, Reynolds, & Chastain, 1984; Griffin et al., 2002; Lynch & McCaffrey, 1997; Spreen & Strauss, 1998). These estimates of premorbid functioning may have more predictive power than educational level alone, except in cases in which the patient had been illiterate (Lecours et al., 1988).

Medical Variables

Etiology/Type of Stroke

Prognosis in aphasia is more positive in cases resulting from traumatic as opposed to vascular etiology (Basso, 1992; Kertesz & McCabe, 1977). In terms of the type of stroke, if the patient survives a hemorrhagic stroke, he or she is likely to experience more recovery than the patient who had an ischemic (i.e., thrombotic or embolic) stroke (Holland et al., 1989; Laasko, 2003), and the recovery pattern is often different (Brookshire, 2003).

Time Since Onset

The fastest rate of recovery is typically observed during the first few months post-onset when spontaneous physiologic recovery processes are taking place. However, research and clinical experiences indicate that patients with aphasia can, and do, continue to make measurable progress for many, many years following the onset of aphasia (Davis, 2000). Although Sands et al. (1969) found that the longer the time between the onset of aphasia and the beginning of intervention the poorer the prognosis, more recent research suggests that deferred treatment is not necessarily detrimental to language recovery (Wertz et al., 1987). Indeed, clinical research studies frequently include participants who are many months, even years, post-onset, and many of these participants show change as a result of treatment.

Site and Extent of Lesion

In general, patients with larger dominant-hemisphere lesions or multiple lesions have a poor prognosis (Kertesz, 1979). Relations between site of lesion and aphasia outcome have also been identified. For example, lesions of the central core of the dominant-hemisphere language area, served by the middle cerebral artery, even when they are small, frequently result in severe aphasias (Hillis et al., 2000). Lesions to left temporobasal areas are also associated with less recovery compared to lesions outside of this region (Goldenberg & Spatt, 1994; Naeser & Palumbo, 1994; Thompson, 2000). Darley (1982) noted that some patients with poor prognosis because of the site and extent of lesion have nevertheless

recovered well. As technology to support neural imaging increases in accuracy and efficiency, increasingly finer-grained relationships may be made between site and extent of lesion and prediction for recovery, such as the studies reviewed by Cappa (2005) and by Hillis (2002b).

Physical and Mental Health Problems

The presence of other physical and mental-health problems in addition to aphasia often results in a poor prognosis (Jorgensen et al., 1995). For example, concomitant motor-speech disorders (e.g., apraxia of speech) have been shown to have a negative influence on aphasia recovery (Keenan & Brassell, 1974; Ogrzeanu et al., 1994). In terms of mental health, depression, anxiety, and other psychological problems may negatively affect outcome (Code et al., 1999; Code & Hermann, 2005). In addition, patients with aphasia who have few medical problems tend to have a shorter length of hospital stay, which has also been associated with better recovery (Holland et al., 1989).

Medications

Certain drugs can adversely affect the ability of a person with aphasia to respond to tasks. For example, dysarthria and stuttering are common adverse reactions to certain antidepressants and anticonvulsant medications (Murray & Clark, 2006; O'Sullivan & Fagan, 1998). Likewise, many anticonvulsant medications may produce undesirable side effects such as confusion, fatigue, and decreased arousal levels, which can affect patient ability to complete language activities (Vogel, Carter, & Carter, 1999). Therefore, the clinician needs to know what medication a patient takes and the impact of each, separately and in combination.

Neuropsychological and Language Variables

Neuropsychological Variables

Although in recent years many studies have described the relationship between cognitive functioning and language deficit in aphasia, most have been with respect to a particular skill or treatment program (Purdy, 2002). Currently, only minimal research has examined the relation between neurocognitive status and language recovery. Results of this research are mixed. That is, some studies, such as that by Goldenberg and Spatt (1994), show a positive relationship between initial neurocognitive test scores and language recovery (Bailey, Powell, & Clark, 1981; Messerli, Tissot, & Rodriguez, 1976). These researchers found that temporobasal lesions are associated with poor aphasia recovery because such lesions cause a disconnection between deep temporal lobe structures associated with memory abilities and cortical areas associated with language abilities. That is, these lesions result in problems in learning language as well as in acquiring compensatory strategies. In contrast, other

studies fail to observe a significant correlation between initial cognitive status and subsequent recovery (Basso, 1987; David & Skilbeck, 1984). Despite some null findings, many clinicians believe that the presence of concomitant attention, memory, and/or executive-function deficits negatively affect patients' ability to attend to and remember language, to problem solve, to learn to develop compensatory strategies, and to generalize learned behavior to new communicative situations (de Riesthal & Wertz, 2004; Helm-Estabrooks, 2002). More importantly, clinical research is attempting to identify those neuropsychological factors that may facilitate (or impede) progress in treatment (Purdy, 2006; Ramsberger, 2005; Shuster, 2004).

Aphasia Characteristics

Severity. The initial severity of aphasia is one of the strongest predictors of outcome (Kertesz & McCabe, 1977; OGREZeanu et al., 1994; Pedersen, Vinter, & Olsen, 2004); that is, patients with severe language impairments tend to show poorer recovery than those with milder language deficits. More specifically, initial ability to speak has been found to share a relationship to the eventual speech performance of the individual with aphasia (Keenan & Brassell, 1974). Similarly, patients who are severely impaired in auditory recognition and comprehension have an unfavorable prognosis compared with those who are less affected in these language areas (Davis, 2000; Robey, 1998).

Language Profile. Type of aphasia may be predictive of the amount of recovery and the residual pattern of language impairment. For example, patients with global aphasia are expected to have the poorest outcome, particularly those who continue to present with global aphasia beyond 3 months post-onset (Laska et al., 2001; OGREZeanu et al., 1994; Paolucci et al., 1998). In contrast, patients with anomic aphasia are expected to have the best outcome such that approximately half of these patients experience complete recovery by 1 year post-onset (Kertesz, 1979).

The language improvement that most patients experience often results in a change of aphasia type over time. For example, many patients with global aphasia eventually present with Broca's aphasia as their auditory comprehension and language-production abilities recover (Holland, Swindell, & Forbes, 1985). In contrast, Broca's, Wernicke's, conduction, and transcortical (sensory, motor, or mixed) aphasias frequently resolve toward anomic aphasia over time (Goodglass, 1992; OGREZeanu et al., 1994; Rapcsak & Rubens, 1994).

Stimulability

Self-correction. A patient's awareness of his or her speech difficulty as well as his or her ability to self-correct relate positively to improvements in speaking abilities (Keenan & Brassell, 1974; Oomen, Postma, & Kolk, 2001; Wepman,

1958). That is, patients who have insight into their language disorder as well as an awareness of situations that either enhance or degrade their communication ability have a better prognosis (Marshall & Tompkins, 1982; van Harskamp & Visch-Brink, 1991).

Cuing. Insight into the prognosis for a patient with aphasia may also be gained from examining the degree to which his or her language behaviors can be easily modified. For example, Keenan and Brassell (1974) observe that aphasic patients whose spoken language is initially stimulative to prompts and cues display better recovery of spoken language than do those patients for whom prompting is ineffective. Clinicians might expect that those patients with aphasia who can learn to produce their own cues would have better language outcomes or demonstrate better generalization of target language behaviors than patients who are dependent upon others to provide cues (Freed et al., 1995; Marshall & Freed, 2006; Marshall et al., 2002).

Personality/Social Variables

Personal Attitude

The desire of a patient with aphasia to improve his or her level of motivation, self-efficacy, and determination may influence the course and outcome of aphasia therapy (Darley, 1977; Murray & Chapey, 2001; Rosenbek, LaPointe, & Wertz, 1989; Shill, 1979). As van Harskamp and Visch-Brink (1991) proposed, the "kernel" of therapy is the stimulation of the patient's willingness to participate actively in the learning process and to practice learned skills at every opportunity. These researchers further stated that "the patient's motivation is of utmost importance: patients need to exert themselves to make progress" (p. 533). In addition, the level and type of participation in everyday activities and in life may well have a profound effect on prognosis since patients need something to talk about and since such participation can have a positive effect on motivation (Chapey et al., 2000). Indeed, research indicates that personality variables and social support are linked to health generally, to morbidity and mortality, as well as to prognosis in treatment in a variety of health conditions such as stroke (Tompkins et al., 1990). An excellent example of the supportive effects of personal variables is humor in treatment (Simmons-Mackie & Schultz, 2003). Tompkins and colleagues (1990) suggested that using valid and reliable psychosocial scales to measure a patient's personality variables has the potential for enriching our understanding of patients' responses to treatment and for facilitating prognoses.

Family Attitude

Family interest in the patient with aphasia and their desire to see improvement in language and communication abilities

will also contribute to a determination of candidacy for treatment and influence the progress made during intervention. For example, a committed support network is needed to help the patient's treatment attendance as well as to encourage the patient's use of treated language behaviors in his or her daily environment (Blackstone & Berg, 2003; Patterson & Wells, 1995; Payne, 1997; Wells, 1999). Indeed, in an article assessing factors that predict optimal post-stroke progress, Evans et al. (1991) found that a patient does significantly better when the primary support person is not depressed, is married, is knowledgeable about stroke care, and is from a functional rather than dysfunctional family. These authors suggest that caregiver-related problems can have a collective effect on rehabilitation outcome and that treatment should therefore reduce caregiver depression, perhaps through participation in activities and in life (Chapey et al., 2000), minimize family dysfunction, and increase the family's knowledge about stroke care. These goals are often difficult to achieve in modern times with family structures that vary and in the presence of multifaceted, busy lives. Tompkins and colleagues (Tompkins et al., 1990; 1987) also stress the importance of developing more reliable and valid measures of social networks and support resources to facilitate statements concerning prognosis.

Paramount in helping families support their significant others with aphasia is education. Families need differing amounts and types of information at different stages in the course of aphasia (Avent, 2005; Avent et al., 2005; Purdy & Hindenlang, 2005). Families with an adequate amount and type of information will be better able to support assessment and treatment activities, and to learn to live with aphasia within a productive family network.

In summary, it should be noted that no one factor discussed above consistently determines a patient's progress and success in therapy, and despite the best intentions, the optimal recovery environment may not be easily created. Clinicians and families should work cooperatively to construct a positive support network for treatment. If a patient seems to have reached a performance plateau, perhaps changing an element of treatment for a trial period would be appropriate before a final decision is reached about termination or postponement of intervention.

Goal 11: Specification and Prioritization of Intervention Goals

In an excellent chapter entitled "From Assessment to Intervention: Problems and Solutions," Snyder (1983) proposes that making the transition from assessment to intervention is like trying to solve a puzzle. Specifically, she stated that "success in solving puzzles seems to require that we have . . . only the correct pieces" (p. 160). Snyder also noted that the assessment process may be lengthy as ". . . it takes time and effort to identify and discard the wrong pieces.

Further we need to be able to conceptualize how the pieces fit together and operate as a whole. The puzzle is not really solved unless it fits together and works" (p. 160). There is no one solution to the assessment-intervention puzzle, particularly when working with patients with aphasia for whom variability is the norm.

The transition from assessment to treatment must be viewed from several perspectives, one of which is the theoretic model that underlies the communication deficit or the approach to treatment. Four recently published books guide clinicians through the process of assessment and treatment from theoretic bases: Hillis (2002a), Murray & Clark (2006), Nadeau et al. (2000), and Whitworth et al. (2005). Each of these books is written from a different theoretic perspective; however, each considers the transition from assessment to treatment as a dynamic process that is driven by a theoretic model and by data.

During the data-collection phase of assessment, the puzzle pieces are gathered and subsequently assembled into the puzzle frame during attempts to organize, systematize, and condense the data in a meaningful way. The "assembly" phase of assessment involves a sophisticated clinical judgment that is applied to the information collected. It is an evaluation of the type, frequency, and pattern of behaviors produced by the patient, an identification of influential biographic, medical, and social variables, and an exploration of the interrelatedness of these various behaviors and variables to specify and prioritize intervention goals.

Within the context of the WHO ICF (ICF, 2001), both the data-collection and hypothesis-formation phases of assessment target the three components of body structure and function, activities, and participation. Indeed, all three areas are the focus of both assessment and intervention from the onset of a clinician's acquaintance with a patient and should not be viewed merely as carryover goals (Chapey et al., 2000). Treatment goals should be created to address any language deficit, but in addition must assist a person with aphasia in progressing toward his or her life goals (Duchan & Black, 2001). Byng and Duchan (2005) discussed the social model of disability and how it might apply to aphasia therapy. The social model of therapy can be used in conjunction with other treatment models as it is intended to relate to the beliefs and attitudes of the clinician and foster a positive rehabilitation environment between the clinician and the patient. Siegert and Taylor (2004) suggested that recognition of theories of goals and motivation should be part of the rehabilitation planning process in an effort to maximize any treatment gains.

For all three WHO ICF levels, aphasia treatment is a multidimensional process that often requires a succession of treatment techniques and methods (Duchan & Black, 2001; Murray & Chapey, 2001; van Harskamp & Visch-Brink, 1991). However, the usual focus of treatment is on auditory comprehension and spoken-language production since these

are the most essential components of daily communication for most people. Reading and writing may be used to facilitate or to cue listening and speaking skills but may not typically be the central focus of therapy. Regardless of the language modality to be targeted in treatment, emphasis is primarily focused on improving comprehension and production of meaning and informational content by the patient with aphasia, and on improving functional use of language in everyday communication activities and environments. Language forms become the focus of therapy only when they are needed to increase the meaning of language and the functions for which language can be used. Indeed, too much attention to the formal linguistic aspects of language may impede the communicative act (van Harskamp & Visch-Brink, 1991). Although a typical session may integrate cognitive, linguistic, and pragmatic goals, the facilitation of meaning, of functional language, of activities, and of life participation should be viewed as the core of language treatment (Murray & Chapey 2001).

Specific treatment goals are formulated by analyzing descriptions of the patient's language and life and determining the area that is most in need of intervention (Chapey et al., 2000). Patterns of strengths and weaknesses are identified to determine behaviors that might be used as a base on which to build more functional and more complex responses (Chapey, 1994). For example, in the activities area, treatment may be initiated at the level at which the patient just begins to experience difficulty in one or more of the following: accuracy, responsiveness, completeness, promptness, and efficiency of behavior (Brookshire, 1972; 1976; Murray & Chapey, 2001). An alternate approach to treatment has been suggested by Kiran and Thompson (2003), who showed that training complex items in treatment facilitated generalization to untrained items that were less complex. Additional research is expanding the goals to which this technique may be applied.

In addition to setting target responses, the stimulus variables and response conditions that facilitate increasingly accurate responses should be defined so that they may be used during therapy (Murray & Chapey, 2001). For example, during assessment, the clinician may note that the patient responds more accurately to visual rather than auditory stimuli, or responds more quickly and accurately when using gestures rather than speech; consequently, the clinician can capitalize upon this information when developing treatment goals and activities. In treatment, the clinician may begin with and build on the patient's strengths to optimize initial success (Chapey, 1986; 1994). As Rosenbek and colleagues (1989) note, once the persons with aphasia's "strengths have been enhanced, they can be used in combination with weaknesses" (p. 138).

Goals and strategies, then, are selected on the basis of assessment results that show communicative behaviors that the patient with aphasia can already produce either consis-

tently or inconsistently, behaviors that he or she can be stimulated to produce, behaviors at the point where he or she begins to have difficulty, or communicative behaviors and activities that he or she values and will need on a daily basis to participate in activities and in life. A task hierarchy is then developed (e.g., recognition of familiar one-word utterances, recognition of less familiar one-word utterances, recognition of two- to three-word familiar phrases and commands, etc.), and specific tasks and stimuli are chosen so that they are simple enough to ensure success and yet complex enough to stimulate learning, and so that they pertain to the patient's daily needs and activities (Chapey, 1986; 1994; Murray & Chapey, 2001).

The actual type of treatment that is selected will depend on what is most appropriate for a specific patient's language and communication deficits, and what is compatible with a clinician's definition of aphasia (Chapey, 1994; Nadeau et al., 2000). By far, the largest number of approaches and the most widely accepted approaches to aphasia therapy can be described as stimulation approaches (Duffy & Coelho, 2001). This concept, first suggested by Schuell et al. (1955), emphasizes that the recovery process is a reorganization and retrieval of disrupted language processes rather than the relearning of highly specific language responses. Specific examples of various approaches to aphasia treatment are presented in subsequent chapters of this text. In many instances, an eclectic, multidimensional approach involving two or perhaps three of these approaches may be used (Byng et al., 1990; Chapey, 1994; Holland & Thompson, 1998; Murray & Chapey, 2001). This viewpoint recognizes the importance of the expertise, the competence, and the judgment of the clinician in using existing knowledge and appropriate tools, and in establishing an individualized regimen for each of his or her patients with aphasia. This viewpoint also acknowledges that patients with aphasia and their caregivers and families may present with a variety of difficulties, and that treatment must not only address language impairments, but also the social, emotional, and vocational activity limitations and participation restrictions that may accompany these language impairments (ICF, 2001; Simmons-Mackie, 2001).

Regardless of approach, the main objective of treatment is to increase a patient's success in using language and related behaviors (e.g., drawing, gestures) to exchange information and ultimately to improve communication and participation in real life (Chapey et al., 2000; van Harskamp & Visch-Brink, 1991). That is, the objective is to enable patients with aphasia to regain as much language and communication as possible, and to accommodate or compensate for their language and communication impairments as best they can, so that they can participate in their daily personal, social, and vocational activities to the fullest extent to which they are capable. The objective of the rehabilitative process, then, is to increase the productive use of cognitive, linguistic, and

pragmatic skills in spontaneous communication, activities, and life participation to the optimum level possible.

Future Trends

Development of Assessment Tools

We still have a great deal to learn about assessment. We can begin this journey by developing more assessment tools (tests, protocols, and coding systems for evaluating behavior) that are psychometrically rigorous, accurate, in-depth, efficient, and clinically relevant. These tools should be standardized and nonstandardized; unstructured, moderately structured, and highly structured; and reliable and modifiable. With respect to the WHO framework (ICF, 2001), the majority of existing assessment tools focus on examining the four language modalities of aphasia at the impairment level; new tests and protocols should include assessment of the activity and participation levels as well. Over the past decade several new aphasia measures have been developed that have the aim of identifying personal activity abilities and limitations, and quantifying and qualifying the consequences of aphasia at the society participation level (Chapey et al., 2001; Holland & Thompson, 1998; Simmons-Mackie, 2001; Simmons-Mackie & Damico, 1996; Worrall et al., 2002). Many of these instruments, although theoretically well-founded, lack demonstrated psychometric rigor, such as that obtained from validity and reliability studies. Consequently, there is a need for further development of tools to assess activity and participation-level abilities and restrictions among patients with aphasia. In addition, refinement and continued development of tools to evaluate the adjustment to aphasia by family members and caregivers is important. Development and use of these tools should take into account the psychosocial status and communication patterns and needs of these individuals as well as their perceptions of their quality of life, and the degree of their role limitations while living with an individual with aphasia (Warren, 1999; Zemva, 1999).

Developing and field-testing an assessment measure is a resource-intensive task (Chapey, 1992; Murray & Chapey, 2001). Several factors present obstacles to test development, such as lack of time within a full-time professional position, funding for development, and pressure for accountability brought about by public and insurance funding of habilitation and rehabilitation (Chapey, 1994). The term "accountability" comes from the words "to account" and means "to furnish a justifying analysis or explanation" (Webster's New Collegiate Dictionary, 1977). Being accountable for one's work is laudable. However, the system of accountability that appears to have emerged is "cost accounting," which does not foster meaningful, functional communication, or reflect current definitions of language, communication, learning, and activities and life participation.

Emphasis on economy rather than therapy effectiveness affects current clinical practice. Specifically, government and private health-care agencies designate that the behaviors that will be produced by the patient in treatment must be specified in writing in advance (Murray & Chapey, 2001). That is, goals are usually operationally written, such as "By the end of this session, John will name three kinds of fruit." This leads to what Frattali (1992) called a deficit-oriented approach to intervention. Current accountability, then, often involves assessing whether the patient reached criterion, or the expected level of performance. Within this framework of accountability, assessment and intervention target specific language modalities that are discrete, highly measurable, surface-structure behaviors that can be predicted in advance and that primarily reflect short-term outcomes (Chapey, 1994). Consequently, this practice encourages a "skills approach" (Chapey, 1992; 1994; Frattali, 1992) to treatment rather than targeting functional communication within a meaningful context and/or activity, or rather than addressing changes in patients' and caregivers' life participation, or perceptions and expectations of themselves and their communicative interactions. All of the latter may be more difficult to measure via long-term outcomes but are far more important to the patient and family.

Tools to Reflect Different Perspectives of Communication Needs

It is clear that future development of assessment instruments must include several perspectives of an individual's communication needs: ICF levels of impairment and activity/participation; functional communication in multiple communication situations; quality-of-life measurements for an individual with aphasia and for his or her family members and /or caregivers; and cognitive deficits underlying communication deficits. There will likely be many assessment tools developed in the coming years (Worrall et al., 2002). Two challenges to the field of speech-language pathology, and to related fields of study such as cognitive neuropsychology, present themselves to persons who accept the challenges of creating new assessment tools. The first challenge is to create a tool that is psychometrically rigorous yet can be easily used in a clinical environment. As discussed previously, many tools are well-constructed yet do not lend themselves to efficient use in a clinical setting. Examples of efforts in this direction are studies that correlate behavior from different tools in an attempt to find the best predictor of behavior that is also most efficient (e.g., Doyle, Goda, & Spencer, 1995).

The second challenge is for clinicians to apply rigorous criteria when evaluating and selecting tools for use in assessment. Clinicians should consider the needs of the patient, constraints of the practice setting (e.g., acute-care facility or home care) and consequences to the patient and to the

diagnostic outcome of using the tool (Messick, 1980). Many sources describe psychometric properties and how to use them to evaluate a test (Shipley & McAfee, 2004), and it will be important for clinicians to use these sources.

Tools to Differentiate Disorders and Levels of Performance

Several current tools differentiate types of aphasia (e.g., BDAE); however, disagreement exists among them. Tools to better differentially diagnose aphasia as well as to describe observed behavior in more depth than is often currently possible will be important contributions to clinical practice. Studies that investigate the use of current assessment tools in creative ways will further assist clinicians in conducting appropriate and meaningful assessments. In addition, improved tools to assess cognitive deficits that underlie communication deficits will aid clinicians in understanding and relating the linguistic and nonlinguistic aspects of performance. These activities will lead to increased sensitivity and specificity during assessment, and ultimately assist in treatment planning.

Evidence-Based Practice

Evidence-based practice (EBP) is a method of clinical decision-making that incorporates information from three sources: current, high-quality research literature; clinical experience; and patient values and preferences (Evidence-based practice, 2005; Sackett et al., 1996). It is important to acknowledge that any one of these three areas independently cannot provide sufficient evidence for clinical decisions. The combination of information from three areas viewed as a unit will support clinical decision-making.

Two primary activities contribute to efforts in the first piece of EBP: reading systematic reviews in topic areas and reading individual research articles. Several groups and individuals have published systematic reviews or meta-analyses of topics in neurogenic communication disorders. Four examples of efforts in this direction are the published guidelines from the National Center for Evidence-Based Practice in Communication Disorders, which is part of the American Speech-Language-Hearing Association (The N-CEP Registry of Clinical Practice Guidelines and Systematic Reviews, 2005), practice guidelines from the Academy of Neurologic Communication Disorders and Sciences (Frattali et al., 2003), the Royal College of Speech Language Therapists (Royal College of Speech and Language Therapists: Clinical Guidelines, 2005), and Robey (1998). Using these resources as a starting point allows the clinician to be efficient in finding evidence to support clinical decisions. Currently most of the systematic reviews relate to treatment of communication disorders rather than assessment. Systematic reviews of the various assessment tools used with different populations and in various clinical set-

tings will be important to develop in the future. A cautionary note is appropriate as there is often more evidence available than is published (Elman, 2006; Robey, 1998).

The second piece of EBP is observation from clinical practice. Clinicians recognize the importance to accurate diagnosis of observing and documenting a patient's performance across several activities. Systematically documenting specific aspects of patients' behavior during assessment activities across multiple patients, clinicians, and clinical settings, and collectively sharing this information, will result in a database of clinical opinion that complements published research studies.

Finally, the third piece of EBP is opinions and perspectives from patients and their families. While the manner in which a clinician conducts assessments may remain relatively consistent across patients, data from an individual assessment will be patient-specific. These data will be valuable in further assessment activities for a patient and in treatment planning. Further, any anecdotal information exchanged between clinicians will contribute to the shared knowledge base.

Taken together, the three pieces of evidence-based practice are critical to guide future practices in assessment of persons with aphasia and other neurogenic communication disorders. However, clinicians have reported that obstacles, such as lack of time, may prevent the use of EBP principles (Dollaghan, 2004; Zipolo & Kennedy, 2005).

Functional Communication, Quality of Life, and Living with Aphasia

Future efforts in assessment must continue to refine methods of examining functional communication skills in persons with aphasia as they communicate with family members and others in their environment. While assessment activities at the ICF level of impairment are important to the assessment process, defining language and communication only in terms of measurable and specific surface structures seems to miss the very core of what constitutes language and communication. Meaning is the essence of language, and language and communication are like an iceberg—much of what is meant and communicated is below the surface; only a small portion of the communication is spoken or written or heard or read (Chapey, 1992; 1994). Likewise, this approach to aphasia assessment and treatment minimizes or ignores the many societal factors (e.g., perceptions and actions of family, friends, or co-workers) that may interact with the patient's language and communication abilities, and, consequently, the degree of participation restriction they experience (Simmons-Mackie, 2001; Simmons-Mackie & Damico, 1996).

A positive QOL is an important factor in a person's life. Perceptions of the patients and their caregivers are legitimate outcome measures, and future efforts aimed at refining the measures currently used to quantify and qualify the

effects of aphasia on the societal participation of our patients and their families, as well as developing new measures, are important clinical research activities. As a field, we must continue to search for a consensus of which core elements constitute functional communication and contribute to QOL, and create assessment tools that have relevance to communicative functioning in a variety of clinical settings as well as outside clinical settings in daily communicative environments (Frattali, 1998b). Of particular value in achieving this goal is the development of multi-dimensional assessment protocols that are thorough (and therefore measure a range of performance and outcomes), reliable, and sensitive to changes over time.

When a person is diagnosed with aphasia, he or she and his or her family members will live with aphasia. An important direction in developing assessment tools is to advance the notion that it is critical to determine the effects of aphasia and, subsequently, treatments for aphasia, on the communicative abilities of patients with aphasia and their families, as well as on the social well-being of patients and their caregivers. Clinicians must be committed to conveying this message to political and fiscal policy-makers so that we can deliver the first-rate care that our patients with aphasia deserve.

KEY POINTS

1. A thorough assessment of language and communication should include evaluation of an individual's cognitive, linguistic, and pragmatic abilities, and quality of life for the patient and his or her family or caregivers.
2. The goal of assessment is typically multifold in that etiologic (e.g., the determination of the presence of aphasia and concomitant problems), cognitive/linguistic/pragmatic (e.g., the identification of specific language strengths and weaknesses), communicative facilitators and obstacles (e.g., events and persons who support or inhibit communication), social aspects of living with aphasia (e.g., activity and participation limitations or restrictions), quality of life (e.g., life satisfaction for a patient and family), and treatment goals (e.g., the provision of insight into possible treatment candidacy and treatment procedures) should be specified and accomplished.
3. During assessment data should be obtained through reported observations and direct observations, which may be unstructured (e.g., conversation), moderately structured (e.g., procedural discourse task), highly structured (e.g., a traditional aphasia battery) and nonstandardized (e.g., experimental protocols).
4. Prior to administering any test or procedure clinicians should examine its psychometric adequacy in terms of reliability and validity.
5. The integrity of cognitive and executive-function abilities should be determined because deficits in these areas may negatively affect production of language and communication skills as well as acquisition of new knowledge.
6. Comprehension and production of language content (i.e., meaning) and language form (i.e., phonology, morphology, and syntax) must be assessed using stimuli that vary in length, complexity, and familiarity. Listening, speaking, reading, writing, and use of alternative or augmentative communication systems (e.g., drawing, gesturing, or using an electronic device) must be assessed.
7. Pragmatic abilities across a variety of communication contexts and partners and with differing amounts of support must be assessed. Functional communication skills should be assessed to determine the interaction of a patient's cognitive, linguistic, and pragmatic abilities during communication in daily life activities.
8. Factors that contribute to successful or unsuccessful communication activities should be identified in assessment (e.g., medical, neuropsychological, or social supports or hindrances). This evaluation should include quality of life-assessment for both patients and their family members and caregivers.
9. Following data collection, clinicians must synthesize the assessment data to form hypotheses concerning the nature and extent of the patient's language and communication deficits. In particular, clinicians should be able to summarize the nature and extent of a patient's language impairment, personal-activity limitations, and societal-participation restrictions within the context of the WHO model of functioning and disability.
10. Future trends in assessment should focus on developing tools that are psychometrically rigorous and clinically relevant, that reflect different perspectives of communication needs, and that differentiate neurogenic communication disorders and levels of performance. Clinicians should also engage in the principles of evidence-based practice. Finally, as assessment activities become increasingly refined, they should encompass all levels of the WHO ICF to assess the nature and extent of the language impairment as well as the effect on activities and life participation for a patient and his or her family.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Pretend that you have been hired to develop a speech-language pathology department in a rehabilitation hospital. In particular, your department will specialize in serving adults with acquired language disorders. Keeping in mind that you have a limited budget to purchase assessment tools and materials, list which unstructured, moderately-structured, highly-structured, and nonstandard observational tools you will purchase. Justify your selection. How and why might this list differ if your department was located in an acute-care hospital or a skilled-nursing facility, or if you were working in home health care?
2. Describe and justify what the assessment battery might be for assessing the cognitive, linguistic, and pragmatic abilities, and quality of life for a patient who was described as “mildly aphasic with reading and writing difficulties” as a result of a bedside evaluation.
3. Imagine you have been given a referral to assess the language and communication abilities of an individual who is 79 years old, who was previously diagnosed with aphasia, and who has a history of bilateral strokes. What complicating conditions might be expected, and how will the assessment process take into consideration their possible effects?
4. Using the WHO ICF model as a guide, design and justify an assessment battery to evaluate the nature and extent of language and communication abilities and quality of life for a person with global aphasia and who is a resident in a skilled-nursing facility. How might this battery differ if the patient lived at home with a spouse who was able to provide appropriate care and companionship?
5. Describe how you would measure outcome of treatment and justify treatment recommendations using data from unstructured, moderately-structured, highly-structured, and nonstandardized observational tools.
6. Review the research literature, consult with colleagues, and review anecdotal information from your clinical practice or experience to determine the presence (or absence) of evidence supporting the use of an assessment tool in the following areas:
 - (a) oral naming
 - (b) written word finding
 - (c) production of spoken morphosyntax
 - (d) oral discourse production (conversational and procedural)
 - (e) written narrative production
 - (f) reading comprehension
 - (g) production of speech acts
 - (h) depression
 - (i) visual neglect
 - (j) executive functioning
 - (k) quality of life

APPENDIX 4.1

Pre-interview or Referral Form for Collecting Family and Medical History and Status Information

Information About the Respondent

Name _____ Date of Report _____
 Phone number _____ e-mail _____
 Relationship to patient _____

Information About the Patient

Name _____ Birth place _____
 Address _____ Birth date _____
 Phone Number _____ e-mail _____

Dear Respondent:

We are asking you the following questions to help us understand the above person, and to plan assessment and treatment activities. Please answer them as fully as possible. If you need more space, use the back of the sheet. Thank you in advance for your time and assistance.

1. What do you feel is the patient's problem? _____

2. What caused the aphasia (head injury, stroke, illness)? _____

3. What was the date of injury or of the onset of the illness (head injury, stroke, illness)? _____

4. Who is the patient's physician? _____
 What is the physician's address? _____
 What is the physician's phone number ? (_____) _____
5. What was the patient's handedness (before stroke or disease onset)? Right _____
 Left _____ Ambidextrous _____
6. Does the patient wear glasses? _____
 Can the patient see well enough to read?
 with glasses _____ without glasses _____
 Does the patient have any other visual problems, such as right or left visual-field cut or cataracts? _____
7. Does the patient have a hearing loss? _____
 Does the patient wear a hearing aid? _____
 If yes, in the right ear _____, left ear _____, or both _____?

8. How would you describe the patient's general health? _____

9. Please list the patient's current medications and dosages (if known):

10. Does the patient have a history of any of the following?

Onset Date and Current Status

Stroke	Yes	No	_____
Aphasia	Yes	No	_____
Other communication disorder	Yes	No	_____
Right- or left-sided weakness	Yes	No	_____
Dementia (e.g., Alzheimer's disease)	Yes	No	_____
Memory impairment	Yes	No	_____
Other neurologic disease	Yes	No	_____
Head injury	Yes	No	_____
Seizure disorder	Yes	No	_____
Clinical depression	Yes	No	_____
Psychiatric problems	Yes	No	_____
Alcohol abuse/problems	Yes	No	_____
Other substance abuse	Yes	No	_____
Other major illness	Yes	No	_____

11. List members of the immediate family:

Name	Age	Relationship	Phone number	Check if living in same environment as patient
_____	_____	_____	_____	_____
_____	_____	_____	_____	_____
_____	_____	_____	_____	_____
_____	_____	_____	_____	_____

12. If the patient is living at home, are there others living in the home besides the immediate family?

If the patient is not living at home, where does he or she live?

13. Are there relatives on the patient's side of the family who have had a similar problem with speech and language? If so, who? _____

14. What is the patient's native language? _____
 If not English, at what age did the patient learn English? _____
 What other languages does the patient speak? _____
 What is the preferred language in the home? _____
15. What is the patient's highest level of education? _____
16. What (is/was) the patient's primary occupation? _____
 Who (is/was) the patient's employer? _____
 Is the patient presently working? _____
 Describe the patient's work history (for example, kind of employment and approximate dates).

17. Patient's mother's name _____ Living _____ Deceased _____
 Patient's father's name _____ Living _____ Deceased _____
18. Marital status: single _____ widowed _____ separated _____
 married _____ divorced _____ remarried _____
19. Does the patient have children _____ or grandchildren _____?
- | Children | Name | City of residence | Age |
|----------|-------|-------------------|-------|
| | _____ | _____ | _____ |
| | _____ | _____ | _____ |
| | _____ | _____ | _____ |
| | _____ | _____ | _____ |
- Grandchildren
- | | | |
|-------|-------|-------|
| _____ | _____ | _____ |
| _____ | _____ | _____ |
| _____ | _____ | _____ |
| _____ | _____ | _____ |
| _____ | _____ | _____ |
| _____ | _____ | _____ |
20. (Answer Question 20 if appropriate.) What is the spouse's name? _____
 What (is/was) the spouse's occupation? _____
 Who (is/was) the spouse's employer? _____
 Is the spouse presently working? _____
 What is the spouse's native language? _____
 If not English, when did the spouse learn English? _____
 What other languages does the spouse speak? _____
 What is the preferred language to communicate with the spouse? _____
21. Does the patient need to be taken care of at all times? _____
 If so, who performs this function? _____
22. To what extent can the patient care for himself (dress, feed, and wash himself)? _____
23. Has the patient's speech and language problem affected the family in any way? If so, how? _____

24. Describe the patient's ability to communicate in general and with family members.

25. When did you first notice that the patient had difficulty talking or understanding? _____

26. How much does he or she talk or write now? _____

27. How much of this speech or writing does the family understand? _____

28. To what degree do other adults understand the patient's communication? _____

29. How do you think he or she feels about his or her communication abilities? _____

30. What strategies have you found useful to help with the patient's communication? _____

31. Is he or she attempting to communicate verbally?	Yes	No
Is he or she attempting to communicate in writing?	Yes	No
Is he or she attempting to communicate using gestures?	Yes	No
Can he or she tell you his or her name and address?	Yes	No
Can he or she write his or her name and address?	Yes	No
Is his or her speech intelligible?	Yes	No
Is his or her writing intelligible?	Yes	No
Can he or she say short sentences?	Yes	No
Can he or she write short sentences?	Yes	No
Can he or she repeat or copy words?	Yes	No
Is there automatic speech (e.g., "Hello," "Thank you," "I'm fine.")?	Yes	No
Can he or she understand conversational speech?	Yes	No
Can he or she read and understand the newspaper?	Yes	No

32. Below are words that describe a person's personality and behavior. Circle those words that you feel apply to the patient's present status.

happy	fiery often	sad	enthusiastic	patient
very friendly	warm	independent	energetic	intense
moody	critical	dependent	prefers to be alone	jealous
authoritarian	supportive	impatient	shy	receptive
bossy	at ease	responsive	cooperative	relaxed
active	indifferent	distractible	outgoing	directive
tense	listless	cold	can't sleep	affectionate
even-tempered	quarrelsome	vigorous	easily fatigued	curious
has temper tantrums		exhibits control of emotions		
follows the lead of others		exhibits self-help		
waits for recognition		has many fears		
has few fears		initiates activities		
walks in sleep		seeks social relationships		
demand attention		willing to try unknown		
stays with an activity				

33. In general, the (spouse-patient) or (family-patient) relationship is (circle one):

comfortable	strained	hostile	indifferent
-------------	----------	---------	-------------

34. Have you read or heard anything about aphasia/head injury/illness? _____ If yes, what did you hear and where did you hear it?

What has your doctor talked to you about aphasia/head injury/illness? _____

What kind of information do you think you need about aphasia/head injury/illness?

35. What are the patient's interests or favorite activities? _____

Can the patient engage in these activities as he or she did before aphasia/head injury/illness? _____

Does the patient show the same interest level in these activities? _____

Are the patient's favorite activities the same now or different than before the aphasia/head injury/illness?

36. Does the patient watch TV? _____ If so, what are his or her favorite programs?

37. Does the patient read much? _____ If so, what type of reading material does he or she enjoy? _____

Did the patient like to read before the aphasia/head injury/illness? _____

Is his or her level of reading the same now or different than it was before the aphasia/head injury/illness?

38. Does the patient write notes or letters? _____ If so, how much writing does he or she do?

Did the patient like to write before the aphasia/head injury/illness? _____

Is his or her level of writing the same now or different than it was before the aphasia/head injury/illness?

39. Has the patient been seen for:

	Dates	Agency	Address
a. Speech therapy	_____	_____	_____
b. Audiology	_____	_____	_____
c. Physical therapy	_____	_____	_____
d. Occupational therapy	_____	_____	_____
e. Psychological counseling	_____	_____	_____
f. Other rehabilitation	_____	_____	_____

APPENDIX 4.2

Examples of Auditory Retention and Comprehension Tasks

Task	Example	Input ^a	Output
<i>Auditory Retention Tasks</i>			
Recognition or repetition of digits	Point to: 8, 4, 2	A	G
	Say after me: 9, 3, 7	A	V
Recognition or repetition of words	Touch the red square and blue circle	A	G
	Say after me: man, cup, hat, dog	A	V
Recognition or repetition of noun phrases	Point to: The man	A	G
	Say after me: The man	A	V
Recognition or repetition of verb phrases	Point to: Ate the lunch	A	G
	Say after me: Ate the lunch	A	V
Recognition or repetition of sentences	Point to: The man ate the sandwich.	A	G
	Say after me: The man ate the sandwich.	A	V
<i>Auditory Comprehension Tasks</i>			
Recognition of objects named	Point to the hat	A	G
Recognition of events named	Point to running	A	G
Recognition of relationships named	Point to family	A	G
Recognition of two or more objects, two or more events, or two or more relationships named	Point to the quarter and the comb	A	G
	Point to washing and to eating		
	Point to family and to in front of		
Recognition of categories named	Point to fruit	A	G
Recognition of two or more categories named	Point to clothing and to food	A	G
Recognition of objects when given the function of the object	Point to the one that is used for writing	A	G
Recognition of two objects when given the function of the objects	Point to the one that is used to buy things and the one that is used to comb hair	A	G
Recognition of an event described	Point to the one that shows what we do every night (sleep)	A	G
Recognition of two events described	Point to the one that shows food being prepared and the one that shows going to work	A	G
Recognition of semantically similar objects, events, relationships (2, 3, 4)	Point to the ones that go together: shopping, walking, cooking	A	G
Recognition of rhyme words	Point to a picture that rhymes with the word peas	A	G
Recognition of antonyms	Point to the opposite of up	A	G
Recognition of synonyms	Point to a word that means the same as sob	A	G
Following directions	Ring the bell	A	G
Understanding concrete sentences	Is this a cup?	A	G
Understanding abstract sentences	Will a stone sink in water?	A	G
Understanding complex or abstract relationships in sentences (adapted from Wiig and Semel [1976])			
a. Comparative relationship	Are towns larger than cities?	A	G/V
b. Possessive relationship	Does the hat belong to the girl?	A	G/V
c. Spatial relationship	Is the man walking in front of the cat?	A	G/V
d. Temporal relationship	Does lunch come before breakfast?	A	G/V
e. Inferential relationship	The man cut the steak. Did the man use a knife?	A	G/V
f. Familial relationship	Is your mother's brother your aunt?	A	G/V
g. Part-whole relationship	Does milk come from cows?	A	G/V

Task	Example	Input ^a	Output
h. Object-to-action relationship	Can a car be driven?	A	G/V
i. Cause-effect relationship	Can smoke cause fire?	A	G/V
j. Sequential relationship	Were the Indians in this country before the white men came?	A	G/V
k. Degree relationship	Are inches larger than feet?	A	G/V
l. Antonym relationship	Is day the opposite of night?	A	G/V
m. Synonym relationship	Does sob mean the same as cry?	A	G/V
<i>Comprehension of Content Categories</i>			
a. Existence	Point to the hat	A	G/V
b. Nonexistence	Point to: "The pie is all gone"	A	G/V
c. Recurrence	Point to: "The man returns"	A	G/V
d. Rejection	Point to: "He doesn't want a bath"	A	G/V
e. Denial	Point to: "The cup is not yellow"	A	G/V
f. Possession	Point to the woman's coat	A	G/V
g. Attribution	Point to the large red circle	A	G/V
Understanding paragraphs	(Read paragraph) Questions: In this story, did Lucky find a bird?	A	G/V

Key: A = auditory; G = gestural; V = verbal.
(From Chapey, 1994; Murray & Chapey, 2001)

APPENDIX 4.3

Various Tasks Used to Assess Auditory Comprehension of Syntax

Task	Example	Input	Output
<i>Understanding Substantive Words</i>			
Pronouns			
a. Personal	Point to: "She ate the cake."	A	G
b. Reflexive personal	Point to: "She kept it to herself."	A	G
c. Indefinite	Point to: "Is there any left?"	A	G
d. Demonstrative	Point to: "This is the cake."	A	G
e. Interrogative	Point to: "Which one won the race?"	A	G
f. Negative	Point to: "Nobody is interested."	A	G
<i>Adjectives (attribution)</i>			
a. Color	Point to the blue one	A	G
b. Size	Point to the large one	A	G
c. Shape	Point to the square one	A	G
d. Length	Point to the short one	A	G
e. Height	Point to the tall one	A	G
f. Width	Point to the narrow one	A	G
g. Age	Point to the new one	A	G
h. Taste	Point to the sour one	A	G
i. Speed	Point to the slow one	A	G
j. Temperature	Point to the cold one	A	G
k. Distance	Point to the one that is near	A	G
l. Comparatives	Point to the larger one	A	G
m. Superlatives	Point to the largest one	A	G
<i>Adverbs</i>			
a. 'ly' adverbs	Point to the friendly one	A	G
<i>Understanding Relational Words</i>			
Prepositions			
a. Locative	Put the hat in the box	A	G
b. Directional	Push the book under the table	A	G
c. Temporal	Do you go to church on Sunday?	A	G
<i>Conjunctions</i>			
<i>Articles</i>			
(Picture of a boy hitting a girl)			
a. Active declarative	The boy has hit the girl.	A	G/V
b. Yes/no question	Did the boy hit the girl?	A	G/V
c. Who question	Whom has the boy hit?	A	G/V
d. Negative	The boy has not hit the girl.	A	G/V
e. Negative question	Has the boy not hit the girl?	A	G/V
f. Passive	The girl has been hit by the boy.	A	G/V
g. Passive question	Has the girl been hit by the boy?	A	G/V
h. Negative passive	The girl has not been hit by the boy.	A	G/V
i. Negative passive question	Has the girl not been hit by the boy?	A	G/V
j. Complex sentences	Is this sentence complete or incomplete: "The nurse who comes in the morning"	A	G/V

Key: A = auditory; G = gestural; V = verbal.

Language intervention strategies in aphasia (3rd ed., pp. 80-120). Baltimore: Williams & Wilkins.)

Section II

Principles of Language Intervention

Chapter 5

Research Principles for the Clinician

Connie A. Tompkins, April Gibbs Scott,
and Victoria L. Scharp

OBJECTIVES

Most clinicians value the intuitive, artistic nature of their endeavors. Most also recognize that effective clinical management cannot proceed by intuition alone. As Kearns (1993) suggests, “failure to apply scientific thinking and measurement during the clinical process is surely as misguided as leaving our empathy, clinical intuition, and caring attitudes behind as we enter the clinical arena” (p.71). This chapter advocates a scientific approach to clinical decision-making, emphasizing primarily the clinician’s role as a consumer of research information. Other sections recount the advantages of a systematic approach to treatment planning and implementation, and suggest ways in which clinicians can contribute to the professional evidence base. Finally, some future trends are considered in the application of research principles to clinical intervention.

PERSPECTIVES AND DEFINITIONS

Setting the Stage: Some Key Concepts and Terms

The Research Process

For the purposes of this chapter, **research** can be viewed as a process of asking and answering questions, which is structured by a set of criteria and procedures for maximizing the probability of attaining **reliability**, **validity**, and **generality** of results (Silverman, 1985). Each of these factors affects the confidence one can have in the findings and conclusions of a research effort.

Reliability refers to the stability, consistency, or repeatability of results. Among the most well-known types are inter- and intra-observer reliability, and test-retest reliability. When standardized instruments or nonstandard probes are used to

document performance, these or related indicators (e.g., parallel/alternate-forms reliability) should be reported and evaluated. Standard error has an important role in the measurement of reliability. Standard error reflects the precision of any particular statistic (mean, median, correlation, proportion, difference between means, etc.) by estimating the random fluctuations that would be obtained if that same index were derived on repeated occasions. A statistic called the “standard error of measurement” estimates the consistency with which a particular test would measure performance on repeated administrations. The larger the standard error relative to the magnitude of obtained scores, the more difficult it is to tell whether any single score is truly different from some other score (e.g., whether there is a change after treatment). It is beyond the scope of this chapter to elaborate on the calculation and interpretation of standard error statistics, but Kerlinger (1973) is a good source for those who want more information.

Two less familiar forms of reliability also require brief mention. The first, **internal consistency reliability**, reflects the homogeneity of test items, and by inference, the extent to which those items measure the same construct. Items that are summed to generate a “total score” index of a single construct, such as “word-finding ability” or “communicative adequacy,” should have acceptable levels of internal consistency. If the items that are added together do not measure the same thing, combining them into a single score is like comparing the proverbial apples and oranges. Second, **procedural reliability** data reflect the consistency of implementation of the experimental conditions or treatment procedures in a research study. Also known as “reliability of the independent variable,” procedural reliability is often neglected in the language intervention literature. We will return to this concept in another section of the chapter.

Validity refers to “truth” of measurement. The definition of validity is illustrated by the following question: Are we measuring what we think we are measuring? Although many assume that validity is a fixed property of tests and measures, inferences about a measure’s validity will vary with its application. That is, claims of validity for any particular measure will be influenced by factors such as the conclusions one wishes to draw, the individuals who are tested, and the procedures that are employed.

For tests and other measurement instruments, the familiar types of validity are content, criterion (predictive and concurrent), and construct validity. Two other validity concepts are important for designing and evaluating research. **Internal validity** reflects how confidently one can attribute observed changes to the experimental treatments or conditions themselves, rather than to artifacts or confounding variables (Campbell & Stanley, 1966). **External validity** involves the generality or representativeness of results and conclusions (Campbell & Stanley, 1966), and concerns the extent to which findings can be expected to apply to particular populations, settings, or measurement and treatment variables.¹ It is important to remember that reliability is necessary for, but does not guarantee, validity. Ventry and Schiavetti (1980) give an example of a scale that is consistently off by 1/2 pound: it is a reliable (consistent) instrument, but not a valid one.

Treatment Outcomes and Their Measurement

In recent years, outcomes measurement has seen increasing emphasis on the multi-dimensional consequences of health problems and health-care provision. The idea is that a positive *outcome* (which can be defined simply as the result of any intervention) encompasses social, psychological, and attitudinal changes in addition to the traditional concerns with physical and physiologic improvements (Donabedian, 1980). Probably the best-known working framework for outcomes measurement is the World Health Organization's (WHO) International Classification of Functioning, Disability and Health (WHO, 2001). This framework distinguishes among three levels of functioning: body structure and function (formerly, "impairment"), activity (formerly, "disability"); and participation (formerly, "handicap"). Measurement at the level of body structure and function addresses specific anatomical, physiologic, or psychological impairments, such as agrammatic output in aphasia. The activity level is concerned with the influence of an impairment on an individual's activities and daily-life skills (e.g., agrammatism, apraxia of speech, and dysarthria may affect the ability to talk on the phone, to order a meal in a restaurant, or to read aloud to grandchildren). And assessment of participation reflects the effects of a health condition on social roles and life situations—for example, severely dysarthric speech restricts a teacher's ability to perform his or her job or diminishes a grandmother's ability to bond with her grandchildren.

According to Frattali (1998a), both efficacy research and outcomes research contribute to outcomes measurement. **Efficacy research** uses rigorously specified, well-controlled

protocols to evaluate a treatment under optimal conditions, whereas **outcomes research** is conducted in typical or routine circumstances. Because well-designed efficacy research minimizes potential confounds, its internal validity can be strong, rendering a high degree of confidence in its results. Outcomes research yields a lesser degree of confidence but may provide insights into processes and phenomena that cannot easily or validly be isolated and controlled.

Finishing this terminological survey, outcomes measurement can be aimed at documenting the efficacy, efficiency, effectiveness, and/or effects of treatment (see Frattali, 1998a, for a full discussion). There is little consensus about the meanings of these terms. Some link the terms "treatment effectiveness" and "treatment efficacy" with the conditions under which the data are gathered, suggesting that outcomes research yields evidence on the effectiveness of treatment, and only efficacy research can meet the standard for treatment efficacy data (see Frattali, 1998a). Robey and Schultz (1998) fold in another distinction, using the term "efficacy" to refer to the benefits derived from treating an individual patient (under ideal conditions), and "effectiveness" to indicate the benefits for a broader population (under typical conditions). So, for Robey and Schultz, demonstrating treatment efficacy is a prerequisite for establishing treatment effectiveness. However, in this chapter we follow Frattali and others in using the term **treatment effectiveness** as a higher-order concept concerning whether a treatment works (Kendall & Norton-Ford, 1982), regardless of the research method used to generate the evidence. From this perspective, both efficacy and outcomes research can be used to investigate treatment effectiveness, but with different degrees of control and consequent confidence in results (Frattali, 1998a).

Science as a State of Mind

Knowledge of methods used to maximize reliability and validity is essential for conducting and evaluating research, and a later section of this chapter examines some reliability and validity concerns related to language intervention studies. But as Chial (1985) reminds us, a commitment to science is also a state of mind. Some principles at the heart of a scientific orientation are summarized in Table 5-1.

An additional principle, central to a discipline such as clinical aphasiology, is a concern for **practical** or **clinical significance**, which calls for evaluating the relevance or meaningfulness of changes that are reported for research and treatment efforts. Is a statistically significant pre-post treatment change of 5% a clinically important difference? What about a two-fold increase in the number of times a client initiates a conversation with an unfamiliar person? There is no easy answer, as the importance of a change depends on factors such as the specific processes or behaviors

¹ The factors that compromise internal and external validity in research also affect the validation of a test instrument; for examples, consult Franzen (1989).

TABLE 5-1

Some Key Principles and Values of Science

Testability: Propositions and questions are specific enough to be evaluated
Replicability: Procedural specificity and detail are sufficient to allow findings to be reproduced
Objectivity: Dogmatism and bias are rejected; counterevidence and alternative interpretations are sought
Systematicity: Theories and experiments are evaluated and developed in a logical, orderly way
Tentativeness: The possibility and sources of error are recognized; the elusiveness of answers is understood
Concern for protection of human subjects: The welfare of those participating in research projects is paramount

being targeted, the client's needs and level of functioning, and the nature of the treatment goals.

The question of clinical significance can be formalized to some extent with reference to the WHO model (WHO, 2001). Improvements at the level of activity or participation are more relevant, meaningful, and important than changes that are limited to the level of body structure and function. We return to these issues later in the chapter.

Science and Clinical Decision-Making

While some clinicians may shudder at the thought of “doing research,” effective diagnosis and treatment are modeled on

the principles that guide scientific inquiry. Silverman (1985) emphasizes four principles in a scientific approach to clinical management: specifying clear objectives; posing answerable hypotheses and questions; observing systematically; and remaining aware of the tentative nature of the findings. We add a fifth: justifying the choice of measures and treatments as appropriate to clients' needs and clinical goals.

Parallels often have been drawn between research and clinical processes (e.g., Kent, 1985b; Silverman, 1985; Warren, 1986). For example, Nation and Aram (1984) suggest that careful diagnosis is like conducting a “mini research project” (p. 54). Table 5-2 illustrates the scientific nature of the diagnostic process (after Nation & Aram) by

TABLE 5-2

Some Useful Descriptive Information About Neurologically Impaired Persons

Brookshire (1983):	Age Education Gender Premorbid handedness Source of subjects	Etiology Time post-onset Severity of aphasia Type of aphasia Lesion location

setting out the chain of diagnostic steps that correlate with scientific problem-solving. The diagnostic literature has underscored this theme for decades. Johnson, Darley, and Spriestersbach (1963), for instance, emphasized diagnosis as a hypothesis-testing process, guided by principles of critical thinking, special observation skills, and impartial, precise, and reliable observation.

Clinically accountable treatment, which can be documented as efficacious and/or effective, is guided by these same procedures and principles. Using a hypothesis-testing model we would postulate what can be done to ameliorate a client's weaknesses and/or to compensate, modify, or accommodate other communicative obstacles the client may face. Then we would test and refine these clinical hypotheses as we evaluate our client's progress. Evidence-based practice (EBP), a recent emphasis in clinical practice, provides one framework and a set of procedures to help us make the best possible clinical decisions. EBP has been defined as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients . . . [by] integrating individual clinical expertise with the best available external clinical evidence from systematic research" (Sackett, Rosenberg, Muir Gray, Haynes, & Richardson, 1996). Individual client characteristics, preferences, and values are part of the EBP framework as well (Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). As the definition implies, clinicians need to learn how to locate, evaluate, and apply the available research in order to engage in EBP. This further underscores the value of science to clinicians, a topic we elaborate next.

The Value of Science to Clinicians

So why should clinicians care about research and science? At least five reasons are immediately evident. First, as discussed just above, the principles and skills of science are essential to accountable clinical practice, including EBP. Second, all of us must think critically to be wise consumers in life. For the purposes of this chapter, the need for critical thinking applies to the published data and continuing-education information that we consume professionally, and to the information we find on the Internet. Without critical evaluation, it is too easy to accept at face value anything that is published or presented at a professional conference, or located in an Internet search, especially when the author or presenter is known as an authority. Third, clinicians always have had an ethical responsibility to evaluate the impact of their services. In this vein, Rosenbek, LaPointe, and Wertz (1989) assert that "untested treatments are immoral, therefore clinical practice must include clinical experimentation" (p. 12). Fourth, and relatedly, clinicians can make important contributions to the evidence base that should form the foundation of diagnostic and treatment activities. Research is sorely needed to evaluate the effects, effectiveness, and

efficiency of various assessment and treatment approaches, with results documented at multiple outcome levels. Drastic reductions in reimbursement for services and increasing requirements to collect and report outcomes data (e.g., HCFA Outcomes and Assessment Information Set [OASIS] for home-care patients; JCAHO ORYX initiative for the accreditation of hospitals and long-term-care facilities, and for collecting core performance data and hospital quality measures) only underscore the urgency of generating a solid evidence base to justify clinical interventions. Finally, a scientific approach kindles informed curiosity, and keeps us thinking and growing professionally. A scientific attitude may help to stave off "burnout"; searching for another question or pursuing a different hypothesis definitely help to keep life interesting. The next sections of this chapter will highlight clinicians as both consumers and potential producers of research.

THE CLINICIAN AS RESEARCH CONSUMER

As clinicians, the research-consumer role is one of the most important that we can adopt. Participating in continuing-education efforts or scouring the Internet for the latest developments, while laudable, are worth little if we simply soak up or disseminate the information without critical evaluation.

Some Questions to Ask in Evaluating Research

The literature is replete with contributions that describe general principles for evaluating published material and presentations. Some of the most important considerations are recapitulated here, in the form of 12 questions for the consumer, with examples and elaboration specific to neurologic or aging populations. Most of these questions can be asked of both "basic" and "treatment efficacy" research. They are culled primarily from Kent (1985a), Silverman (1985), and Ventry and Schiavetti (1980),² but are represented in similar form in contemporary writings on the subject of research evaluation (e.g., Schiavetti & Metz, 2005). The order of the questions reflects the order in which a research consumer could answer them, when reading a research article. The American Speech-Language-Hearing Association (ASHA) Web site also provides excellent information about how to assess both the level and quality of evidence provided by any single study (www.asha.org/members/ebp/assessing.htm).

1. Are rationales and hypotheses provided, and are they convincing? The weight one gives to rationales and hypotheses will vary depending on their sources, which can include critical examination of literature,

² Some of these issues have been elaborated further by Tompkins (1992).

knowledge of normal and disordered processes, and clinical observation and intuition. Sound rationales and hypotheses most often originate from more than one of these roots. A rationale such as “I wonder what would happen if...” is, on its own, far from substantial and needs support and development from other sources. In most other instances, though, the value of a rationale will not be so clear-cut. Each of us must decide whether a convincing case is made for the study questions or hypotheses, whether they are explicitly posed or implied.

2. Are the research questions answerable? From the perspective of research evaluation, an answerable question is one that is explicitly specified. A well-specified question is like an appropriately written behavioral objective. There is an obvious difference between clinical goals such as “improving auditory comprehension” and “achieving 85% comprehension of Yes/No questions about implied main ideas in spoken eighth-grade level paragraphs.” The latter is measurable. To take another example, the generic efficacy question, “Does aphasia treatment work?” lacks operational specificity, and is impossible to answer in any one or even several studies. A more answerable question would indicate the nature of the treatment, the characteristics of patients to whom it is to be applied, and the criteria for determining if it has “worked.”
3. Do the participants represent the group(s) they are meant to represent? Using an example from aphasia, Darley (1972) emphasized long ago that researchers must define and operationalize what they mean by “aphasia.” The occurrence of one or more dominant hemisphere “strokes” certainly is not sufficient evidence to render the diagnosis of aphasia. Neither, alone or in combination with etiologic information, is poor performance on an aphasia test; low scores could reflect a number of other pre- or post-morbid conditions. Damage to the central nervous system also causes several varieties of non-aphasic language disturbance (e.g., language of confusion; language of generalized intellectual impairment in dementia; Wertz, 1985). This diagnostic distinction is more than a simple semantic one. We would not expect traditional aphasia treatments to benefit someone with an isolated dysarthria, or someone whose language impairments are embedded in an assortment of other cognitive problems such as confusion and severe memory disorder. To address this question, a research report should describe the criteria, rationales, and reliability for judgments about the essential communicative diagnoses and client characteristics. For qualitative or subjective judgments in particular, it is desirable to have independent verification by someone who is unaware of, or “blind” to, each participant’s specific status, and who does not have a stake in the outcome of the study.

4. Are the participants sufficiently described for the reader to assess the believability, replicability, and generalizability of results? Again drawing on aphasia to illustrate, a number of variables may influence results in treatment studies, such as duration of aphasia, severity of deficits, aphasia type, etiology, prior neurologic and psychiatric history, sensory and motor status, and literacy (Rosenbek et al., 1989; Shewan, 1986). Similar sets of factors affect research with other neurologically impaired populations, and some of the same variables are relevant for characterizing communication behaviors of normally aging adults. Of course, it is also important that component skills or prerequisites for processing and responding to treatment or probe stimuli (e.g., visual and auditory perceptual abilities) are specified and measured.

Brookshire (1983) suggests a minimum list of descriptors for clients with aphasia in his treatise on the subject of subjects. Others (e.g., Rosenbek, 1987; Rosenbek et al., 1989; Tompkins, Jackson, & Schulz, 1990) have offered additional possibilities and discussed novel ways to operationalize some of the tried-and-true descriptors (see Table 5–3). It is not practical, or even necessary, to expect all of these variables to be described in every study. However, having a greater number of well-operationalized descriptors such as these may make it easier for consumers to determine how to apply results, and for investigators to attempt replication and extension of reported findings. As Brookshire (1983) notes, including characteristics such as those discussed here also is important for the internal validity of a study. If such factors are not reported, readers cannot rule out the possibility that the results have been influenced in unintended ways. Detailed subject information is critical as well to begin formulating hypotheses about why certain participants do not respond as expected, or about which individuals might benefit most from particular interventions.

TABLE 5–3

Scientific Steps in the Diagnostic Process

1. Define and delimit the problem
2. Develop hypotheses to be tested; know what evidence is needed to evaluate them
3. Develop procedures to test hypotheses systematically
4. Collect the data: minimize bias and maximize validity
5. Analyze the data: score and organize objectively
6. Interpret the data: evaluate meaningfulness and support or reject hypotheses
7. Generalize from data: reason from the evidence to draw tentative conclusions

5. Are the procedures, conditions, and variables adequately specified? This question most obviously refers to the issue of replicability, but inadequate specification also may raise internal-validity concerns that diminish confidence in the results. Research reports should clearly present the essential aspects of procedures and conditions, and the operational definitions of the dependent (outcome) and independent (predictor) variables. For aphasia treatment trials, some important characteristics of the independent variable (the treatment) include the type and training of the clinician, amount and frequency of treatment, type of treatment, intensity of treatment, and nature of the no-treatment comparison condition (Rosenbek et al., 1989; Shewan, 1986). Treatment procedures, criteria or decision rules, and responses also should be described as precisely as possible. In addition, if several conditions are contrasted, clear operational distinctions should be provided and validated.
6. Are the procedures, conditions, and variables reliable and valid? Let us focus first on *reliability* issues. As noted earlier, the reliability (and validity) question can be asked of standardized measures. But often, psychometrically sound measures are not appropriate or available, and investigators develop or modify dependent measures of their own. When these specialized measures are used, researchers should provide the best data they can to address reliability concerns. Test-retest and standard-error information are crucial. Without them, it is impossible to determine whether changes on an outcome measure might be due to unstable (unreliable) measurements rather than an intervention. An estimate of test-retest characteristics can be made from multiple assessments taken in a baseline (pre-intervention) phase of single-subject experiments, and repeated measures can be taken for a similar purpose prior to implementing experimental procedures or treatments in a group study. The appropriate standard-error statistic can be calculated and evaluated as well.

Just as crucial are inter-observer and intra-observer reliability for dependent and independent variables, to be assessed in each phase of a study. Dependent-variable reliability data are needed to ensure that the scoring of outcome measures is objective and repeatable. Without evidence of acceptable agreement between independent judges, and of consistent scoring by the same judge, the research consumer has to question whether idiosyncratic decisions or unintentional bias could have affected the results. Independent-variable reliability data also are essential, to demonstrate that all aspects of the independent variable (in this case, the treatment) have been delivered consistently and as intended. Thus, research reports should document evidence of procedural reliability for various aspects of an intervention, such as the timing and selection of cues or prompts, and

the accuracy and delivery of feedback (see examples in Bourgeois, 1992; Massaro & Tompkins, 1993).

A variety of issues and procedures in observer reliability assessment have been discussed by Kearns and his colleagues (Kearns, 1990, 1992; Kearns & Simmons, 1988; McReynolds & Kearns, 1983). One caveat is that certain well-known correlation coefficients that often are reported to document reliability (e.g., Pearson r , Spearman ρ) are not the best choices for this purpose. These statistics only index the degree of association between two sets of scores, without taking into account exact score agreement. But two sets of scores can be highly associated (i.e., people who score high one time also score high the second time) and still be significantly different (see, e.g., Wertz, Shubitowski, Dronkers, Lemme, & Deal, 1985). If exact score agreement is of concern, as would be the case for reliability assessment, several other correlations are appropriate, including variants of the intraclass correlation coefficient (Shrout & Fleiss, 1979). Some other points to keep in mind are that levels of chance agreement should be considered when evaluating the acceptability of reliability indices (see Kearns, 1990, 1992), and that ceiling effects can skew reliability results.

We turn now to *validity* issues to continue illustrating Question 6. One specific concern relates again to the abundance of specially designed, nonstandardized measures in aphasiology research and treatment. It is unreasonable to expect such measures to have known validity, but readers should expect at minimum some evidence and logical arguments about the choice of items included, and about their internal-consistency reliability. From a broader perspective, a validity assessment should ask whether the reported observations were appropriate for answering the questions asked, and whether the investigator observed and described what he or she wished to³ (Silverman, 1985). Along these lines, readers should scrutinize the choice of outcome measures in light of the stated research goals. For example, if the goal of a study is to assess knowledge of particular syntactic constructions in aphasia, how appropriate would it be to rely on a test that requires spoken production of those constructions? The answer depends on a lot of factors, but one might question the validity of this plan because problems of response formulation and execution could mask intact syntactic knowledge. The validity of the connection between treatment and outcome measures also is paramount. As a hypothetical example, one might question whether reading comprehension, as an

³ Under these guidelines, it should be clear that Question 3 above bears on the validity of subject selection.

outcome goal, would be expected to improve after a treatment that focused on oral reading of single words. Readers should look for investigators to justify the link between their independent and dependent variables.

Let us return for a moment to an earlier maxim: reliability is necessary (though not sufficient) to ensure validity. The validity of a treatment also depends in part on demonstrating procedural reliability, or compliance with the experimental protocol.⁴ Wertz (1992) raises the issue of compliance in treatment studies, but his point applies to other kinds of research as well. Deviations from a protocol part way through a study, such as modifying selection criteria to include more participants, relaxing the amount of treatment or practice provided, or changing the clinician, can vitiate the validity of a research effort.⁵

A special validity problem in studies of people with aphasia and related impairments is how to account for “spontaneous recovery” in evaluating treatment outcome. This is discussed in Question 9 below.

7. Is the behavior sample adequate? Four senses of “adequacy” are considered here. The first concerns repeated measurement with the same instrument or task, which was emphasized above. Typically, one-shot measurement is not sufficient. Repeated measurements may be needed to assess the stability of the participants’ pre-treatment baseline performance, to gather data to approximate test-retest reliability before initiating a treatment or experimental manipulation, and/or to observe the timing or pattern of changes over the course of a study. The second sense of adequacy refers to the number of observations in each task. Generally, the more observations or items included in a measure, the more reliable that measurement will be. Brookshire and Nicholas (1994) demonstrate this point, showing that discourse measures based on single (short) speech samples are less stable than those based on a combination of samples. The third sense of adequacy refers to collecting multiple indicators at each measurement occasion, including measures that index treated behaviors and conditions as well as untreated behaviors and conditions. For example, multiple measurements are needed in treatment studies to assess whether an effect has generalized beyond that which is specifically trained (and perhaps as a control for “spontaneous recovery”; see Question 9). Finally, comprehensive assessments in multiple environments or contexts will enhance the generalizability of results.

8. Are precautions taken to reduce potential, even unknowing, bias? It is well-documented that both examiners’ and participants’ expectations can introduce critical biases in a research investigation. Hence the emphasis in medical research on “double-blind” studies, which keep both investigators and participants unaware of whether any individual participant is assigned to a treatment or control group. In language intervention studies, beyond keeping investigators blind to each participant’s group (and even diagnosis) whenever possible, another control for experimenter bias is to have different examiners provide treatment and evaluate treatment data. An additional check on examiner bias is achieved when independent inter-observer reliability is demonstrated to be high for selecting participants, adhering to procedures, scoring outcomes, and judging the existence and magnitude of treatment effects. The influence of participant expectations (“placebo effects”) can be evaluated through simultaneous measurement of treated and untreated “control” behaviors. If all behaviors respond similarly over the course of treatment, it is possible that something other than the treatment was responsible for the changes. Question 9 elaborates on this approach as a check on the influence of spontaneous recovery.

9. Are the data interpreted appropriately? Two facets of this question are considered. One element concerns whether the results could be due to something other than the factors that interest the investigator. This is an issue of internal validity. Threats to internal validity probably can never be ruled out entirely, but an investigator should acknowledge and discuss their possible influence, and be appropriately cautious in providing interpretations and conclusions.

It is beyond the scope of this chapter to review all threats to internal validity (see discussions in Campbell & Stanley, 1966; Ventry & Schiavetti, 1980; and Schiavetti & Metz, 2005; and for a more general reference on alternative interpretations, see Huck & Sandler, 1979). However, several major internal-validity threats are discussed here from the perspective of language-intervention research. One that is important in group-treatment trials is the composition of no-treatment control groups. A randomly assigned control group is essential for demonstrating efficacy in group studies (Wertz, 1992). But since it has generally been believed that it is unethical to deny treatment, this crucial condition is rarely met.⁶ Rather, control

⁴ Assessing procedural reliability also would be important for studies comparing treatments; treatment delivery would need to be monitored to ensure that the treatments retained their intended distinctions.

⁵ But a later section of this chapter will point out the flexibility of single-subject experimental designs, as long as modifications are analytically motivated and systematically applied.

⁶ Wertz et al. (1986) solved this dilemma by including a deferred treatment group, whose progress during the no-treatment phase could be analyzed as control data. Elman and Bernstein-Ellis (1999) used a similar approach in a study of the efficacy of group treatment for aphasia.

groups typically are self-selected, consisting of patients who, for example, live in remote areas without access to treatment, elect not to participate, or cannot pay for treatment. A self-selected control group may differ from the treatment group in critical ways that are relevant to the response to treatment. The consequence is that differences in outcome between treatment and control groups may be attributable to these pre-treatment inequalities and not to the treatment *per se*. A related difficulty centers around differential dropout from a study. There are a variety of reasons that clients drop out of treatment studies: they may be too ill or too severely impaired to participate; they may have improved enough that they no longer want treatment; they may not be aware of a continued need for treatment; they may not like the treatment they are receiving. Any of these sorts of factors may make the groups unequal, biasing the results of the study.

Another difficult problem for the internal validity of language intervention research is a possibility of concurrent other treatments and/or prior treatments interacting with the treatment of interest. Perhaps the other treatments paved the way, bringing the client to the point at which he or she was ready to profit from the intervention under study. This is one example of an order effect. More generally, the order and sequence with which conditions are applied in a study may influence the reported results. Sequence and order effects may even affect results on a day-to-day basis. For example, if conditions are arranged in a fixed order or sequence, fatigue or warm-up effects may adversely affect some performances and not others. Conditions should be randomized or counterbalanced in group studies, and in across-subject replications of single-subject experimental designs.

The influence of spontaneous or physiologic recovery is nature's version of an "interacting treatments" problem. Physiologic improvement brings about behavior changes that can be extremely difficult to separate from changes we would like to attribute to our treatments. Some researchers have tried to skirt the issue by conducting their treatment investigations in neurologically stable patients, years beyond the presumed effects of spontaneous recovery. One limitation of this approach is that no one knows the duration and timeline of spontaneous recovery (particularly for those with traumatic brain injuries). Another concern is that most language and communication treatment is delivered in the period shortly after onset of the disabling condition, so it is imperative to evaluate interventions for those who may still be undergoing neurologic restitution.

For a large group-treatment trial, random assignment to treatment and control groups is one solution.

Then the effects of spontaneous recovery are assumed not to differ between groups (Wertz, 1992). However, random assignment does not ensure group equality, particularly for the small sample studies that tend to populate the literature on aphasia and related disorders. Another approach is to measure several "control behaviors" that are approximately equal in difficulty to the target behaviors, but that the treatment is not expected to influence. If the recovery curve is steeper for treated than for untreated functions, treatment may be responsible for the changes.⁷ Multiple baseline designs (McReynolds & Kearns, 1983), which track untreated behaviors while others are treated, can provide evidence of this sort for individual participants. Each time treatment is applied to a previously untreated behavior, the slope of change for that behavior should accelerate if treatment is exceeding the influence of spontaneous recovery. Single-subject experimental designs that allow reversal and reinstitution of treatment effects for the same behavior in the same individuals (McReynolds & Kearns, 1983) also can provide convincing evidence of the influence of treatment over spontaneous recovery.

A related issue in interpreting the results of intervention studies is that apparent treatment effects might have resulted from the time and attention given to the client, rather than from the content and/or process of treatment. Again, the simultaneous measurement of treated and untreated behaviors can help to address this issue. This problem also can be diluted by taking repeated measurements in a pre-treatment baseline phase, where participants are being given time and attention.

Another set of potential problems in attributing results to the experimental conditions involves the influence of factors that have demonstrated relationships to language and cognitive performance in non-neurologically-impaired individuals. Some of these include age, hearing ability, medical risk factors, education/premorbidity intelligence, and literacy (see Tompkins, 1992, for elaboration). It is important to remember that not all "errors" are due to a patient's neurologic condition. A good example of this point comes from Yorkston and her colleagues (Yorkston, Farrier, Zeches, & Uomoto, 1990; Yorkston, Zeches, Farrier, & Uomoto, 1993), who demonstrated that certain measures of word usage and grammatical complexity differed according to socioeconomic status in

⁷However, another dilemma is that it is not known whether the rate, timing, or extent of spontaneous recovery is comparable for different behaviors or functions. Lesser change in an untreated function may simply represent a difference in the "recovery schedule," or in the complexity of the treated and untreated behaviors.

non-brain-damaged adults. Similarly, Tompkins et al. (1993) reported that several connected speech attributes thought to characterize adults with right hemisphere brain damage did not distinguish their speech samples from those of normally aging adults. And, in a study of 180 normal native Spanish speakers, Ardila and Rosseli (1996) found significant relationships between performance on a picture-description task and the variables of age, gender, and education. The lesson is that findings for people with neurologic impairments must be evaluated against the appropriate control data and expectations.

The last statement exemplifies the second facet of Question 9: given what we already know, does the interpretation ring true? Evaluating interpretations at this level requires knowledge of or access to current theory and data, and a sense of their validity and replicability.

10. Are maintenance and generalization programmed and probed in treatment studies? This question is related to issues of adequate behavior samples and multi-dimensional outcomes. It is important to plan treatments to maximize the likelihood of their generalizing (see Kearns, 1989; Thompson, 1989), and to assess whether treatment effects in fact do generalize to untrained exemplars and to other ecologically valid measures, situations, and conversational partners. Kearns (1993) indicates that generalization planning involves “comprehensive, multifaceted evaluation; the establishment of generalization criteria; incorporation of treatment strategies that might facilitate generalization; continuous measurement and probing for functional, generalized improvements; and, when necessary, extending treatments to additional settings, people and conditions until targeted levels of generalization occur” (p.71). If generalization beyond the treated tasks is not apparent, the practical significance of treatment effects is in doubt. Similarly, maintenance of treatment gains should be assessed. It is rare for long-term maintenance data, much more than a few weeks after the end of treatment, to be provided in language-intervention studies. One exception is found in Freed, Marshall, & Frazier (1997), who monitored maintenance of intervention gains for 13 weeks after the end of treatment (see also Marshall & Freed, 2006). Evaluating maintenance of gains over extended time intervals should become a priority.
11. Are individual participant characteristics related to the reported outcomes? Individual performance can be analyzed in group data, and factors that appear to contribute to success or failure can be evaluated. Most clinical manipulations, such as inserting pauses to improve a client’s auditory language comprehension, affect some individuals and not others (e.g., Nicholas & Brookshire, 1986). In order to apply findings to

other individuals, it is important to try to identify what characterizes those with good and poor response.

12. Is there some attempt to evaluate the meaningfulness or importance of changes attributed to the experimental manipulations? We return to the issue of practical significance here, and raise the related concept of “effect size.” Metter (1985) suggested that some neurologists’ skepticism about aphasia treatment stems from concerns about the relevance of specific improvements in treated deficits to real-life, functional goals. Goldstein (1990) reviews several approaches for examining clinical significance, including normative comparisons of target performance, and subjective evaluations of changes effected. Results of these types of assessments currently appear in some language intervention research. For example, normative comparison data in the aphasia literature have been gathered by assessing the frequency of requests for information by neurologically intact adults in conversations with unfamiliar partners (Doyle, Goldstein, Bourgeois, & Nakles, 1989), and by examining non-brain-damaged adults’ usage of social conventions (Thompson & Byrne, 1984). Studies by Doyle, Goldstein, and Bourgeois (1987) and Massaro and Tompkins (1993) exemplify two varieties of subjective evaluation, assessing listeners’ ratings of the adequacy of selected communication parameters following language intervention. Whitney and Goldstein (1989) used a hybrid approach, in which subjective evaluations were made of aphasic adults’ speech samples intermixed with samples from non-brain-damaged control speakers.

When a research procedure or clinical intervention is not expected to lead directly to a functional outcome, several other measures of “importance” can be reported. Analysis of effect size has a precise statistical meaning (e.g., Cohen, 1977), but the idea is to determine how “large” or meaningful some statistically significant difference really is. Wertz (1991) suggests evaluating the size of a difference between groups of scores by examining their distributions for overlap or separation. This could be done by calculating the 95% confidence intervals for each set of scores, using standard-error estimates. Another way to assess the importance or strength of an experimental effect is to set a predetermined difference criterion; for example, designating a change of at least one standard-deviation unit, or a doubling or tripling of baseline performance, as clinically meaningful. To convey some indication of the strength of an observed group effect, researchers can report the number or percentage of participants in a group study whose performance conforms to the overall, average pattern, and/or who

achieve the designated criterion for meaningful change.

THE CLINICIAN AS INVESTIGATOR

As a prelude to this section, it is important to acknowledge that recent changes in the service-delivery climate have made it virtually impossible for most clinicians to participate in research efforts. But despite some very real practical limitations, we think there is value in the perspective and information that follows. We are convinced that the most important thing we can do as a discipline to garner both credibility and reimbursement for our services is to appeal to the soundest evidence base possible to justify their efficacy and effectiveness. While it is clearly necessary to collect outcomes data for treatments as they are typically delivered, it also is critical to conduct treatment research that goes beyond what is dictated by the current clinical climate, as a means to determine what would be possible under less constrained circumstances (e.g., with more intense treatment, or more sessions to establish overlearning). The small number of researchers in our discipline simply cannot tackle these problems alone. Thus we hope that clinicians who read this will be inspired to take part, at some level, in these crucial evidence-gathering efforts.

Contributing to the Scientific Data base

Clinicians can contribute meaningfully to their professional literature, although there will almost certainly be obstacles along the way (see, e.g., Schumacher & Nicholas, 1991; Warren, Gabriel, Johnston, & Gaddie, 1987). A collaborative relationship with established investigators will be a crucial source of guidance and support. One goal of ASHA's focused initiative on evidence-based practice (EBP) is to provide a Web-based environment to link clinicians and researchers for collaborative investigations (www.asha.org/members/ebp/fi-06-ebp.htm). Exploring such connections, clinicians might, for example, find an opportunity to become an important part of a data-gathering team for a relatively large investigation initiated by someone other than themselves. Interested clinicians also may be able to initiate collaborative investigations on topics of their own choosing. For example, with the support of established researchers, clinicians may be able to evaluate the outcomes of their own interventions—in some cases through efficacy research but more likely by collecting outcomes data. Alternatively, clinicians may be able to contribute more generally to information in the field, helping to provide much-needed data through original studies or replications and extensions of existing work. The next sections of this chapter focus on clinician-initiated research, but the information is also relevant for interested clinicians who would rather assume a more peripheral research role.

Clinicians Evaluating Their Own Interventions

Treatment-Efficacy Investigations

Single-subject or within-subject experimental designs (e.g., McReynolds & Kearns, 1983) are probably the most appropriate designs for clinicians who wish to become involved in evaluating the efficacy of their own treatments. While the EBP movement emphasizes evidence from systematic research and large randomized controlled trials, single-subject experimental designs will remain important whenever sufficient evidence is lacking (e.g., for atypical or rare client profiles, for understudied populations such as individuals with bilingual/multilingual aphasia, for newer service-delivery models such as telerehabilitation, or for relatively new additions to the scope of practice such as right hemisphere language disorders).

Derived from behavioral psychology, single-subject experimental designs are not glorified case studies. Well-conceived single-subject experimental designs are built around important components of scientific inquiry, such as operational definitions, attention to reliability and validity, and control of extraneous variables. The designs incorporate repeated measurements of observable, operationally-defined target behaviors, with independent scoring of a portion of those behaviors by more than one examiner, to demonstrate objectivity and consistency. Stable pre-intervention baseline data, collected on the clearly specified dependent variables, are used as reference points for evaluating the efficacy of replicable interventions conducted with well-defined participants. The effects of these interventions are evaluated continuously within and across design phases (e.g., baseline, treatment, return to baseline or maintenance); across behaviors; and/or across patients. Although tightly controlled and well suited to maximize internal validity, the designs allow flexibility in treatment when a need for modification becomes apparent (Connell & Thompson, 1986; Kearns, 1986a; McReynolds & Thompson, 1986).

Those unfamiliar with single-subject experimental designs may equate them with pretest-posttest studies, but the two are quite dissimilar. In a pretest-posttest design, a target behavior (e.g., some aspect of reading comprehension) is assessed once prior to treatment, an intervention is applied, and then the target behavior is measured again. While this design often is used to gather "outcomes data," it generates only a weak form of evidence about a treatment's effects because of inherent threats to internal validity; any number of factors other than the treatment of interest could have caused a change from the first measurement to the second. In fact, some would not grant the status of "evidence" to the results of pretest-posttest studies (for further discussion, see Campbell & Stanley, 1966; Ventry & Schiavetti, 1980).

Single-subject experimental designs are discussed in detail in a number of sources (e.g., Connell & Thompson,

1986; Kearns, 1986a; McReynolds & Kearns, 1983; McReynolds & Thompson, 1986). Kent (1985a) provides a useful table illustrating a variety of research questions, along with some of the single-subject designs that are appropriate for addressing those questions. Examples of studies using these designs with neurologically-impaired adults also are available in the aphasiology literature (e.g., Ballard & Thompson, 1999; Doyle, Oleyar, & Goldstein, 1991; Edmonds & Kiran, 2006; Feeney & Ylvisaker, 2003; Freed et al., 1997; Garrett & Huth, 2002; Kearns & Potechin Scher, 1989; Kiran & Thompson, 2003; Massaro & Tompkins, 1993; McNeil et al., 1998; Moss & Nicholas, 2006; Thompson & Shapiro, 1995; Whitney & Goldstein, 1989; Yoshihata, Toshiko, Chujo, & Kaori, 1998).

Despite the strengths of these designs, there remain relatively few published examples. The difficulty of implementing controlled research in a clinical environment is no doubt largely responsible for this situation. In describing their efforts to evaluate a treatment approach for a patient with fluent aphasia, clinicians Schumacher and Nicholas (1991) recount a variety of problems that they faced when conducting research in their clinical setting. They question the feasibility of single-subject research in the clinical arena, unless a clinician is provided with release time for research, or with assistance for collecting and analyzing data. Warren et al. (1987) suggest that the major difference between typical clinical procedure and rigorous study is the time required to conduct behavior probes for no-treatment tasks and phases. In addition, designing and implementing generalization probes outside the treatment setting takes time and planning. Beyond feasibility problems, the often highly-specific treatments used in single-subject research do not necessarily generalize to the needs of other clients (e.g., Franklin, 1997).

These barriers notwithstanding, we agree with Schumacher and Nicholas (1991) and Warren et al. (1987), who clearly believe that clinicians can generate worthwhile research in certain conditions. Those who have the drive to tackle a research problem, and who consult with knowledgeable researchers before starting, could probably evaluate a number of questions in their clinical settings, particularly if they enlist assistance in scoring, checking scoring reliability, and the like. If several clinicians in one location are interested, they can share these tasks, or graduate students from local university programs can be recruited and trained to assist. Some of the kinds of studies that clinicians can probably implement most readily are described below.

Treatment-Outcomes Research

In an ideal world, ethical considerations would motivate and support the collection of credible evidence about treatment effectiveness. In the real world, emerging regulations and accreditation requirements will ensure the accumulation of

at least some level of treatment-outcomes data. ASHA's National Outcomes Measurement System (NOMS) has provided one vehicle for collecting and analyzing outcomes data. With a goal of developing a national database for speech-language pathologists and audiologists, the NOMS project advocated the use of 11 pre- and post-treatment functional measures, scored on 7-point scales, to provide some estimate of treatment effectiveness. Demographic and consumer satisfaction data also have been collected. The NOMS database was intended to serve as a resource for selecting interventions and advocating for or justifying reimbursement for clinical services. ASHA's recent EBP initiative (www.asha.org/members/ebp/default) has in large part subsumed these goals, bringing ASHA practices in line with those in the broader community of clinical service providers around the world.

As indicated above, treatment outcome studies are conducted in the typical setting without stringent controls, yielding less confidence in results than would rigorously-designed studies. However, clinicians can enhance the rigor of their treatments, their data-gathering efforts, and the resultant outcomes data by attending to the scientific principles discussed thus far.⁸ To recapitulate, these include operationally specifying the nature of the client's abilities and the treatment plans; maximizing reliability and validity of measurement and treatment implementation; collecting an adequate behavior sample, including repeated measurements; attempting to control or account for extraneous factors such as spontaneous recovery; programming for and measuring generalization to untreated behaviors and settings; assessing the maintenance of behavior change after treatment ends; examining potential factors related to success or failure; and assessing social validity to determine whether any changes effected have "made a difference."

Clinicians Contributing More Generally to the Professional Literature

Several avenues are probably most feasible for clinicians who wish to contribute to our clinical evidence base: evaluating outcomes (or efficacy) related to established treatment programs; replicating or extending existing studies; analyzing factors that may be important in interpreting assessment data or in implementing treatments; and gathering comparative performance data from persons without neurologic impairments. Each of these is considered briefly below.

Evaluating Outcomes of Established Programs

Numerous treatment programs exist, and are recommended to clinicians, with only a cursory evidence base, if any.

⁸ Of course, as Kent and Fair (1985) warn, equating science with effective clinical problem-solving may dilute or trivialize the meaning of the former, and misrepresent or overlook some of what occurs in the latter.

Clinicians are well-situated to evaluate these sorts of programs. One model of this kind of work is provided by Conlon and McNeil (1991), who examined the efficacy of Visual Action Therapy (Helm-Estabrooks, Fitzpatrick, & Barresi, 1982) for adults with global aphasia. Another example comes from Freed and colleagues (1997), who assessed the long-term effectiveness of PROMPT treatment (Chumpelik, 1984) for a client with apraxia of speech and aphasia. When attempting to evaluate these kinds of programs, clinicians may note that the specification of treatment procedures is inadequate to allow consistent treatment delivery. In this case, a good deal of planning and work must go into the project up front to specify stimulus choices, cueing/prompting criteria and hierarchies, scoring procedures, and the like. However, after that it becomes a much simpler matter to carry out the treatment program and to use it with other potential candidates. An example of this approach can be found in Massaro and Tompkins (1993), who operationalized a Feature Analysis treatment program (Szekeres, Ylvisaker, & Cohen, 1987) that has been recommended for traumatically brain-injured patients, and gathered some data about the program's efficacy with two patients.

Conducting Replication and Extension Studies

Replication and extension studies are particularly lacking in the speech-language pathology research base. But they are important in part because so much of our research has been done on small samples of participants, who exhibit a limited range of characteristics. Attempting to replicate the findings from an already published project with another sample of participants, or to extend the study using different participants, stimuli, or settings, is an excellent way for a clinical researcher to begin. Some examples of replication and extension studies can be found in Beard and Prescott (1991); Bloise and Tompkins (1993); and Kimelman and McNeil (1987). Bastiaanse, Bosje, & Franssen (1996) also reported a study replicating a treatment approach used in two previous investigations for word-finding problems. The work of Kearns and Potechin Scher (1989) and Byng, Nickels, and Black (1994) presents an even less-frequent phenomenon: replication and extension by the original investigators. Typically, page limits on publications preclude researchers from providing complete methodological detail, so anyone who wishes to replicate a study would need to contact the original authors for specific materials and procedures.

Analyzing Factors that Influence Delivery and Interpretation of Assessments of Treatments

Questions about the content, procedures, or interpretation of assessment tools have motivated a variety of clinical research. These kinds of questions typically stem from clinical observation; as such, they are good candidates for the interested clinical investigator. In one example, Nicholas,

MacLennan, and Brookshire (1986) evaluated a number of reading-comprehension batteries, and documented the extent to which the comprehension questions could be answered without reading the associated passages. In other work, Nicholas, Brookshire, MacLennan, Schumacher, & Porazzo (1989) revised and standardized the administration and scoring procedures for the Boston Naming Test, to improve their specification. The authors reported extended normative data for their revision as well. Investigations also have focused on determining the psychometric properties of abbreviated versions of standardized assessment instruments, such as DiSimoni, Keith, & Darley's (1980) evaluation of a shortened form of the Porch Index of Communicative Ability (Porch, 1981). Another set of inquiries has focused on whether hypothetically important elements of treatment programs have an effect in practice. For example, several studies have examined whether the "new information" principle of PACE therapy (Promoting Aphasics' Communicative Effectiveness; Davis & Wilcox, 1985) has observable effects on narratives elicited from adults with aphasia (Bottenberg & Lemme, 1991; Brenneise-Sarshad, Nicholas, & Brookshire, 1991).

Gathering Normal Comparison Data

Judgments of our clients' abilities and performance should be made against a backdrop of knowledge about the non-neurologic factors that may influence performance on language and cognitive tasks. Among the possible influences, noted earlier, are factors such as age, education, literacy, socioeconomic status, physical health, or hearing impairment; however, few relevant data are available. Clinicians can design protocols to gather group data as a partial response to this need. Some examples are provided by Parr (1992), who examined everyday reading and writing practices of normal adults; Hansen and McNeil (1986), who studied writing with the nondominant hand; Elman, Roberts, & Wertz (1991), who documented the influence of education on judgments of non-neurologically-impaired adults' writing and drawing samples; Tompkins et al. (1993), who assessed some characteristics of performance in normally aging adults' picture descriptions; and Yorkston et al. (1990; 1993) who reported on the discourse performance of non-brain-damaged participants who were similar in terms of socioeconomic status to the "typical" traumatically brain-injured patient.

In any context, practical concerns affect the kinds of questions or problem areas that one can study. Time-demands and the need for consultation and support personnel have already been emphasized; having equipment and facilities on hand also is important. For group data-collection, the availability of appropriate participants is a major issue. Funding also is a likely concern, but it may be possible to run some studies, particularly those evaluating established

treatments, as part of routine clinical practice (see, e.g., Kearns, 1986b; and Massaro & Tompkins, 1993)—particularly if the clinician is willing and able to spend some extra time in the workplace. In the end, personal interests and the perceived value of the research may be the most important motivators for clinicians deciding to embark on the research enterprise.

Some Competencies for Researching Clinicians

With assistance from expert collaborators as needed, a clinician-investigator should be able to formulate answerable questions that have practical significance, and to make the necessary observations — with acceptable levels of validity and reliability — to offer tentative answers. These skills presume current knowledge in the content area (e.g., the nature of neurologic disorders and their treatment; the nature of normal language and cognition) as well as familiarity with guidelines for evaluating research. Persistence and tolerance for imperfection are important personality characteristics, because, as Warren (1986) reminds us, there is no perfect design for any study. Compromises are always necessary, in research as well as in clinical endeavors.

Initiating a Research Project

When clinicians decide that they have the appropriate interests, competencies, and supports, they can begin developing a research project. The first step is to hone the idea that sparked interest in the investigation. This can be accomplished by consulting with experts and by reviewing the available literature, to see what aspects of the research problem have not been addressed adequately, or at all. Computerized databases such as PsycLIT, PsychINFO, and Medline, and abstract journals such as *Psychological Abstracts* and *Index Medicus* will help interested readers locate the relevant literature. Google Scholar (<http://scholar.google.com>) is also a good source for a discerning eye; the National Institutes of Health's CRISP database (<http://crisp.cit.nih.gov>) provides abstracts of funded research projects; and the ASHA Web site (www.asha.org/default.htm) allows ASHA members to search the main speech-language pathology and audiology journals. For those who wish to study neurologic disorders of language and communication, particularly in adults, publications from the Clinical Aphasiology Conference (e.g., Lemme, 1993; Prescott, 1989, 1991a, 1991b; and more recently in dedicated issues of the journal *Aphasiology*) are all available at <http://aphasiology.pitt.edu>, and are particularly valuable references. *Aphasiology* (www.ingentaconnect.com/content/02687038/) also periodically dedicates an entire issue to a feature called a "Forum", which presents a lead article on a topic, and subsequent commentary by other investigators. This format alerts readers to subject matter and questions of

current interest. Gaps in the evidence-base can also be identified by searching current compendia of treatment evidence and/or treatment guidelines. For aphasiology and related disorders, some such information resides at the ANCDs Web site (www.ncds.org/practice.html). ASHA's National Center for Evidence-Based Practice also provides a searchable registry of systematic evidence reviews (www.asha.org/members/ebp/compendium) and links to other relevant sites (e.g., the Royal College of Speech-Language Therapists site, www.rcslt.org). It is worth noting that some relevant evidence will be overlooked in such compendia, due to various potential biases in the EBP review process (e.g., publication bias, funding bias; Elman, 2006).

While reviewing the relevant literature, the reader should try to determine what factors point to the need for further investigation in an area of interest. For example, the quality of the study may be at issue: control for spontaneous recovery or examiner bias may be in doubt; the operationalization of the dependent measures may be debatable; the findings may have limited generalizability given the size and characteristics of the participant sample; or the durability and meaningfulness of results may not be addressed. A project can be developed to rectify particular issues of concern, or to replicate and extend findings in research that is essentially sound.

Planning can proceed by focusing on the questions that have been outlined above, for research consumers. Brainstorming with others about the best ways to operationalize and measure variables, or about how to minimize factors that might confound the results, is a valuable activity. And again, it is probably wise to check preliminary ideas and plans with someone who has research expertise. Doing so before a study is initiated can help avoid later problems of interpretation. It is also recommended that the methods be pilot-tested on at least a few people before the actual data collection begins. Even experienced investigators generally identify wrinkles that remain to be ironed out during initial feasibility testing.

Finally, in the planning phase, clinician-investigators should ascertain the requirements and procedures of their institution's Research and Human Rights Committee, Institutional Review Board, or similar committee. These committees are responsible for reviewing all planned research protocols in order to protect the rights of research participants and to minimize research risk in relation to projected benefits. Typically, these committees ask for a description of the aims, procedures, and risks and benefits of the proposed research, along with specific precautions taken to protect participants' research rights and the privacy of their personal information and research data. A detailed consent form, spelling out these elements for the participants, also is essential.

Often an investigator has to make modifications to a research protocol after the research committee's initial review, and in general, it can take quite a while for such

committees to grant final approval. As a result, an investigator's goals may have to be modified to some extent unless and until there is an already-approved research protocol. For example, it may not be possible to investigate changes for an individual client during the typical period of spontaneous recovery from stroke. With help from a research collaborator, the clinician-investigator may be able to frame a research question and appropriate methods prospectively, in a way that can be applied to the next patient(s) who fit the study criteria.

Opportunities for Funding and Consultation Assistance

Funding may be an important consideration, either for partial salary coverage in order to obtain release time to plan and conduct a project, or for paying research assistants or participants. A variety of funding opportunities may be available for clinician-investigators, depending on their level of expertise. Several are outlined below.

1. The American Speech-Language-Hearing Foundation (ASHF) has for a number of years sponsored New Investigator research grants for those who have recently completed their latest degree program. ASHF also awards New Century Scholars grants, which have two funding elements: one for doctoral students who plan to work in an academic setting in the United States after graduation, and one for teacher-investigators. Information about each of these opportunities is available at <http://www.asha.org/foundation/grants/>.
2. ASHA provides a range of information, and even some funding. For example, (a) the ASHA Research Listserv (www.asha.org/members/research/reports/research_list.htm) gives a weekly update on opportunities for funding, fellowships, conferences, and workshops. Requests to subscribe to this on-line mailing list can be sent to asha-research-digest-request@lists.asha.org. (b) A section of the ASHA Web site called "Grants and Funding for Researchers" (www.asha.org/members/research/grants/) includes topics such as "Grants and Grantsmanship," which primarily gives information about grants available from the National Institutes of Health (NIH), including those for new investigators; and "Resources for Grantwriting and Funding," which provides a directory of grants, foundations, and agencies that have funded clinical-research efforts in communication disorders, as well as a list of relevant publications and Web sites. (c) ASHA's Special Interest Division 2 (Neurophysiology and Neurogenic Disorders) offers a small grant to supplement ASHF New Investigator awards. (d) For students of all levels, ASHA publishes a manual called "Funding Sources: A Guide for Future Audiologists, Speech-Language Pathologists, and Speech, Language, and Hearing Scientists." This manual provides information on funding assistance and is sold in ASHA's on-line store (www.asha.org/shop).
3. Governmental funding may be available, as well, through highly competitive grants. For example, the NIH offers a variety of opportunities. The NIH Small Grants Program (R03; www.nidcd.nih.gov/funding/types/researchgrants.asp) provides 2 years of funding to support pilot projects and feasibility research for investigators with limited research experience. NIH Career Development Awards, or K-awards, are intended for people who hold a doctoral degree, but who have primarily clinical training (<http://grants1.nih.gov/training/careerdevelopmentawards.htm>). For predoctoral or postdoctoral student-investigators, the NIH also funds individual fellowship grants (F31, F32 awards, http://grants1.nih.gov/grants/funding/funding_program.htm). Language researchers would most likely apply for NIH funding from the National Institute on Deafness and Other Communication Disorders (NIDCD, www.nidcd.nih.gov/index.asp), but some projects might be fundable by the National Institute on Aging (NIA, www.nia.nih.gov) or the National Institute of Mental Health (NIMH, www.nimh.nih.gov). For those who wish to have more information about the grants process, the NIH offers regional seminars on program funding and grants (see <http://grants1.nih.gov/grants/seminars.htm>). Other governmental sources of funding include (a) the U.S. Department of Veteran's Affairs Merit Review program (www1.va.gov/resdev/funding/professional_dev.cfm), which provides funds for initiating research efforts to new investigators both inside and outside that system; and (b) the Canadian Institutes of Health Research (<http://www.cihr-irsc.gc.ca/e/780.html>, formerly Medical Research Council of Canada), which lists opportunities for research in Canada and supports training awards for clinician-scientists and new-investigator salary awards, among others.
4. Internal institutional funding may be available in some cases. Some hospitals and rehabilitation centers sponsor competitions for funding, or release time, to encourage staff research efforts. Many universities grant seed monies for pilot projects that are expected to lead to larger efforts; a clinician-investigator's project, sponsored by a faculty member, might be partially fundable in this way. Universities also may have funds to help support dissertation research. Universities also offer courses on grantsmanship.
5. Individual grant support may be available from private foundations associations and foundations, such as the Alzheimer's Disease and Related Disorders Association (www.alz.org/professionals_and_researchers_researchers.asp), the American Association of University

Women (www.aauw.org/education/fgaindex.cfm), and the Sigma Xi Research Society (www.sigmaxi.org/programs/giar/index.shtml).

The value of consulting assistance has been emphasized repeatedly in this chapter. The way to get the most out of a consultative relationship is to consult before beginning a project, rather than trying to salvage mistakes later. But best-laid plans being what they are, a good consultant also may be able to help rescue some elements of an errant project after the fact. A clinician-investigator should not be afraid to seek help with a project by contacting people with the appropriate expertise.

There are a variety of avenues for identifying potential consultants. As noted previously, ASHA is creating an Internet resource to link clinicians and researchers for collaborative research (www.asha.org/members/ebp/fi-06-ebp.htm). Conferences and workshops provide another venue. The AHSF has put on several workshops on treatment-efficacy research, and in recent years, ASHA has sponsored travel fellowships that give new and minority investigators the opportunity to present research, completed or in progress, at the Science and Research Career Forum and the Research Symposium that coincide with ASHA's annual convention. The Academy of Neurologic Communication Disorders and Sciences (ANCDS, www.ancds.org) provides its members with opportunities to exchange information and ideas, and with an annual education and scientific meeting the day before the ASHA convention. A clinician-investigator who is the first author on a research effort can secure an invitation to the Clinical Aphasiology Conference (www.clinicalaphasiology.org) by submitting a research abstract for evaluation by the program committee, whether or not the paper is accepted for presentation; two authors can attend if the paper is accepted. Student investigators also have an opportunity to compete for funding to attend the Clinical Aphasiology conference, thanks to a conference grant from the NIDCD. Attending such conferences is valuable for both continuing education and networking purposes, but simply reading published conference proceedings or consensus reports can also point clinicians towards experts who might be willing to serve as research consultants.

University faculty members or master clinicians who publish their work would be good contacts as well. Other sources of possible expert consultants are professional journals, which list their authors and reviewers, and Web sites associated with specific disorders (e.g., www.aphasia.org; www.strokeassociation.org; www.parkinson.org) that provide information and links about relevant research. Information and consultants for interdisciplinary investigations also can be culled from the national and international governing bodies for related disciplines (e.g., occupational therapy: <http://www.aota.org/>; physical therapy: <http://www.apta.org/>; neurology: <http://www.aan.com/>). The

ASHA Web site provides its members with helpful information for establishing interdisciplinary collaborations (www.asha.org), which applies to initiating and sustaining any types of collaborative relationships.

Selling the Administration on Your Research Plans

Investigators in most clinical settings would need administrative approval and support for their research efforts. Silverman (1985) provides arguments related to increasing the institution's accountability to various consumers, such as clients, payers, and the community; maximizing the effectiveness of service delivery; and garnering recognition and grant support. Warren (Warren et al., 1987), a clinician and an administrator, also points out the value of efficacy data for demonstrating accountability to quality-assurance evaluators and third-party payers. The costs involved are justifiable with relation to the enhanced confidence with which outcomes can be linked to treatments provided.

FUTURE TRENDS IN THE CLINICAL APPLICATION OF RESEARCH PRINCIPLES

Level of Outcome and Clinical Significance

Clinical significance and meaningfulness of outcomes have been recurrent themes in this chapter. Third-party payers' requirements for functional treatment goals indicate that these concerns are paramount from a reimbursement perspective as well. It is anticipated that the future will see much more attention to documenting the clinical importance of changes effected by interventions.

To date, research and clinical intervention in aphasia and related disorders has focused most often at the level of body structure and function (impairment) rather than on social communicative functioning (but see, e.g., Brown et al., 2006). As suggested earlier, this may have contributed to the poor opinion of our profession held by some neurologists and other medical personnel. It is certainly critical to implement and evaluate interventions that target more ecologically valid outcomes, such as conversational proficiency, whenever possible. But one obvious dilemma in doing so is that there are almost assuredly intermediate or prerequisite steps to clinically-relevant outcomes. As such, it is probably legitimate to focus for some period of time on the impairment level, especially in the initial stages of treatment. When treatments are not intended or expected to result immediately in clinically significant gains, it will be incumbent upon investigators to specify the eventual pathway from their treatment focus to the desired end result, indicating why or how their treatment goal should be an important step along the way to some meaningful outcome.

Another problem in targeting ecologically valid outcomes is that they can be difficult to operationalize, and consequently

to measure. A variety of generic rating scales have been used to quantify “functional outcome” (see Frattali, 1998b), but in many cases, their reliability, validity, and sensitivity to change have been questioned. The ASHA-FACS (Functional Assessment of Communication Skills; Frattali, Thompson, Holland, Wohl, & Ferketic, 1995), which provides a more extensive and specific evaluation of communicative disability for adults with aphasia and traumatic brain injury, is a good supplement to these general assessments. Recent research has expanded the value of the ASHA-FACS Social Communication Scale (Donovan, Rosenbek, Ketterson, & Velozo, 2006). Donovan and colleagues found that a 4-point rating could be substituted for the original 7-point rating; that caregivers could rate items reliably on this subscale; and that the Key form can be used to demonstrate treatment progress. These investigators also cautioned that the Social Communication subscale measures two constructs (understanding and conversing) instead of just one. The Communicative Activities in Daily Living (CADL-2; Holland, Frattali, & Fromm, 1999) is another option for assessing functional communication. More recently, the Burden of Stroke Scale (BOSS; Doyle, 2002; Doyle, McNeil, Hula, & Mikolic, 2003) was established as a valid and reliable patient self-report measure of function and well-being (Doyle et al., 2004). The BOSS allows assessment of communication difficulty and distress, among other measures.

Two additional means for demonstrating the functionality of treatment outcomes are to achieve generalization to everyday settings and tasks and to document the social validity of treatment outcomes. And if effects that are generalized and meaningful can be shown to have staying power, so much the better. To examine the durability of clinically important changes, investigators should begin to assess clinical significance or social validity using data from several phases of treatment studies, including that collected during maintenance probes.

Social-validity assessments are relatively new and infrequently used, so standards and criteria for conducting them are still evolving. The future should see more attempts to develop a rigorous technology for determining social validity. The concerns of reliability, validity, and generalizability are paramount here as they are in any measurement effort. Questionnaires and rating scales should be constructed so that the resulting data are sound.

Silverman (1985) discusses several other critical factors such as the design of the social validity tasks; numbers and characteristics of raters, including their knowledge of subject group or time of sample; and selection of the scaling method. One of the salient questions (Campbell & Dollaghan, 1992; Goldstein, 1990; Tompkins, 1992) has to do with the choice of the “gold standard” for a normative comparison approach to determining clinical significance. When patients are severely impaired, an appropriate standard might be one that approximates the communicative performance of a milder, but functional, aphasic communi-

cator. For mildly involved patients, a normal criterion may be appropriate. Whatever the comparison group, though, we foresee more care in specifying individual participant variables that should be relevant, including some of those identified above. The common practice of matching comparison and treatment subjects only for chronologic age and gender will be recognized as insufficient.

As procedural issues are being sorted out, much more work also will be needed to assess the correspondence between these sorts of social-validity data and other measures of communication performance in natural environments. The assessment of real-life behaviors, experiences, and phenomena is at the core of a nontraditional research approach that complements the scientific orientation described earlier in this chapter. This “qualitative research” approach (see, e.g., Denzin & Lincoln, 1998; Strauss & Corbin, 1998) involves detailed data-gathering through extensive interviewing and observation of communicative behaviors and social interactions in a variety of authentic contexts. The investigator relies on “disciplined subjectivity” (Heron, 1996, p. 143) to interpret the accumulated information and generate hypotheses about processes that are at work. Simmons-Mackie & Damico (1996) emphasize the goodness-of-fit between the qualitative research perspective and the assessment of “participation” (WHO, 2001) in aphasia. They describe a Communicative Profiling System that uses qualitative methods to evaluate communication behaviors and strategies, contextual influences on communication, and the available network of communication partners. Conversation Analysis (Goodwin & Heritage, 1990; Shiffrin, 1994), a qualitative research method derived from discourse studies, provides another frame of reference for evaluating communicative success in aphasia. This approach has been used in several investigations (e.g., Ferguson, 1993; Milroy & Perkins, 1992) to explore dynamic aspects of conversational collaboration, and has been adapted for clinical use in such programs as SPPARC: Supporting Partners of People with Aphasia in Relationships and Conversation (Lock, Wilkinson, Bryan, Maxim, Edmundson, Bruce, et al., 2001). Some treatment studies (e.g., Perkins, 1995; Perkins, Crisp, & Walshaw, 1999) have combined quantitative and qualitative methods in an effort to establish a more complete clinical picture than would be obtained by either approach alone. While lacking elements of rigor identified earlier in this chapter and particularly susceptible to (unintended) examiner bias, qualitative approaches can provide a rich source of ideas for those who are interested in documenting, describing, and characterizing meaningful outcomes.

Developing the Evidence Base in Bilingual/Multilingual Aphasia

Growing numbers of people across the United States have diverse language backgrounds, and more than half of the

world's population is at least bilingual. Yet there are very few systematic, theoretically, and methodologically sound studies that examine within- and across-language treatment for bilingual/multilingual aphasia. Edmonds and Kiran (2006) recently published an admirable investigation with a single-subject experimental design that provides a useful model for future work. The difficulties in this area of study are many: e.g., a lack of conceptual models of bilingual/multilingual language processing, of assessment tools with adequate psychometric properties, of clinicians with diverse language backgrounds, and of access to interpreters. Nonetheless, this area of clinical investigation is vital, and is fully expected to receive increasing attention in the future.

Evaluating Effectiveness of Nontraditional Treatment Approaches

Even before funding pressures prompted increasing exploration of alternatives to direct individual language treatment, some interest in nontraditional options was evident. We expect to see heightened attention to establishing the effectiveness of nontraditional intervention approaches, including those that involve communication partners, provide therapy in a group context, rely on computerized treatment delivery, involve telerehabilitation, or incorporate pharmacotherapy.

Targeting communication-partner behaviors, instead of or in addition to those of the individuals with communication disorders, remains a relatively untapped but potentially important direction in treatment research (see Turner & Whitworth, 2006, for a recent review). After all, communication is an interactive process, and its success hinges on the interplay between participants. Turning some attention to the neurologically intact member of a communicative dyad would have considerable ecological validity. And with clients receiving less direct treatment, it will become more imperative to rely on communication partners as intervention agents.

Some research has already explored interventions that focus on the communication partner rather than the person with aphasia (e.g., Kagan, Black, Duchan, Simmons-Mackie, & Square, 2001; Purdy & Hindenlang, 2005; Simmons-Mackie, Kearns, & Potechin, 2005). For example, Simmons, Kearns, and Potechin (1987; see also Simmons-Mackie et al., 2005) evaluated an intervention to diminish inappropriate partner behaviors, such as interrupting before the participant with aphasia has time to respond. Additionally, Flowers and Peizer (1984), and Simmons-Mackie & Kagan (1999) reported systems designed to quantify partner strategies and to identify those that were more or less successful in communicative exchanges, so that they could be addressed in treatment. Measures of conversational burden (e.g., Marshall, Freed, & Phillips, 1997; Packard & Hinckley, 1999) also have been used to describe dynamic partner interactions, and to isolate variables such as topic initiation

that can be manipulated in therapy. In their recent review, Turner and Whitworth (2006) underscore in particular the limited available information about the influence of a conversation partner on the outcomes of a person with aphasia. And in a twist on this theme that emphasizes the level of participation, Cruice, Worrall, and Hickson (2006) recommend training the friends of people with aphasia on how to maintain social relationships with their aphasic friends. In short, the area of conversation-partner training remains ripe for further investigation and evaluation.

Relatedly, the future also may see more efforts to train communication partners as intervention agents (e.g., Bourgeois, 1991; Burgio et al., 2001; Kagan et al., 2001). This approach may accomplish several goals simultaneously: it can bring the intervention to the natural environment, free some of the clinician's time, and allow more treatment to be delivered than would otherwise be feasible or affordable. It also may empower communication partners by giving them some specific things to do in the event of communication breakdown. One such model, Supported Conversation for Adults with Aphasia (SCA), has been developed by Kagan (1995, 1998). SCA offers individuals, including those with severe aphasia, the opportunity to interact with volunteer partners who are trained to support conversational-level communication using a range of methods and expressive modalities. In a randomized, single-blind, controlled study, Kagan et al. (2001) demonstrated the effectiveness of SCA in improving the conversational skills of trained communication partners. After training, the adults with aphasia who conversed with these trained partners were also improved, on both information transfer and interactional variables.

Obviously, either of these approaches can have a number of pitfalls. A clinician would have to invest time to train the communication partners, and to monitor delivery of treatment and/or evaluation of responses. Personalities and prior patterns of interaction between communication partners also may mitigate against these methods, or diminish their effectiveness. In addition, it may be difficult to get reimbursement for services that target communication partners, unless creative outcome measures are employed or until sufficient high-quality evidence is available. And of course, rigorous evaluation of effectiveness will be necessary, as it is for any language-intervention approach. Despite these possible drawbacks, the potential benefits of interventions that involve the neurologically-intact communication partner are likely to spur further exploration in the future.

Another nontraditional intervention approach, group treatment, has the potential to enhance generalization of treatment gains because the group context provides a relatively natural setting within which to target both linguistic and communicative goals. Group therapy for aphasia is increasingly being considered a viable adjunct to individual treatment, and in many cases may serve as the primary therapeutic milieu. This

undoubtedly is due in part to reimbursement constraints, but evidence is emerging that group aphasia therapy can effect positive outcomes. The seminal Veteran's Administration cooperative study comparing the effects of individual and group aphasia treatment (Wertz et al., 1981) as well as other more recent studies (e.g., Avent, 1997; Bollinger, Musson, & Holland, 1993; Elman & Bernstein-Ellis, 1999; Marshall, 1993) have demonstrated improvements on both standardized and referential language measures, as well as in functional communication abilities, for individuals at all severity levels in various group-treatment approaches. Kearns (1994) reviews factors to be considered in providing and evaluating group therapy for individuals with aphasia, and a number of other current references discuss methods for delivering and assessing group treatment of patients with aphasia (e.g., Elman, 1999; Marshall, 1999). Group-treatment approaches have also been used with the relatives of people with aphasia, with or without the aphasic partners in attendance. A few recent examples are provided by Hinckley and Packard (2001) and van der Gaag et al., (2005). These studies have demonstrated improvements for the person with aphasia at the levels of impairment (communication skills), (van der Gaag et al., 2005), functional activities (Hinckley & Packard, 2001), and family relationships/quality of life (Hinckley & Packard, 2001; van der Gaag et al., 2005). Group treatment also has been evaluated in other populations, such as traumatic brain injury (Rath, Simon, Langenbahn, Sherr, & Diller, 2003). One obstacle to analyzing the effectiveness of group treatment specifically is the complexity of implementing rigorous data-collection for multiple participants, who may have multiple goals.

Computer-aided approaches to language treatment are also burgeoning, and the future promises to see expansion of efforts in this area as well. The accumulating evidence in aphasia (e.g., Fink, Brecher, Schwartz, & Robey, 2002; Katz & Wertz, 1997; Laganaro, Di Pietro, & Schnider, 2003; Raymer, Kohen, & Saffell, 2006; Wallesch & Johannsen-Horbach, 2004) shows some promise of improvements in language performance with computer-delivered therapy, as well as generalization of learned skills to noncomputer language contexts, mostly when a clinician is also involved. The potential advantages of group treatment, such as cost-effectiveness and the opportunity to tailor tasks for individual patients, must be weighed against possible disadvantages such as a lack of procedural flexibility and limited opportunities for communicative interaction and exchange for the person with aphasia. A more complete discussion of the merits and drawbacks of computer-aided aphasia rehabilitation was published by Roth and Katz (1998). As with the other nontraditional treatment approaches that are discussed here, computer-delivered aphasia therapy must be subjected to rigorous evaluation over time to establish its effectiveness and efficacy. Wertz & Katz (2004) recently provided an evaluation of selected studies in the area, along with their thoughts about improving the evidence base.

Telerehabilitation is another clinical service model that is on the rise (see, e.g., www.atmeda.org, the Web site of the American Telemedicine Association). ASHA recently held a grant competition for model telepractice programs as part of its initiative to increase Web-based service delivery (www.asha.org/about/publications/leader-online/archives/2003/q2/030415d.htm). This initiative was designed to facilitate the delivery of quality health-related information and clinical services to those who face access barriers, such as lack of availability of clinicians with appropriate and specialized expertise. The aphasiology literature is beginning to include some examples of studies that use telepractice methods to measure performance in aphasia and related disorders (e.g., Brennan, Georgeadis, Baron, & Barker, 2004), but there is a long way to go to document the effectiveness and efficacy of treatment thus delivered. To the extent that specific telepractice models and methods can be conceptualized as subsets of the area of computer-assisted intervention, recommendations for improving the evidence base on computer-aided treatment (e.g., Wertz & Katz, 2004) will be highly relevant to telerehabilitation as well.

Lastly, two forms of biologic intervention may have promise as nontraditional approaches to treating aphasia. One, still in its infancy, involves artificially implanting tissue into the brain to increase the number of synaptic connections among or between residual intact regions. Research that uses tissue or cell transplantation aims to reorganize neural circuitry to help the recipient regain function (Small, 2004). Pharmacotherapy is another biologic approach for which definitive benefits remain unknown. Some critical reviews of pharmacotherapy in aphasia (e.g., Small, 1994; Small, 2004) document the spectrum of its use and reported effectiveness, which ranges from no benefit to some positive results when administered as an adjunct to traditional language therapy. Pharmacologic intervention has been investigated for several decades now, but further research is necessary to determine its value for aphasia and related language disorders.

KEY POINTS

1. Research and clinical decision-making processes have a number of parallels.
2. A scientific orientation to clinical management has value for a variety of reasons; among these are that clinical accountability is enhanced by following the hypothesis-testing approach that guides scientific inquiry, and that reimbursement decisions for treatment will rest increasingly on a clinician's knowledge and application of high-quality evidence.
3. Clinicians should become critical consumers of the relevant evidence base, regardless of the format in which it is provided (e.g., EBP reviews, individual studies, conference presentations, continuing-education coursework).

4. Reliability, validity, and generalizability of results are important concepts in the evaluation of research. Clinical significance should be addressed as well in evaluating research and treatment efforts.
5. Outcomes measurement comprises both “efficacy research,” which involves rigorous, controlled experimental documentation of the effects of treatment, and “outcomes research,” which documents the results of treatment in typical circumstances. Outcomes research yields less confidence in results but is important for evaluating phenomena that cannot easily be isolated or controlled.
6. As used in this chapter, the term “treatment efficacy” refers to evidence that is generated from efficacy research, while “treatment effectiveness” refers more broadly to evidence about how well a treatment works, regardless of the rigor of the research method.
7. Outcomes assessment also can be characterized with reference to a multi-dimensional model of the consequences of health conditions, such as the World Health Organization classification scheme of body structure and function, activity limitation, and participation restriction.
8. A set of principles, reviewed and illustrated in the chapter, can be used to evaluate both basic and applied research. These focus on issues germane to study rationale, design, and interpretation.
9. Clinicians can satisfy empirical, ethical, and practical concerns by becoming involved in clinical research, and their participation in this process is crucial to the development of a sufficient evidentiary basis for treatment. Clinicians may best be able to contribute by collecting treatment-outcomes data, participating in treatment-efficacy studies, replicating and extending existing studies, evaluating published assessment tools and treatment approaches, and/or gathering normative comparison data.
10. Several public and private funding resources are available to both new and experienced clinician-investigators.
11. Established researchers can offer valuable consultation and collaboration to support clinician-investigators in their research endeavors.
12. The future is expected to see increasing emphasis on evaluating the functional and social consequences of treatment, increasing the evidence base in bilingual/multilingual aphasia, and documenting the effectiveness of nontraditional treatment approaches involving communication/conversation partners, group treatment, computer-based interventions, telerehabilitation, and pharmacotherapy.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Discuss the benefits of a scientific approach to clinical decision-making. Are there any drawbacks?
2. Debate Rosenbek, LaPointe, & Wertz’s (1989) opinion that “untested treatments are immoral. . .” (p. 12).
3. Which of the threats to internal validity of a treatment study would be the easiest to solve or avoid? Why? Which would be the most difficult, and why?
4. (a) Evaluate a published treatment study, using the 12 criteria in this chapter. (b) Keeping in mind that no research effort can be, or is, perfect, and using your treatment-study evaluation as a guide, discuss how your confidence in the outcome has been affected.
5. Discuss how the concepts related to internal validity could be applied to improve your clinical work.
6. Can you see yourself contributing to the scientific data base in some way? Why or why not? And if “Yes,” how?

Chapter 6

Aphasia Treatment: Recovery, Prognosis, and Clinical Effectiveness

Leora R. Cherney and
Randall R. Robey

OBJECTIVES

The objectives of this chapter are to (1) describe the typical time course and pattern of recovery in individuals with aphasia; (2) review current information regarding the neuroanatomical and neurophysiologic mechanisms underlying recovery and rehabilitation; (3) identify neurologic and personal factors affecting prognosis; and (4) review scientific evidence regarding clinical outcomes of treatments provided by speech-language pathologists.

Clinicians who treat individuals with aphasia have frequently sought to uncover indicators of recovery. Reliable information regarding factors associated with positive recovery as well as factors associated with negative recovery impact several clinical decisions and actions, including determining prognosis, counseling significant others, and identifying candidates for treatment. Basso (1992) has differentiated between neurologic factors and anagraphic factors. Neurologic factors are related to etiology, size and site of lesion, and severity and type of aphasia. In addition, through modern neuroimaging technologies, there has been an increased focus on pathophysiologic indicators of recovery, the long-term cerebral changes related to resolving aphasia, and the neurophysiologic consequences of therapeutic interventions. Anagraphic factors include personal characteristics such as age, sex, handedness, and health status. One of the difficulties encountered in research on recovery from aphasia and prognosis is that many of these factors are interrelated. For example, site of lesion determines to some extent the type of aphasia; size of lesion and type of aphasia have some implications for severity; and type of aphasia may not be independent of age. Nonetheless, clinicians have relied on the extensive literature examining the effects of these factors on recovery to guide their clinical decision-making.

The range of clinical decisions extends beyond prognosis and candidate identification. Once the decision to treat is warranted, clinicians must settle on justifiable treatment(s), a weekly schedule of treatment, and the duration of treatment. The purpose of this chapter is to review the information base underpinning the broad range of clinical decisions, from prognosis to treatment schedules. The chapter proceeds in two major sections. First, studies related to recovery are summarized, with particular emphasis on the factors that may be considered when determining prognosis. Second, the scientific base underlying treatment-related decisions is reviewed. However, the sectioning has been imposed merely for organization purposes and it will be readily apparent that these topics are not mutually exclusive, and, in fact, interact with one another.

RECOVERY

Time Course of Recovery

Two stages in the recovery of function have been differentiated, an early stage and a late stage (Kertesz, 1988). The early stage, when maximum language recovery takes place, coincides with the period of spontaneous recovery, and is considered by investigators to occur within 1 to 3 months post-onset of aphasia (Kertesz & McCabe, 1977; Vignolo, 1964). Spontaneous recovery drops precipitously by 6 to 7 months post-onset (Vignolo, 1964), with little or no spontaneous recovery occurring after 1 year (Kertesz, Harlock, & Coates, 1979; Kertesz & McCabe, 1977). Therefore, spontaneous recovery has a decelerating curve, steepest in the first month post-onset, subsequently flattening out, and finally reaching a plateau between 6 and 12 months post-onset (Basso, 1992; Benson & Ardila, 1996).

A prospective study of 330 patients with aphasia supports a pattern of recovery from aphasia consistent with that of spontaneous recovery (Pederson, Jorgensen, Nakayama, Raaschou, & Olsen, 1995). Patients with aphasia were evaluated on admission to the hospital, weekly during their

hospital stay, and then at 6 months post-discharge. The investigators found that stationary language function was reached in 84% of the patients within 2 weeks, and in 95% of the patients within 6 weeks from onset of stroke. Similarly, Pashek and Holland (1988), in their longitudinal study of 43 individuals with aphasia, noted that improvement most frequently began at about 1 to 2 weeks post-onset; furthermore, by 3 months, the clinical status of most of the patients approximated the clinical status that was measured at 12 months.

Late or long-term recovery may take place months or even years after onset of stroke. However, the degree of recovery can vary greatly from patient to patient. For example, Hanson, Metter, and Riege (1989) conducted a retrospective study that followed 35 males with aphasia from 3 to 55 months post-onset. Patients were evaluated with the Porch Index of Communicative Abilities (PICA) on five factors—speaking, writing, comprehension, gesturing, and copying. Language performance continued to evolve over years, with some patients improving significantly, others stabilizing, and others (10 of 35) regressing. No medical factor could be found to account for the regression, but it was noted that language decline occurred in those patients with relatively milder aphasia.

Pattern of Recovery

Despite individual variation in rate and extent of recovery, there seem to be some general patterns of recovery that have been identified for each type of aphasia. Kertesz and McCabe (1977) studied the evolution of aphasia using the Western Aphasia Battery aphasia quotients obtained serially at 45 days, and at 3, 6, and 12 months. They found that 39 of 93 patients (41.9%) changed aphasia type as they recovered. Similarly, Pashek and Holland (1988) followed 43 subjects from the acute stage (within 5 days post-onset) and subsequently at 3, 6, and 12 months post-onset. Using descriptive criteria to define aphasia type, they found that approximately 60% of the sample evolved and were reclassified, with each type of aphasia showing a pattern of evolution. They noted that change most frequently began at about 2 weeks post-onset, with most types of aphasia evolving within the first month (except conduction aphasia, which typically showed a change at about 6 months post-onset) to that of anomic aphasia. Patients who presented initially with a fluent aphasia continued to demonstrate a fluent type of aphasia. Anomic aphasia was often the end-point attained by patients regardless of whether they initially presented with fluent or nonfluent aphasia (Kertesz & McCabe, 1977; Pashek & Holland, 1988).

McDermott, Horner, and DeLong (1996) have provided further information about the evolution of the different aphasia types. They followed 39 patients and evaluated them regularly with the Western Aphasia Battery. They confirmed

that the direction of evolution appears to operate under some constraints, and that aphasia subtypes differ in their evolution. Like Pashek and Holland (1988), they found that patients who presented initially with a fluent aphasia continued to demonstrate a fluent type of aphasia.

The investigators also noted that aphasia severity may interact with the evolution of aphasia (McDermott et al., 1996). Patients with nonfluent or fluent aphasia who evolved from one aphasia type to another were less severely affected than those who did not evolve. However, magnitude of change, and not initial severity, was the critical variable underlying aphasia evolution. Those patients who evolved from one aphasia type to another had greater aphasia quotient changes from the first test session to the second than those who did not, suggesting that improvement in language performance is a necessary condition for evolution of aphasia type. Specifically, it was found that an aphasia quotient change of 20 points or more predicated aphasia type evolution in about two-thirds of the patients with both fluent and nonfluent aphasia.

Several studies have investigated the evolution of typology in patients with severe or global aphasia. Pashek and Holland (1988) found that age was a factor in the evolution from global aphasia. There was a trend for younger patients to evolve to a Broca's aphasia, while older patients remained global or evolved to a Wernicke's aphasia.

Nicholas, Helm-Estabrooks, Ward-Loneragan, and Morgan (1993) followed 24 subjects with severe aphasia, of which 17 were global. Patients were evaluated with the Boston Assessment of Severe Aphasia (BASA) at 1 to 2 months, 6, 12, 18, and 24 months post-onset. The greatest amount of improvement occurred in the first 6 months. While most of the patients with global aphasia showed improvements on the BASA, they did not change classification and remained global.

From a study of 54 patients with global aphasia, Ferro (1992) concluded that there are five different types of global aphasia, depending on the site of lesion, and that each type has a different outcome. Patients with global aphasia resulting from large fronto-temporoparietal lesions with or without subcortical damage had the poorest prognosis and remained global at follow-up. In contrast, the best prognosis was found for those patients with large subcortical infarcts. None of these patients remained global; one patient was not aphasic at follow-up, while the others evolved to transcortical motor aphasia or anomic aphasia. The other three possible localizations for the infarcts that cause acute global aphasia are (a) frontal lesions with or without subcortical involvement; (b) posterior parietal infarct, with or without subcortical involvement; and (c) a double lesion composed of a frontal and temporal cortical infarct. These patients showed a variable degree of recovery, improving to Broca's or transcortical aphasia. Ferro (1992) also found that the first 3 months was the crucial period for improvement, in

contrast to the findings of Sarno and Levita (1971), who suggested that the greatest changes for global aphasia were evident in the 6- to 12-month period post-stroke.

Several longitudinal studies have considered the pattern of recovery as it relates to the individual language modalities, and a consistent trend has emerged. Typically, a higher percentage of patients improve in comprehension as opposed to production, and a higher percentage improve in oral as opposed to written language (Hanson & Cicciarelli, 1978; Kenin & Swisher, 1972; Lomas & Kertesz, 1978; Prins, Snow, & Wagenaar, 1978). Basso, Capitani, and Moraschini (1982) found that improvements of oral and written comprehension and production were usually associated. However, in some patients who do not receive rehabilitation, comprehension may be the only modality to improve.

These results are supported by Mazzoni et al. (1992), who assessed a selected sample of 45 patients, none of whom received language therapy, over a 7-month period. The investigators found that comprehension had the best recovery, independent of type and severity of aphasia. In addition, differences in language recovery were evident in relation to type of aphasia. For patients with fluent aphasia, oral expression and written expression improved steadily throughout the 7 months. Auditory comprehension improved for 4 months, while reading comprehension improved over the first month. For patients with nonfluent aphasia, significant improvement was evident in auditory comprehension over a 4-month period. Expression showed less recovery, often because it was negatively influenced by the presence of oral apraxia, while no significant changes were evident in written language. Similarly, Hanson et al. (1989) contend that recovery of language modalities may be dependent on the category of the aphasia. However, they caution that differences in recovery between aphasia categories may become apparent only after 2 years post-onset.

Severity of Aphasia

The initial severity of the aphasia is an important factor to consider in the recovery from aphasia, not only because of its direct impact on outcome (Basso, 1992; Marshall & Phillips, 1983; Marshall, Tompkins, & Phillips, 1982; Paolucci et al., 1996), but also because of its interaction with other factors affecting recovery. Indeed, Pederson et al. (1995) have stated that initial aphasia severity is the single most important factor for ultimate language function. In their investigation of the time course of recovery, they found that patients with more severe aphasia demonstrated a longer period of language recovery than patients with less severe aphasia. More specifically, 95% of patients with severe aphasia reached maximum function within 10 weeks; 95% of patients with moderate aphasia reached maximum function within 6 weeks; while only 2 weeks was required for 95% of those with a mild aphasia to achieve maximum function.

Mazzoni et al. (1992) also found that initial severity was related to outcome of each language modality. For a moderately severe group of 21 patients, both oral expression and written expression improved uniformly over 7 months; auditory and reading comprehension showed no significant improvement, because performance on these modalities was initially at a near normal level. For a severely impaired group of 24 patients, auditory comprehension and, to a lesser extent, reading comprehension improved significantly, while no significant improvement was observed for oral or written expression. Similarly, Mark, Thomas, and Berndt (1992) found that initial severity as measured by performance on language tests, rather than neuroradiologic characteristics, correlated strongly with outcome for a group of patients with global aphasia.

Neural Mechanisms of Recovery

The preceding discussion has focused primarily on descriptive accounts of the behavioral changes that occur during recovery from aphasia. However, it is important to consider, also, the neuroanatomical and neurophysiologic mechanisms contributing to recovery. While these are not completely understood, technologic advances in the area of brain imaging have allowed researchers to address those factors that play a role in early and long-term recovery.

Spontaneous recovery, which occurs naturally without special treatment, may be due, in part, to the resolution of local factors such as the reduction of cerebral edema, the absorption of damaged tissue, and improvement of local circulation. However, these factors probably do not play a role in long-term recovery of function (Bach-Y-Rita, 1990).

Rather, of greater interest to the rehabilitation professional, are those factors associated with brain plasticity. Brain plasticity, which permits enduring functional changes to occur, refers to the capacity to modify structural organization and functioning. According to Bach-Y-Rita (1990), several mechanisms may contribute to brain plasticity: (1) Diaschisis refers to depressed function or hypometabolism of structurally normal cortical regions remote from the lesion, due to the sudden interruption of synaptic connections with the region. Diaschisis may occur within the damaged left hemisphere as well as in the contralateral right hemisphere (Andrews, 1991; Feeney & Baron, 1986). Some long-term recovery may occur with the dissipation of diaschisis, although its mechanisms are not well understood. (2) Regenerative and collateral sprouting refers to changes in connections between neurons from intact cells to denervated regions. Collateral sprouting has been demonstrated in some neural structures, including the thalamus and the cerebellum. While collateral sprouting may be a mechanism of functional recovery, it also may be a maladaptive response, leading to abnormal function. Further studies are needed to clarify its importance to recovery from central-nervous-system lesions.

(3) Unmasking of preexisting but functionally depressed pathways or substitution may be the most important mechanism for recovery. This cortical reorganization occurs when axons and synapses that are present but not used for the particular function under study can be called on when the usually dominant system fails.

Hillis and Heidler (2002) also hypothesize that functional recovery from aphasia involves at least three overlapping stages. The acute stage, occurring in the first few days after stroke, involves the recovery of transiently impaired neural tissue in the ischemic penumbra, the area of the brain surrounding the core infarct. Although this area receives sufficient blood to survive, it is not enough to function. Restoration of function occurs only following increased blood flow to this area. The second stage of recovery begins within days of the stroke, continues for weeks, months, or possibly years after onset, and involves reorganization of structure and function relationships. When the reorganization is complete, further recovery (the third stage) depends on establishing new pathways for processing components that were “cut off” by the brain damage as well as learning compensatory strategies to facilitate more effective communication.

Neuroanatomical Factors: Lesion Size and Site

A basic assumption about recovery from aphasia has been that lesion size exerts a negative influence on recovery (Demeurisse & Capon, 1987; Ferro, 1992; Goldenberg & Spatt, 1994; Kertesz et al., 1979; Kertesz, Lau, & Polk, 1993; Ludlow et al., 1986; Mazzoni et al., 1992; Selnes et al., 1983). Furthermore, lesion size may affect each modality differentially. For example, Selnes, Knopman, Niccum, Rubens, & Larson (1983) found that there was a significant negative correlation between lesion volume and recovery of comprehension for large but not smaller lesions. According to Mazzoni et al. (1992), patients with small lesions demonstrated significant recovery in oral and written expression; comprehension changes were not significant because comprehension was relatively unimpaired initially. Patients with medium-sized lesions improved significantly in all modalities except written expression, while those with large lesions demonstrated improvement in auditory comprehension only. However, Basso (1992) asserts that while the negative effect of extent of lesion on initial severity of aphasia is unquestionable, once initial severity has been taken into account, the effect of lesion size on recovery is not clear-cut.

In a series of studies that looked at location and extent of lesion on CT scans and the severity of impairment in different groups of individuals with aphasia, Naeser and colleagues (1987, 1989, 1990) indicated that rather than total lesion size, it is the size of the lesion within specific areas that may affect recovery from aphasia. In their study of 10 patients with Wernicke's aphasia (Naeser et al., 1987), there

was no correlation between total temporoparietal lesion size and severity of auditory comprehension. However, a correlation was found between the amount of temporal-lobe damage within Wernicke's area and severity of auditory comprehension. If the damage was in half or less of Wernicke's area, patients exhibited good comprehension at 6 months post-onset. If the lesion involved more than half of Wernicke's area, patients exhibited poor comprehension, even at 1 year post-onset. Furthermore, anterior-inferior temporal-lobe extension into the middle temporal gyrus area was associated with particularly poor recovery.

Similarly, Kertesz et al. (1993) correlated outcome measures of aphasia severity and comprehension with lesion extent in 22 patients with Wernicke's aphasia. Like Naeser et al. (1987), they found that the extent of involvement within specific structures, rather than overall lesion size, contributed to the prediction of language recovery. The angular gyrus and the anterior mid-temporal area were important for overall language recovery, while the extent of involvement of the angular gyrus contributed most significantly to recovery of auditory comprehension at 1 year. With regard to rate of recovery, involvement of the supramarginal gyrus was associated with poor recovery rates of both overall language and auditory comprehension. Partial sparing of the posterior superior temporal gyrus was associated significantly with the highest recovery rates for comprehension.

The importance of lesion extent within specific structures has also been demonstrated with regard to spontaneous language output (Naeser et al., 1989). Twenty-seven patients with aphasia were divided into two groups based on the severity of their spontaneous speech. The more severe group presented with no speech or only stereotypes in which no meaningful verbal information was conveyed; the less severe group presented with Broca's aphasia characterized by reduced, hesitant, poorly articulated, agrammatic speech. CT scan analysis revealed no single neuroanatomical area that contained an extensive lesion that could be used to distinguish the more-severe from the less-severe group. However, the two groups were separable on the basis of the CT scan when extent of lesions in two subcortical white-matter areas were combined. The two subcortical white-matter pathway areas which, when damaged, severely limited spontaneous speech were the most medial and rostral portion of the subcallosal fasciculus, and the periventricular white matter near the body of the lateral ventricle, deep to the lower motor/sensory cortex area for the mouth.

The involvement of Wernicke's area is also an important factor to consider in recovery from global aphasia. Naeser et al. (1990) examined CT scans of 14 patients with global aphasia. Based on the CT scan information, patients were divided into two groups. One group had large cortical/subcortical frontal, parietal, and temporal lobe lesions that included more than half of Wernicke's area. The other group had large cortical/subcortical frontal and parietal

lesions; Wernicke's area was spared, although the lesion extended to the subcortical temporal lobe including the temporal isthmus. Language assessment was conducted initially at 1 to 4 months post-onset and then again 1 year post-onset. Significantly more recovery in auditory comprehension had taken place at 1 to 2 years post-onset for the group that did not have lesions involving Wernicke's area. There was no significant difference between the two groups in recovery of spontaneous speech, word repetition, and naming, where severe deficits continued.

None of the studies discussed above have examined the effects of lesion size in patients who are more than 3 years post-onset. However, two studies have shown that in some patients with aphasia, a visible expansion in lesion size can be observed on CT scans after at least 3 years (Naeser et al., 1998; Van Zagtén, Boiten, Kessels, & Lodder, 1996). The increase in lesion size in the left hemisphere had no adverse effect on language, as long as the expansion was unilateral and gradual (Naeser et al., 1998). While the physiologic mechanisms underlying the lesion expansion are not understood, these results provide further support for the contention that lesion size alone is not necessarily an important factor to consider for recovery (Heiss, Kessler, Karbe, Fink, & Pawlik, 1993; Heiss, Kessler, Thiel, Ghaemi, & Karbe, 1999).

Most studies on the effects of lesion size and location have not considered how these factors impact language therapy outcome. However, Goldenberg & Spatt (1994) investigated whether size and site of lesion had differential effects during spontaneous recovery as compared to a period of intensive treatment (since language therapy may employ mechanisms that are different from those at work during spontaneous recovery). They followed 18 patients with aphasia across a period of 8 weeks of spontaneous recovery, 8 weeks of intensive language therapy, and a follow-up period of 8 weeks without treatment. Consistent with previous findings, they found that lesion size negatively influenced recovery in all phases, but lesion location was more important to consider. Patients with lesions to the temporobasal regions showed a similar amount of spontaneous recovery than patients without such lesions, but less improvement during therapy and less total recovery.

Neurophysiologic Studies of Recovery

The neuroimaging CT and MRI studies discussed previously have allowed quantification of site and size of lesions, focusing primarily on the structural damage related to the aphasia. More recently, technologic advances such as PET, SPECT, and functional MRI (fMRI) have permitted investigators to focus on the functional consequences of the lesion.

Results of these neurophysiologic studies are not always comparable because of differences in the imaging techniques and the task paradigms that are used. For example,

task paradigms have included reading sentences (Thulborn, Carpenter, & Just, 1999), verb retrieval (Warburton, Price, Swinburn, & Wise, 1999), and word repetition (Ohyama et al., 1996). Furthermore, patient differences in the size and location of the lesion, and variability in time post-onset and type and severity of aphasia also prevent direct comparison of study results (Cherney & Small, 2006). Despite the rapidly accumulating body of literature, understanding of the complex process of cortical reorganization of language-related brain regions during recovery from aphasia remains limited. More poorly understood is the way in which therapeutic interventions change brain systems responsible for language.

A critical issue relates to whether language improvement during recovery and rehabilitation is supported by left hemisphere zones spared by the lesion, by recruitment of homologous right hemisphere regions, or both. Several studies in patients recovering from aphasia have reported shifts in activation to the contralateral undamaged right hemisphere and have interpreted these as a compensatory function (Buckner, Corbetta, Schatz, Raichle, & Petersen, 1996; Cardebat et al., 1994; Ohyama et al., 1996; Thulborn et al., 1999; Weiller et al., 1995). However, more recently, it has been suggested that right hemisphere homologous activation is a maladaptive response reflecting loss of active transcallosal inhibition (Belin et al., 1996; Blank, Bird, Turkheimer, & Wise, 2003; Rosen et al., 2000) and that it stands in the way of more complete recovery.

Evidence supporting an anomalous role for the right hemisphere during recovery comes from several sources. Naeser and colleagues (2005) demonstrated improved naming in four subjects with chronic nonfluent aphasia when slow rTMS was used to inhibit activation in the anterior portion of right Broca's homologue. They postulated that suppression of this maladaptive right-hemisphere response with subsequent reduction of hyperactivity had a beneficial effect on the more widespread bi-hemispheric neural network for naming, promoting better modulation in both the right hemisphere and the remaining left hemisphere temporoparietal language structures important for picture naming. Other studies have demonstrated that the levels of activation in the right homologous regions do not correlate with measures of verbal production (Fernandez et al., 2004; Naeser et al., 2004; Perani et al., 2003; Rosen et al., 2000) or comprehension (Breier et al., 2004; Fernandez et al., 2004). Rather, better recovery has been associated with greater left-hemisphere activation (Karbe et al., 1998a, 1998b; Miura et al., 1999; Warburton et al., 1999).

The relative contribution of right and left hemisphere activity to language recovery may depend on the length of time following stroke onset. Several imaging studies support the notion that right-hemisphere activation occurs early during recovery (Fernandez et al. 2004; Xu et al., 2004). However, Heiss et al. (1999) showed that activation in the

right inferior frontal gyrus was temporary and decreased within 8 weeks after stroke onset. In contrast, perilesional left-hemisphere activation may represent sparing or restoration of normal function in tissue around the infarction that was inactive early on after injury (Heiss et al., 1999; Heiss, Thiel, Kessler, & Herholz, 2003; Rosen et al., 2000).

Further support for a pattern of increased right-hemisphere activation followed by reshifting of activation to the left hemisphere is provided by Saur and colleagues (2006). Fourteen patients with aphasia were studied using fMRI and an auditory comprehension task at three time points after left-hemisphere stroke: in the acute phase (mean 1.8 days after stroke onset); in the subacute phase (mean 12.1 days post stroke onset); and in the chronic phase (mean 321 days post stroke). Distinct patterns of activation were apparent at each time point, with strongly reduced activation of remaining left language areas in the acute phase, followed by an up-regulation with recruitment of homologous right-hemisphere language zones. Thereafter, when language comprehension had mostly recovered, there was a return to the normal pattern of activation, with greatest activation in the left hemisphere, particularly Wernicke's area.

The extent to which right-hemisphere activation occurs during early recovery may depend on the site and size of the left-hemisphere lesion. Abo et al. (2004) observed right frontal activation during repetition in a patient with a left frontal lesion; right inferior parietal activation occurred in a patient with left temporoparietal damage. Similarly Xu et al. (2004) observed right inferior frontal activation during a covert word-generation task in a patient with left frontal damage, but not in two patients with left temporoparietal damage. These observations suggest that the site of the right-hemisphere activation depends on the site of the lesion, at least for the types of tasks used in these functional imaging studies. Other investigations have suggested that right-hemisphere participation is present when there is greater damage to the left-hemisphere language areas (Cao, Vikingstad, George, Johnson, & Welch, 1999; Heiss et al., 1999; Karbe et al., 1998a, 1998b).

Neurophysiologic Studies Following Rehabilitation

Studies that directly assess the functional anatomical changes that occur as a consequence of language therapy are beginning to emerge; however, results differ across studies and there is no consensus about our understanding of the way in which therapeutic interventions may change brain systems responsible for language. Even the simpler question regarding the relative contributions of the intact portions of the damaged left hemisphere versus homologous and other regions of the right hemisphere remains unanswered. New left-hemisphere activation may be particularly important when a positive response to the intervention has been observed. Left-sided activations have been reported following

treatment with Melodic Intonation Therapy (MIT) (Belin et al., 1996), phonologic training via reading aloud (Small, Flores, & Noll, 1998), repetitive naming of semantically related pictures (Cornelissen et al., 2003), and memorization of articulatory gestures followed by repetition, reading aloud, and picture naming of a core of words (Leger et al., 2002).

The MIT study was particularly notable since one of the original rationales of this therapy was that it would help the "transfer" of language functions from the dominant but injured left hemisphere to the musically adept right hemisphere (Sparks, Helm, & Albert, 1974). Yet it seemed to do the exact opposite, increasing activation in the damaged left hemisphere. In the study by Leger et al. (2002), not only did left-hemisphere activation increase, but the pattern of activation following treatment was more similar to the pattern seen in normal controls, with activations noted in Broca's area (left inferior frontal gyrus) and the superior part of the left supramarginal gyrus. Interestingly, Cornelissen et al. (2003) found that all three of their subjects behaved in a similar way, with a single perilesional area in the left inferior parietal area displaying statistically significant training-induced changes.

In contrast, Musso et al. (1999) demonstrated a correlation between increased activity in the right temporal cortex and comprehension scores in four subjects with Wernicke's aphasia following brief intensive training of comprehension between scanning sessions. In addition, Thompson (2000) described changes in the right hemisphere homologues of both Wernicke's and Broca's area during a sentence-picture matching task following a sentence-processing therapy.

It should be noted that most of these studies report on just one or two patients. Thus the caveat that must accompany interpretations of all case studies in aphasia recovery is that there is significant individual variability in anatomy and functionality, and the patterns observed in one patient may not be relevant to those observed in another. For example, Cherney and Small (2006) studied two patients with chronic aphasia and compared their functional neuroanatomical responses to a younger control group on two tasks, an oral-reading task involving overt speech and a "passive" audiovisual story-comprehension task. Following identical therapy, behavioral (language) and functional neuroanatomical changes were reexamined using the same fMRI tasks. For the participant with a frontal lesion who was most responsive to therapy, brain activation increased in the right hemisphere during oral reading, but decreased bilaterally in most regions on story comprehension. The other participant with a temporoparietal lesion showed decreased activation, particularly in the right hemisphere, during oral reading but increased activation bilaterally on story comprehension. Results highlight individual variability following language therapy, with brain-activation changes depending on lesion site and size, language skill, type of intervention, and the

nature of the fMRI task. Combining individual differences with task differences leads to a wide variety of possible outcomes. Therefore, it may not be sufficient to characterize observed changes in language-related activity patterns after stroke as “left” or “right,” when in fact they are highly task-dependent and individually different (Cherney & Small, 2006).

Clearly, many questions remain regarding the effect of rehabilitation on patterns of language organization. In particular, research is needed to address the various factors that potentially influence recovery patterns, such as the type of aphasia, the site and size of the lesion, and the focus of the intervention; further, investigation is also needed in interpreting the relationship between observed changes and the nature of the language task. In particular, the behavioral outcomes associated with different types of treatment may be reflected in differential reorganization of the language network.

As further studies yield new information or confirm previous information, we will move closer to understanding the neural mechanisms that mediate recovery and rehabilitation. This is an important issue because better knowledge of these mechanisms may lead to better management of the patient with aphasia and better prediction of outcome.

Personal Factors Affecting Prognosis

Although personal and biographic factors appear to play only a minor role in recovery from aphasia as compared to neurological factors (Benson & Ardila, 1996), these factors should not be ignored. Indeed, factors of age, handedness, and gender have been studied experimentally, with some conflicting evidence regarding their effects.

Age

Some studies that have addressed the effects of age on recovery suggest that younger patients have a more favorable outcome than older ones (Gloning, Trappl, Heiss, & Quatember, 1976; Holland, Greenhouse, Fromm, & Swindell, 1989; Marshall et al., 1982; Sands, Sarno, & Shankweiler, 1969; Vignolo, 1964). Other studies have not found age to have a significant effect on recovery (Basso, Capitani, & Vignolo, 1979; de Riesthal & Wertz, 2004; Heiss et al., 1993; Keenan & Brassell, 1974; Kertesz & McCabe, 1977; Messerli, Tissot, & Rodriguez, 1976; Pederson et al., 1995; Sarno, 1992; Sarno & Levita, 1971; Wertz & Dronkers, 1990).

In a review of prognostic factors in aphasia, Basso (1992) cautions that the interaction of age with type of aphasia must be considered because patients with fluent aphasia may be older than patients with nonfluent aphasia (Basso, Capitani, Laiacina, & Luzzatti, 1980; Code & Rowley, 1987; de Renzi, Faglioni, & Ferrari, 1980; Ferro & Madureira, 1997;

Miceli et al., 1981; Obler, Albert, Goodglass, & Benson, 1978). Since type of aphasia may be the prognostic factor rather than age, any studies of the effects of age on recovery must control for type of aphasia.

Similarly, the effects of age on recovery must be considered in relation to etiology. Advanced age may be associated with etiologic factors predicting poor outcome (Henley, Pettit, Todd-Pokropek, & Tupper, 1985). For example, patients with aphasia resulting from open or closed head injury appear to recover better than patients with aphasia resulting from stroke (Kertesz & McCabe, 1977; Basso et al., 1982; Benson & Ardila, 1996). This may be explained in part by age differences, since trauma usually affects younger individuals. Individuals with hemorrhagic strokes, who usually are somewhat younger than patients with occlusive strokes, typically have a good prognosis for language recovery after the mass effect is eliminated; in contrast, the prognosis for occlusive strokes is more limited depending on the site of the infarction (Basso, 1992; Benson & Ardila, 1996; Rubens, 1977).

The effects of age on recovery should also be considered in relation to general health status. For example, in a prospective study of outcome following ischemic stroke, older individuals with a more severe initial stroke demonstrated poorer general outcome at 3 months post-onset (Macciocchi, Diamond, Alves, & Mertz, 1998). The study also indicated that there was a correlation of age with comorbidities such as medical, psychosocial, and psychiatric disorders, which may not emerge as independent predictors of outcome. Such factors as history of prior stroke, as well as history of hypertension, diabetes, or cardiac disease, have been associated with poorer outcome after stroke, and the impact of these co-morbid disorders may be greater in older persons. These findings are consistent with those of Marshall et al. (1982) and Marshall and Phillips (1983) who found that general health was a predictive variable of speech and language performance, and with Hilari, Wiggins, Roy, Byng, and Smith (2003) who identified number of co-morbid conditions rather than age as a significant predictor of health-related quality of life in a large group of individuals with chronic aphasia. Similarly, duration of hospitalization may be related to age and general health status, and therefore indirectly related to language outcome (Holland et al., 1989).

Gender

It has been proposed that gender differences may influence the pattern of recovery in patients with aphasia (McGlone, 1977, 1980). In two studies investigating the effects of sex on recovery from aphasia, females had a better prognosis than males for oral expression (Basso et al., 1982) and for auditory comprehension (Pizzamiglio, Mammucari, & Razzano, 1985). However, other studies have found no significant

difference in recovery for males and females (Kertesz & McCabe, 1977; Pederson et al., 1995; Pickersgill & Lincoln, 1983; Sarno, Buonaguro, & Levita, 1985). Therefore, at this time, there appears to be no converging evidence favoring either gender (Basso, 1992).

Handedness

Some authors have proposed that left-handers and ambidextrous and mixed-handers have a more bilateral representation for language processing, and therefore recover more rapidly from aphasia, than right-handers (Gloning, 1977; Luria, 1970; Subirana, 1958). Furthermore, it has been suggested that recovery from aphasia is more frequent among patients with familial sinistrality (Luria, 1970). However, better prognosis for non-right-handers is not supported by the data from later studies (Basso, Farabola, Grassi, Laiacina, & Zanobia, 1990; Borod, Carper, & Naesser, 1990; Pickersgill & Lincoln, 1983). An issue affecting the interpretation of these studies is that handedness may be evaluated by different methods, and that different criteria may be adopted for considering a hand as dominant. Therefore, like gender, the findings about the effect of handedness on recovery are inconclusive.

Psychosocial Factors

Emotional and psychosocial changes accompany aphasia (Hemsley & Code, 1996; Hermann & Wallesch, 1993; Starkstein & Robinson, 1988). For example, post-stroke depression was found in 25% of patients with stroke during the acute stages; this incidence rose to 31% at 3 months post-onset, decreased to 16% by 12 months post-onset, and then rose again over the next 2 years to 29%, a proportion higher than that at the acute stage (Astrom, Adolfsson, & Asplund, 1993). However, little is known of the interactions between these changes and recovery from aphasia. Many factors, such as motivation, are not easily amenable to experimental study. Nonetheless, emotional and psychosocial well-being may play a significant role in recovery from aphasia, and preliminary evidence suggests a relationship between mood state, progress in rehabilitation, and functional communication (Code & Muller, 1992; Fucetola et al., 2006; Hermann & Wallesch, 1993; Starkstein & Robinson, 1988). However, Hemsley and Code (1996) found unique patterns of individual emotional and psychosocial adjustment over time in patients with aphasia and their significant others, even in patients where aphasia type and severity were similar. Therefore, they caution that psychosocial and emotional adjustment and its prognostic impact on communication and rehabilitation progress cannot be anticipated.

In summary, many studies have focused on the prognostic indicators that may help predict outcome in patients with aphasia. Several of these studies and their key findings have

been discussed. Since it appears that no single factor alone can predict outcome, clinicians must assess the information about each variable and make inferences about how they, in combination, affect the extent to which language recovery will occur. Additionally, clinicians must be cognizant of the various ways that outcomes can be measured and, in determining prognosis, consider not only language-impairment and functional-communication measures, but also consider quality-of-life-measures. Clinicians also must decide if the expectation that treatment will effect positive change is justified. The next section reviews the information base for warranting these treatment decisions.

OUTCOMES OF TREATMENTS FOR APHASIA

The Current Context for a Review of Scientific Evidence

Three important factors influence any assay of scientific evidence on clinical outcomes of treatment protocols. The first influential factor is a logical and broadly recognized system for assessing clinical treatments. That system begins in Phase I, with discovery-oriented research for the purpose of uncovering new treatment protocols. The system progresses through Phase II research in which new protocols are developed and tested for their basic properties. A successful outcome in Phase II may warrant a Phase III clinical trial for testing the *efficacy* of a treatment. That is, Phase III research puts to test the general expectation of benefit among persons in a specific clinical population. A successful clinical trial justifies Phase IV research for assessing specific outcomes in day-to-day clinical practice, which is also known as the *effectiveness* of a treatment (Robey, 2004a; Robey & Schultz, 1998). In the last phase of clinical research, Phase V, the focus of research moves from clinical outcomes and the decisions of speech-language pathologists to public-health issues and the decisions of public-health analysts, economists, and policy makers.

The five phases of treatment research represent a normal progression of development and knowledge building. For a developing treatment protocol, one would expect to find some Phase I and Phase II studies. Only for a mature treatment protocol is a record of Phase III, IV, and V studies a reasonable expectation. Therefore, in the normal course of events, a broadly recognized treatment protocol with a substantial record of development and widespread application in general practice is associated with a literature base that includes several studies in each of the phases of clinical research.

In clinical aphasiology, the majority of treatment research findings come from Phase I and Phase II studies. A large proportion of the scientific evidence on treatment outcomes for aphasia has been obtained through studies having the characteristics of Phase IV treatment-effectiveness research. A relatively small fraction of the scientific evidence on treatments for aphasia has been obtained

through Phase III clinical trials. That is, the distribution of the scientific-evidence base in clinical aphasiology doesn't completely conform to the expected distribution when clinical research unfolds in a structured developmental sequence of clinical research.

Why the discrepancy? Although the five-phase system for the sequential development of clinical research is recognized in the broader clinical-outcome research community, only within the past few years have aphasiologists been thinking about the system for (a) conducting evidence-based reviews (EBRs) of past research, and (b) designing and implementing new research studies. It is not surprising, then, that the historical record of research findings doesn't conform completely with a system, that for all intents and purposes, didn't exist for the researchers who were making large and important contributions.

Should the body of clinical research completed prior to the application of a certain set of ground rules be held strictly accountable to those ground rules? Should findings coming from studies that do not uniformly conform to the new structure be dismissed? For both questions, the answer is straightforward: of course not. The fact is that many high-quality studies inform researchers and practitioners about the best clinical practices. Prudence and good sense move scientists and practitioners to extract the value contained in the existing body of valid scientific evidence and then build on that record within the broadly recognized system.

The second influential factor in reviewing clinical scientific evidence is the recent advent of evidence-based practice in speech and language pathology. EBP embraces many research designs for investigating the effects of treatment protocols: case studies, case series, case-control studies, cohort studies, cross-sectional studies, parallel-groups studies, and single-subject studies, among others. These are the research designs of Phases I and II clinical research. In a developmental sense, they establish the basic research underpinning the ultimate EBP research design: a clinical trial. Sometimes, however, the scientific evidence produced through Phase I and Phase II research designs are discounted as being less scientifically valid than the evidence produced through clinical trials that must preserve internal validity (Cook & Campbell, 1979) through rigorous experimental controls such as random assignment.

The notion that inherent properties endow certain research designs with greater or lesser degrees of scientific validity, or value, misdirects attention from the essential questions: (a) What form of research is most appropriate for testing the salient hypothesis at a particular point in the developing line of clinical research, and (b) How validly was it carried out? Unfortunately, the practice of appraising the value of scientific evidence based solely on the name of the research design producing it is a natural consequence of appraising literature only through levels-of-evidence tables

commonly found in EBP (Dollaghan, 2006).¹ However, no research design possesses inherent properties conferring (or not) scientific validity to the observed result. The quality of evidence produced through any research design is directly linked to the quality of operational definitions (purposefully determined and otherwise) for implementing that design. Within a structured system of clinical research, certain research designs are appropriate and essential within each phase of experimentation and the quality of any result derives from the experimental rigor that went into producing it.

Taken in isolation, a tabulated hierarchy of research designs does not establish *more or less scientific validity* for the findings arising out of each level in the hierarchy. Rather, presuming scientific validity at all levels in the hierarchy, evidence produced through a certain level may be *more or less influential* for informing clinical practice (e.g., When may a practitioner ethically provide a treatment protocol in general practice based on best-quality evidence?). The notion advanced here is not that experimental rigor doesn't matter; indeed, it is the crux of the matter. Scientific rigor is assessed through the usual means at all levels (e.g., statistical power, effect size, the bandwidth of confidence intervals, a lack of bias, treatment fidelity and compliance, construct validity, and so forth in the long and familiar listing of validity issues). Neither is any of this to say that clinical trials are irrelevant. Indeed, they are absolutely essential for their purpose and render highly valued results when great care is evident in all aspects of experimental rigor and scientific validity.

The third factor influencing a review of scientific evidence on clinical outcomes of treatment protocols is directly related to EBP: the randomized controlled clinical trial (RCT). Because RCTs nominally embody experimental controls exceeding other research designs, they are often thought to produce experimental results constituting the gold standard for influencing clinical practice. Presuming scientific validity and all other things held constant, a successful RCT does establish the assertion of treatment efficacy. However, a RCT is not always possible or desirable in clinical research on behavioral treatments. At one time, many clinical aphasiologists objected to randomized assignment of individuals with aphasia to no-treatment control groups on ethical grounds. As will become evident in the following sections, the question for researchers has moved beyond "Is treatment better than doing nothing at all?" to "Does protocol X bring out greater change than protocol Y?"

¹The fundamental ideas underpinning this and the next paragraphs are attributed to the scholarship of Dr. Christine A. Dollaghan in her roles as Chair of the Advisory Committee on Evidence-Based Practice (American Speech, Language, Hearing Association), and author of a forthcoming text on evidence-based practice.

Basing random allocation to one of two (or more) competing treatments eliminates the original concern.

Systematic Reviews and Meta-Analyses

A review of scientific clinical evidence begins with existing systematic reviews and meta-analyses. In the aphasia-treatment literature, a small corpus of these reviews is available for inspection.

In a Cochrane systematic review, Greener, Enderby, and Whurr (2006a) examined pharmacologic treatments for aphasia. Ten clinical trials met their inclusion and exclusion criteria. The pharmacologic agents in these trials included Piracetam, Bifemelane, Pribedil, Bromocriptine, Idebenone, and Dextran. Greener et al. (2006a) concluded that design constraints combined with absent or unclear information in the manuscripts made thorough assessments of scientific quality unattainable. That complication in a relatively small set of studies rendered the interpretations, conclusions, and generalizations coming out of the review equivocal on many important points. Nonetheless, for one agent, Piracetam, a small treatment effect was detected for improved language performance.

In a different Cochrane systematic review, Greener, Enderby, and Whurr (2006b) examined randomized controlled trials of behavioral treatments for aphasia by speech-language pathologists. Notably, only twelve studies met the entrance criteria for review. Of those, several were relatively dated, and all were characterized by limitations in either (a) research methodology (e.g., design characteristics, sample characteristics), or (b) the incompleteness with which important operational definitions and outcomes were communicated. Greener et al. (2006b) concluded that randomized controlled trials have demonstrated neither the efficacy of treatments for aphasia nor the lack of efficacy.

The highlights of another systematic review of treatments for aphasia (among other communication disorders) was reported in Enderby (1996). Enderby found that treatments were generally effective when treatment protocols were (a) matched carefully with the characteristics of a certain clinical presentation, and (b) provided intensively.

A handful of meta-analyses have been conducted on aphasia-treatment research findings. In a meta-analysis, estimates of effect size are calculated for each study assessing a common research hypothesis; those estimates are then averaged, or synthesized, to achieve a single result that incorporates all tests of that research hypothesis. An estimate of effect size is a quantity for measuring the degree of departure from the null state (e.g., no change from pre-treatment to post-treatment). When an effect size equals zero, no change is evident. As the degree of change brought about by a treatment protocol increases, the value of the corresponding effect size increases.

It is important to note that these meta-analyses have not been restricted to clinical trials. Rather, they have included a variety of aphasia-treatment studies. Greenhouse and colleagues (1990) reported the first meta-analysis of aphasia-treatment literature. They analyzed 13 pre-post tests of aphasia treatment and found an average weighted effect size of 0.80, corresponding to a medium-to-large effect.

Whurr, Lorch, and Nye (1992) conducted a meta-analysis of 45 aphasia-treatment studies and obtained an average effect size of 0.59 separating treated and untreated populations. Although many studies were characterized by methodologic limitations, they concluded that treatments were generally effective.

Robey (1994) conducted a meta-analysis of between-subject effects (i.e., treatment versus control) and within-subjects effects (i.e., pre-test versus post-test) with time-post-onset controlled for each set of effects. The results indicated that the recovery of treated individuals was, on average, nearly twice as extensive as the recovery of untreated individuals when treatment was begun before 3 months post-onset (MPO). Furthermore, treatment brought about an appreciable improvement in performance when begun after the third MPO. Robey (1994) also found that the effect sizes for treated-versus-untreated comparisons exceeded Cohen's (1988) criterion for a medium-sized effect when treatment was initiated before the third MPO and exceeded the criterion for a small-sized effect in the chronic stage when treatment was initiated after 12 MPO.

In a meta-analysis of 55 studies, Robey (1998) obtained results confirming the 1994 findings. Furthermore, Robey found that, in general, (a) greater amounts of treatment brought about larger treatment effects, (b) the average effect size for Schuell-Wepman-Darley Multimodal-stimulation (SWDM) was larger than the overall average, and (c) large gains were achieved by persons with severe aphasia.

Robey, McCallum, and Francois (1999) and Robey, Schultz, Crawford, and Sinner (1999) reported analyses of effect sizes obtained through 12 single-subject research studies. The estimates of effect size indicated generally large and robust treatment effects.

The convergence of this combined evidence leads to the conclusion that treatments for aphasia are generally effective (Albert, 1998). In the past, efficacy per se has not always been demonstrated through valid clinical trials in the modern sense. Nevertheless, the weight of scientific evidence warrants the conclusion that treatments (generally considered) are effective in bringing about desired outcomes.

As Enderby (1996) points out, historically, most dependent variables in aphasia treatment research have been improvements in impairments (WHO, 1980). More recently, treatment studies have begun reporting essential outcomes expressed in terms of activity limitation, social validity, and quality of life.

TABLE 6-1

Number of Aphasia-Treatment Studies at Each Phase of Clinical Research

Clinical Outcome Domain	Phase of Clinical Research				
	I	II	III	IV	V
Overall language performance	12	8	12	—	—
Lexical retrieval	83	37	1	—	—
Syntax	35	26	—	—	—
Speech production/fluency	44	11	1	—	—
Language comprehension	14	—	—	—	—
Reading	39	7	1	—	—
Writing	30	8	2	—	—

Primary Studies

In the past several decades, hundreds of research reports have been published regarding treatments for aphasia. Many of these papers have been considered by the Aphasia Treatment Writing Committee of the Academy of Neurologic Communication Disorders and Sciences (ANCDS), which is conducting meta-analyses for each of several treatment-outcome domains. Building upon the work of the Veterans Affairs Field Advisory Council (Daniels, Stach, & Maher, 2001) and Robey (1998), the committee organized studies for which estimates of effect size were available by six clinical-outcome domains: overall language performance, lexical retrieval, syntax, speech production/fluency, language comprehension and reading and writing (Robey & Beeson, 2005). Table 6-1, a cross-tabulation of those clinical-outcome domains with the number of treatment studies at each phase of clinical research, illustrates the maturity of lines of inquiry in aphasia-rehabilitation research.

Clearly, the line of scientific inquiry on treatment protocols in which the outcome domain is overall language performance (i.e., a test battery for compiling a broad spectrum of language impairments) has advanced to clinical trials more frequently than any of the other domains. This likely reflects a long history of research in this outcome domain. Just as clearly, researchers (a) have established a relatively extensive base of pre-trial research in the remaining domains, and (b) are beginning to take some of their treatment protocols to trial. Indeed, clinical trials seem a next logical step, particularly for treatment protocols to improve lexical retrieval and syntax.

Specific Treatments

The next sections review a few examples of studies in each clinical-outcome domain. These examples are certainly not

intended as exhaustive. Examples were selected for their capacity for efficiently illustrating as much information as possible. Indeed, with each category, some studies are associated with greater magnitudes of effect size than those selected for presentation, and other studies are associated with lesser magnitudes. A full treatment of these data will appear in the report of the ANCDS Writing Committee.

Overall Language Performance

Many studies assessing overall language performance as a dependent variable report a general index of aphasia severity taken from a comprehensive test of aphasia such as the Boston Diagnostic Aphasia Examination (BDAE; Goodglass, Kaplan, & Barresi, 2001), the Porch Index of Communicative Abilities (PICA; Porch, 1981), or the Western Aphasia Battery (WAB; Kertesz, 1982). The treatment protocol is often some variation of the Schuell-Wepman-Darley Multimodality (SWDM) treatment (see Duffy, 1994). An innovative exception is a clinical trial testing Computer Reading Treatment provided over a 26-week period (Katz & Wertz, 1997). Using Cohen's (1988) estimator of effect size for within-subject effects ($d_{pre,post}$; see Robey, 2004b, p. 315), the magnitude of change from pre-treatment to post-treatment was $d_{pre,post} = .51$ for the PICA Overall results and $d_{pre,post} = .21$ for the WAB AQ results. Estimates of effect size for the two corresponding control conditions, computer stimulation and no treatment, were $d_{pre,post} = .14$ and $d_{pre,post} = .06$ respectively. For context, these estimates of effect size may be compared to the average effect sizes reported by Robey (1998) for individuals with aphasia in the chronic stage of recovery who were treated (i.e., $\bar{d}_{pre,post} = .66$) and untreated (i.e., $\bar{d}_{pre,post} = .05$). In each case, the Katz and Wertz (1997) estimates are within the confidence intervals for the averaged values.

Syntax

Treatment protocols for improving syntactic production are many and varied. Frequently encountered examples include linguistic-specific treatment (Thompson, 2001) and syntactic stimulation (Davis & Tan, 1987). Jacobs and Thompson (2000) tested a protocol for increasing the accuracy of object-cleft and passive sentences with four persons with Broca's aphasia. Using Busk and Serlin's (1992) first estimator of effect size for single-subject data,² d_{BS-1} , the magnitude of change brought about in each participant can be quantified. Combining the estimates of effect size for each of the direct treatment effects (i.e., response to trained tokens) yields an average effect size of $d_{BS-1} = 27.73$. A similar averaging of effect sizes for untrained tokens across the

²Note that values of Cohen's $d_{pre,post}$ for group data and values of d_{BS-1} for single-subject data are not directly comparable. The equations differ importantly.

four participants provides a means for quantifying the magnitude of change in terms of generalization. In this case, d_{BS-1} for generalization equaled 1.41. For context, in a small meta-analysis of single-subject studies, Robey et al. (1999) found a median effect size for direct treatments of $d_{BS-1} = 3.98$. An average effect size for generalization effects has not yet been established.

The grouped data for four aphasic individuals studied by Thompson, Shapiro, Kiran, & Sobecks (2003) provides insight to another dimension of generalization. Combining the estimates of effect size for three standardized tests resulted in a value of $d_{pre,post}$ equaling 1.02. The comparison value from extant literature is again $\bar{d}_{pre,post} = .66$ from Robey (1998).

Word Retrieval

Treatment protocols for phonologic cueing, semantic cueing, or combined phonologic and semantic cueing are found throughout the research literature on improving word retrieval. Wambaugh, Doyle, Martinez, and Kalinyak-Fliszar (2002) studied both forms of treatment using cueing hierarchies with each of three participants in a single-subject research design. The magnitude of change for both treatment protocols combined over all three participants was $d_{BS-1} = 4.53$. The corresponding magnitude of change for generalization was $d_{BS-1} = 3.27$. Each of these direct treatment effects is referenced to the median value of $d_{BS-1} = 3.98$ reported by Robey et al. (1999). Using a group research design, Hickin, Best, Herbert, Howard, & Osborne (2002) studied the response of eight individuals with aphasia to a treatment protocol combining phonologic and orthographic cues. The direct treatment effect was $d_{pre,post} = .86$; the generalization effect for untreated tokens was $d_{pre,post} = .18$. Once again, the comparison value is $\bar{d}_{pre,post} = .66$ from Robey (1998).

Language Comprehension

Treatment protocols for improving language comprehension take many and varied forms. A particularly well-developed protocol by Crerar, Ellis, and Dean (1996), termed the "Computer Based Microword" has individuals with aphasia make decisions about a closed set of tokens and their relationships with one another. Crerar et al. measured improvements in accuracy rates for prepositions and verbs among 14 participants. The resulting estimates of effect size were $\bar{d}_{pre,post} = .81$ for prepositions and $\bar{d}_{pre,post} = 2.41$ for verbs. Both values exceed the corresponding reference value from Robey (1998) of $\bar{d}_{pre,post} = .66$.

Speech Production or Fluency

Treatment protocols in this category comprise Response Elaboration Training (Kearns, 1985, 1997), Constraint

Induced Therapy (Pulvermüller et al., 2001), Voluntary Control of Involuntary Utterances (Helm-Estabrooks & Albert, 2004), and Melodic Intonation Therapy (Helm-Estabrooks & Albert, 2004), among others.

Wambaugh and Martinez (2000) conducted a single-subject study of three individuals using a variation of Response Elaboration Training. The averaged estimate of effect size was $d_{BS-1} = 5.95$ for a direct treatment effect using correct information units as the dependent variable (reference value from Robey et al., 1999: $d_{BS-1} = 3.98$).

Pulvermüller et al. (2001) reported a group study comparing the effects of Constraint-Induced Therapy (CIT) with those of conventional treatment. The estimate of effect size for the 10 individuals receiving CIT was $d_{pre,post} = .62$ using a value derived from a battery of standardized tests as the dependent variable (reference value in Robey et al., 1999: $\bar{d}_{pre,post} = .66$). Furthermore, the comparison of the two forms of treatment resulted in a between-subjects effect size of $d_{CIT\ vs\ Conventional} = .513$. The closest value in Robey (1998) for serving as a corresponding reference value is $d_{Tx\ vs\ No-Tx} = .31$ for studies comparing treatment to no-treatment in post-acute aphasic individuals.

Reading and Writing

The literature contains relatively few reports of treatment protocols having a primary outcome of improved writing or improved reading. An example of a treatment protocol for improving reading comprehension is found in Cherney, Merbitz, and Grip (1986). These authors administered Oral Reading for Language in Aphasia (ORLA) to a heterogeneous group of persons with aphasia 3 to 5 times per week for 20 to 80 sessions. The estimate of effect size for reading comprehension was $d_{pre,post} = .525$ (reference value is $\bar{d}_{pre,post} = .66$).

An example of a treatment protocol for improving writing is provided by Beeson, Hirsch, & Rewega (2002), who studied four individuals with aphasia and severe agraphia. Two participants received Anagram and Copy Treatment (ACT) and Copy and Recall Treatment (CART), which were completed as a home assignment. Two participants received the CART home-assignment only. Multiple-baseline single-subject data with the number of correctly written words was the dependent measure. The average effect size for the two participants receiving both forms of treatment was $\bar{d}_{BS-1} = 24.03$ (reference value: $\bar{d}_{BS-1} = 3.98$).

Conclusion

Although a great portion of the external evidence for informing clinical practice was published before the conventions of evidence-based practice were broadly recognized, the available scientific evidence supports the conclusion that treatments for aphasia, generally considered, bring about

large and beneficial changes. In fact, the evidence on the general question of efficacy/effectiveness of treatments by speech-language pathologists is compelling: treatments by speech-language pathologists bring about desired outcomes (Albert, 2003; Basso, 2005). Furthermore, researchers are producing evidence that opens insight into differential forms of treatment effects: multiple dimensions of outcome obtained through a certain treatment protocol associated with a certain clinical population.

Two large and important challenges confront clinical aphasiologists. The first challenge is describing scientific evidence more fully than has largely occurred in the past. High-quality scientific evidence produced through high-quality clinical research can only be recognized as such if the manuscript contains the quality indicators required by readers for rendering those assessments. Fortunately, guidance in this regard is readily available. For instance, quality indicators for manuscripts reporting randomized controlled trials is the substance of the Consolidated Standards of Reporting Trials Statement (CONSORT; <http://www.consort-statement.org/statement/revisedstatement.htm>). Similarly, for manuscripts describing non-randomized controlled trials, quality indicators are listed and described in the Transparent Reporting of Evaluations with Nonrandomized Designs Statement (TREND; <http://www.trend-statement.org/asp/trend.asp>). Meeting this first challenge is certainly not beyond the means of researchers.

The second challenge is testing focused clinical-research questions through precise experimental designs. Presently, we are experiencing a period of transition in which increasingly more focused hypotheses (e.g., a certain treatment protocol is tested in a certain clinical population using clinically relevant measures of outcome) are tested in progressively more precise experiments (e.g., narrow confidence intervals). As Greener, Enderby, and Whurr (2006a) point out, much needs to be done in this regard, but the work is underway.

FUTURE TRENDS

1. Progressive refinements and advancements in imaging technology make possible ever more detailed assessments of pathology, surviving anatomy, and neurophysiology. In large samples, those forms of information, combined with salient history and thorough assessments of communication behavior at certain points in recovery, will undoubtedly clarify indicators and moderators of recovery and rehabilitation.
2. That concert of information will enhance the clinical decisions of aphasiologists regarding prognosis and treatment scheduling.
3. Demonstrated efficacy and effectiveness is an imperative of funding for clinical services and clinical research. From that perspective, aphasiologists must test the

efficacy and effectiveness of well-defined treatment protocols through well-controlled experiments that are appropriate for the particular point in the developing line of clinical research. Documentation of quality indicators in the resulting manuscripts will facilitate recognition of the research as high quality.

4. The test of a certain protocol must focus not only on changes in impairment from pre-test to post-test, but also on the effects of certain treatment schedules, certain models of service delivery, direct comparisons of specific treatment protocols, indications and contraindications of candidacy for a protocol, and the permanence of change brought about by a protocol.
5. The scope of clinical experiments must continue to broaden through assessments of treatment effects expressed in terms of direct treatment effects, generalization effects, and maintenance effects, and the social validity of change expressed in terms of activity limitation, participation limitation, quality of life, consumer satisfaction, and costs versus benefits.
6. As in all forms of scientific inquiry, initial findings will be strengthened through independent replications of critical tests.

KEY POINTS

1. Despite individual variation in rate and extent of recovery, there seem to be some general patterns of recovery that have been identified for each type of aphasia. Furthermore, there is a consistent trend in the pattern of recovery as it relates to the individual language modalities.
2. The neural mechanisms contributing to recovery from aphasia are not completely understood. Technologic advances in the area of brain imaging (e.g., PET, SPECT, fMRI) have moved researchers closer to understanding the neural mechanisms that mediate early and late recovery.
3. It is not clear whether language improvements during recovery and rehabilitation are supported by left-hemisphere regions spared by the lesion, by recruitment of homologous right-hemisphere regions, or both. Brain-activation changes during recovery and rehabilitation show individual variability and may be affected by several factors, including lesion size and site, time post-onset, type of language intervention, and fMRI task.
4. There appears to be no single factor alone that can predict outcome in patients with aphasia. Personal and biographical factors such as age, handedness, and gender have been studied experimentally, with some conflicting evidence regarding their effects.

5. The body of scientific evidence supports the conclusion that treatments for aphasia, generally considered, are effective.
6. For many treatment protocols, pre-trial research has established a firm basis for moving on toward conducting clinical trials. That is, in many areas, aphasia-treatment research is poised to advance within the five-phase model of clinical research.
7. Future research, and particularly manuscripts describing clinical research, should conform to the broadly recognized conventions regarding the quality of research findings for informing evidence-based practice.

Chapter 7

Delivering Language Intervention Services to Adults with Neurogenic Communication Disorders

Brooke Hallowell and
Roberta Chapey

OBJECTIVES

The objectives of this chapter are to (1) describe the contexts in which clinicians serve adults with neurogenic communication disorders; (2) explore the gerontologic context of aphasia intervention; (3) describe the many professional roles of the aphasiologist; (4) discuss key legislative issues that affect service delivery; (5) present an overview of the means by which clinicians and service-providing agencies are reimbursed for services; (6) stimulate discussion of the active ways in which clinicians may serve as advocates for patients in the current service-delivery climate; and (7) discuss future trends in service delivery.

At no other time in the history of aphasiology has the context in which clinicians work so influenced the delivery of intervention-services to persons with neurogenic communication disorders. Throughout the world, changes in health-care policy, reimbursement schemes, national health plans, political climates, insurance mechanisms, clinical licensure, and professional training are having dramatic impacts on our access to patients, as well as on the services we may deliver to them. In the United States, particularly, recent impacts of managed-care in the private sector and evolving federal health policies are significantly impacting the practice of aphasiology.

In this chapter we discuss the contexts in which aphasiologists work and the multiple roles they play. Legislative issues and other factors affecting reimbursement for clinical services are then presented in terms of their implications for the delivery of services to persons with aphasia. Strategic actions in which aphasiologists may engage to further the effectiveness of services, patients' access to care, and the financial stability

of service-providing agencies are highlighted. The nature of the "ultimate excellent clinical aphasiologist" is explored in light of the demands of the current health care climate.

SERVICE DELIVERY CONTEXTS FOR LANGUAGE INTERVENTION

Speech-language pathologists rehabilitate adult patients with aphasia in a variety of settings, such as hospitals, rehabilitation centers, skilled-nursing facilities, nursing homes, clinics, private offices, and the patient's own home.

Hospitals

Most major community hospitals have a comprehensive program for stroke rehabilitation, including a basic rehabilitation team comprised of a physician, a rehabilitation nurse, a social worker, a physical therapist, an occupational therapist, and a speech-language pathologist. Optimally, a physiatrist, a psychologist, and a rehabilitation counselor are also members of this team. The immediately post-stroke or post-trauma patient is frequently placed in an acute medical area and may receive speech-language evaluation, intervention, and counseling at the bedside. Recent trends in reducing the length of time patients are allowed to remain in acute-care contexts, however, have limited acute-care clinicians to a primary focus on screening and diagnostic services rather than on concerted intervention (Katz et al., 2000). Acute-care clinicians are also involved in educating patients' significant others about the nature of aphasia.

In most instances, convalescent stroke and trauma patients are placed near rehabilitation services, in a specific area that is properly equipped for rehabilitation and staffed by personnel with special training in rehabilitation. Adequate space and equipment are usually provided to ensure high-quality evaluation, treatment, and counseling services, which are rendered for both inpatients and outpatients. The advantage of providing speech-language services in this setting is that a hospital may provide integrated, coordinated, comprehensive team management for patients

with stroke and aphasia. The same may be said for rehabilitation centers.

Rehabilitation Centers

A rehabilitation center may be a component of a hospital or may exist as a separate, independent facility that has a close working relationship with one or more hospitals. In either case, there are usually both inpatient and outpatient services that provide comprehensive team rehabilitation. For patients who have recovered from the acute stages of stroke or trauma, the decision as to whether they should receive subacute rehabilitation as outpatients or inpatients or be transferred to another facility depends on several variables, such as the extent of disability; overall health status; geographic location of potential placement sites and access to transportation; the degree of need for integrated comprehensive intervention in nursing, speech-language pathology, physical therapy, and occupational therapy; insurance coverage; the patient's financial resources; and the degree of family support and involvement.

Skilled Nursing Facilities

The distinctions among terms such as long-term-care center, nursing home, skilled-nursing facility, and even rehabilitation center have become less and less clear in recent years (Gill, 1995). Since the late 1980s, rehabilitative care has gravitated away from acute-care hospitals, and toward facilities that were once merely considered long-term-care centers or "rest homes" (facilities to which most residents traditionally had been admitted with the anticipation that they would stay there for the rest of their lives). Rather than staying in the hospital until they are rehabilitated to the point of being able to return to their homes, most stroke and trauma patients are now discharged from acute-care centers to subacute care centers, often outside the hospital context. A majority of skilled nursing facilities now offer comprehensive rehabilitative services, both for short-term patients who are expected to return to their homes, as well as for long-term residents. Consequently, over the past 20 years, most United States residents have seen the signs for "nursing homes" in their local neighborhoods change to signs for "skilled nursing and rehabilitation centers" and the like.

Nursing Homes and Long-Term-Care Centers

Even in long-term-care contexts that do not specialize in short-term rehabilitation, speech-language therapy, occupational therapy, and physical therapy services are generally offered. In most instances, these homes also provide ongoing environmental stimulation and attempt to meet the patient's social and emotional needs. Speech-language clinicians in these contexts often work on a contractual basis with the nursing home, either as independent professionals or as

employees of a rehabilitation company that contracts with multiple nursing homes in a given area. Thus, nursing-home clinicians frequently work on an itinerant basis, providing speech-language services to two or more facilities.

Many long-term-care centers have varied types of residential facilities that differ according to the levels of care needed by residents. They range from apartments, for adults capable of living independently but wishing to be close to central social and medical facilities, to nursing home rooms, in which residents are provided constant skilled medical and rehabilitative care. In the United States, federal programs do not generally cover the cost of long-term care. Some Medicaid programs cover long-term nursing-home expenses, but only for individuals whose savings are minimal enough to qualify for such programs. Thus, financial concerns are often at the forefront for residents of long-term-care facilities and their adult children. During the past 10 years, many new long-term-care insurance programs have become available. Although potentially costly, they do help individuals plan carefully for long-term-care expenses they may incur as they grow older. Routine help in the home and in adult day care centers can forestall or eliminate institutionalization for many elderly people.

Independent Language, Speech, and Hearing Centers

One type of independent speech and hearing clinic is the freestanding not-for-profit agency. Another is the communication disorders clinic housed within a university training program in communication sciences and disorders, in which student-clinicians are supervised in the provision of services. A third type of speech and hearing center is the office of the independent speech-language pathologist in private practice.

In all of these settings, services are provided for persons of all ages with any of a variety of communication disorders. Typically, all three types of settings have suitable rooms and proper equipment to provide appropriate assessment, intervention, and counseling services to patients. Outpatient services are the primary offering, although many free-standing agencies provide contractual services through hospitals, nursing homes, rehabilitation centers, and home-health agencies as well. Although independent agencies do not generally have formal rehabilitation teams, individual speech-language clinicians often refer patients to other rehabilitation professionals when appropriate and establish close communication with other professionals who are working with a given patient. In addition, many private practices are established in partnership with other rehabilitation personnel, or are located in buildings that house such personnel.

University Clinics

Most clinical academic programs in the field of communication sciences and disorders provide on-campus clinical services that may serve individuals with aphasia. Many programs also

provide services through contracts with outside agencies, such as hospitals, nursing homes, and rehabilitation centers. The mission of university-based clinics involves not only the delivery of quality services but also the provision of quality mentored clinical education for student-clinicians. Models for the operation of university-based clinical services vary widely, with some supported through university funds, some depending on self-support through clinical revenues and grant funds, some depending on partnerships with agencies and supervisors who are not employed by the university, and many relying on a combination of such supports. Depending upon the availability of qualified supervision and allowance for free or discounted services, some university-based clinics are able to offer long-term services to people with chronic communication challenges. In such cases this is especially helpful to patients who have exhausted insurance coverage for diagnostic and treatment services but still benefit from continued intervention. Likewise, it is helpful to students, who benefit from the enhanced experience this provides. Special opportunities for expert consultations with faculty members, input from experienced clinical supervisors, and participation in clinical research are additional advantages available to people with aphasia in university contexts.

Home Health

Many patients with stroke and aphasia return to their homes after the acute medical emergency has subsided, or after a period of therapy at a rehabilitation center. When this happens, community-based home health agencies provide a variety of services to the patient through a well-structured, closely coordinated program. Indeed, home-care services to the elderly have grown rapidly because of the pressure on hospitals to reduce costs (Whitten, 2006). Insurers like such services because they are cost-effective and often more efficacious, and many elderly adults prefer to receive services in their own home (Leff et al., 2005; Whitten, 2006). Community-based programs provide reasonable prices and high-quality care and have better long-term results than residential facilities (Kerr, 1992; Whitten, 2006). Skills mastered in treatment programs do not have to be transferred to the home environment because they are taught where they will be used. In addition, independence and self-reliance are fostered.

There is a growing trend in the United States for older people to move in with their children, and to move to homes on properties of their children, especially after the onset of major health concerns. However, as the general population continues to age, the number of adult children available to provide such care will be reduced. Another growing trend is for elderly adults to develop formal or informal co-housing communities. In addition, many belong to naturally occurring retirement communities, which allow individuals to remain at home with the help of programs and resources shared among the resi-

dents. This helps the residents to coordinate transportation, health monitoring, and social activities. Aphasiologists are increasingly likely to be engaged in serving individuals living within such communal arrangements.

The range of home health services may include speech-language pathology, physical therapy, occupational therapy, visiting nurse and physician care, and psychiatric, psychological, and social work evaluation and therapy. Additionally, dietary counseling, homemaker or household assistance, and special assistive devices and financial assistance may be available.

Telehealth

Telehealth is the “use of electronic information and communications technologies to provide and support health care services when there is a distance between participants” (Hallowell & Henri, 2007). Telehealth applications hold increasingly greater promise for improving access to care in remote geographic areas where skilled service providers may be scarce or absent. They also are helpful in cases in which transportation to and from service providers is limited or financial resources (including insurance coverage or directly subsidized services) to support one-on-one in-person services are insufficient (Berman & Fenaughty, 2005; Field, 1996; Myers, Luecke, Longan, & Revell, 1998). In addition to expanding access for disadvantaged and rural populations, opportunities are emerging for expansion of home-health services through distance technology (Brown, 2005; Hickman & Dyer, 1998; Martinez, Villarroel, Seoane, & del Pozo, 2004; Ogasawara et al., 2003; Whitten, 2006). An additional advantage of telehealth is that it may expand access to services for people who live in areas that are unsafe, such as in high-crime urban neighborhoods and active international war zones (Doolittle, Otto, & Clemens, 1998; Khazei, Jarvis-Sellinger, Ho, & Lee, 2005).

Much of what is known about the potential for remote service delivery for diagnosis and treatment in communication disorders is derived from research on applications in other disciplines. New developments in technologic access will be shaped by ongoing developments in health policy as it affects telehealth. In the United States, cases in which states have developed regulations for the delivery of services of medical practitioners between states (Scott, 2004) may also be applied to speech-language pathologists.

Few published empirical studies directly address the effectiveness of telehealth delivery specifically related to aphasia. Several studies comparing face-to-face and telehealth assessments support the reliability, feasibility, and acceptability of telehealth evaluations of speech and language disorders (Duffy, Werven, & Aronson, 1997; Glykas & Chytas, 2004; Mashima et al., 2003; Sicotte, Lehoux, Fortier-Blanc, & Leblanc, 2003; Wertz et al., 1992; Wilson & Onslow, 2004).

According to a review by Hallowell and Henri (2007), the factors that will be most influential in continuing efforts to

expand service delivery options in speech-language pathology include:

- Licensure issues, especially for services provided between states,
- Training in use of telehealth technology,
- Establishment of standards,
- Reimbursement issues,
- Patient confidentiality issues,
- Attitudes of providers and patients,
- Means of ensuring quality of clinician-patient relationships,
- Potential cost savings,
- Demonstration of clinical outcomes, and
- Telecommunications infrastructure and cost.

GERONTOLOGY AND APHASIA

Life expectancy has increased by more than 20 years since 1901. Life expectancy in the United States is between 74 and 77 years for men and 80 to 82.5 years for women. For those 65 years old, men can expect to live over 17 additional years and women almost another 21 years (Qu & Weston, 2003). The United States will continue to age rapidly as baby boomers (people born between 1946 and 1964) reach age 65 (after 2010). In 2050, over 20% of the population is expected to be age 65 and over (compared with about 13% today) (Kinsella & Velkoff, 2001). Given the rapid growth of the aging population worldwide, the extension of life-expectancy, and the fact that aphasia tends to occur in older adults, understanding the gerontologic context of aphasia intervention is crucial. It is important that clinical aphasiologists understand the process of aging, the multiple dimensions of age-related health concerns and challenges, and the hallmarks of successful aging and wellness. It is also important that they apply this information to their clinical interactions.

Aging is the sum total of all experiences, adaptations, and changes, both physical and emotional, that an individual undergoes during his or her lifetime. Three types of aging are commonly described in the gerontology literature: chronological, biological, and behavioral (Bergeman, 1997; Wei & Levkoff, 2000). Chronologic age is the number of years an individual has lived. Biological age is the relationship between aging and programmed cell death or an individual's susceptibility to disease. Behavioral age relates to how old an individual acts and thinks. It is the ability to function independently and perform activities of daily living (ADLs). A plethora of genetic, social, and cultural factors shape the experience of being old. As clinicians, we assess which specific factors may impact each patient.

Gender and Aging

Given that women live, on average, 7 years longer than men (Cruickshank, 2003), sensitivity to the multiple possible challenges to gender issues in older women is important.

Since men tend to become ill and die earlier than women, women often provide for their care. Also, heterosexual women tend to marry a person older than themselves, leaving a large number of women widowed and living alone during their last years. In a study by Wachterman and Sommers (2006), 56.2% of women were widowed at the time they died, compared to 19.5% of men. Also, 23.2% of women compared to 11.5% of men spent the last year of life in nursing homes. The dedication of a couple's financial resources to the first one to be sick leaves many women with fewer financial resources at the end of their lives (AARP Public Policy Institute, 2002). These factors all make aging a critical women's issue.

For elderly individuals who receive care from a family member, approximately half of their assistance is provided by a spouse and half from adult children such as a daughter or daughter-in-law. Although estimates of the proportion of men versus women who serve as caregivers are variable across research studies and across cultures, a large majority of caregivers worldwide are women. Up to about 75% of adult caregivers in the United States are women (Dettinger & Clarkberg, 2002; Family Caregiver Alliance, 2006; Marks, Lambert, & Choi, 2002).

Ageism and Civil Rights

Applicable knowledge about cultural aspects of aging and means of countering ageism in clinical practice is essential. Ageism is a process of systematic stereotyping and discriminating against people because of their age (Butler, Carpenter, Kay, & Simmons, 1969). It is the notion or mindset that people are less human, inferior, less worthy, incompetent, selfish, a threat to the economic security of others, poor, disabled, isolated, decrepit, grumpy, frumpy, sexless, uninteresting, needy, neurotic, comical, powerless, temperamental, mentally unstable, or not the same people they once were—all due to the number of years they have lived (Andrews, 1999; Comfort, 1976; Copper, 1988; Levin & Levin, 1980; Perry, 1999; Quadagno, 1999; Russo, 1999).

Some older people experience prejudice not only from others but from themselves. Many express a sense of shame, failure, and unworthiness related to their age. The message that being old is funny or embarrassing is so ingrained that many take this view of themselves, a phenomenon known as internalized ageism. Primary bases of age discrimination have been said to include:

- irrational fears of an aging population,
- the association of age with sickness and frailty,
- cultural values demanding that one work and have demonstrable productivity in order to prove one's worth,
- common negative portrayals of older people on television and in other media, and
- a Western cultural focus on appearance as a critical human value (Cruickshank, 2003; Schlesinger, 2006).

The harmful impact of such prejudice reinforces discriminatory practices in health care, employment, housing, law, education, and in family interactions. It also sets a fertile stage for elder abuse. Schlesinger (2006) reports the alarming statistic that one to three million Americans over age 65 have been injured, exploited, or otherwise mistreated by someone on whom they depend for care or protection. Health-care professionals are not immune to ageist practices. For example, Williams and Giles (1998) report that the results of a study comparing physician interaction with young versus old patients demonstrate that the old are addressed with less respect and less patience, given less precise information, and asked fewer open-ended questions. They note that patronizing speech to older patients in medical settings occurs in the tone, simplicity, or brevity of the communication. Older patients with aphasia are especially susceptible to these and additional communication problems in medical settings (Murphy, 2006).

Ageism and Women

A good deal of age-related discrimination targets older women (Cruikshank, 2003). The roots of societal prejudice against older women in Western culture have been related to:

- Masculine performance values emphasized at the expense of human, loving, psychosocial, and more feminine values in Western culture;
- The extremely low proportion of visible role models for women over 60 in politics, the media, and business;
- The common preference among older men to be with much younger female companions;
- Portrayal of women as objects and within the context of sex and violence through many media;
- A much stronger contrast of beauty versus the effects of the destructive ravages of time encoded in many daily advertising, news, and entertainment media involving women compared to those involving men (Copper, 1988; Markson & Taylor, 2000; Mellancamp, 1999; Palmore, 1999).

There are two critical reasons for which it is incumbent upon clinical professionals in our field to be proactive in counteracting negative societal values related to gender. First, the fact that the older an individual is, the greater the likelihood that person is a woman, suggests that our older patients are often susceptible to female gender bias. Second, the fact that the number of practicing clinical aphasiologists, in particular, and of practicing speech-language pathologists in general, is comprised of females, makes the body of practicing clinicians a strong force for gender-related advocacy.

Financial Aspects of Aging

Due to increasing longevity and a variety of other social factors, many seniors in the United States live below the

poverty line and most others are concerned about money. Many seniors in the country believe that they will be able to live on interest generated from tax-deferred savings but quickly learn that they must begin to withdraw these savings at the age of 70.5 at a substantial yearly rate. Indeed, approximately three-quarters of the principle must be withdrawn by the age of 85, leaving those who live beyond 85 at a significant financial disadvantage (Anderson & Anderson, 2003).

Successful Aging and Wellness

Another factor affecting older adults is wellness. Anderson and Anderson (2003) identify crucial links between six dimensions of health and their impact on how long we live and our vulnerability to chronic illnesses:

- biological well-being,
- psychological and behavioral well-being (thoughts and actions),
- environmental and social well-being (environment and relationships),
- economic well-being (personal achievement and equality),
- existential, religious, and spiritual well-being (faith and meaning), and
- emotional well-being.

Each of these dimensions is linked to the others such that changes in one dimension can precipitate changes in another. Health and longevity may thus depend upon risk and protective factors from across several of the interacting dimensions. Given that aging well involves living well, clinical aphasiologists ideally embrace the characteristics of successful aging and quality of life and appreciate health as more than the absence of disease and disability. A list of recommended readings in this important area is given in Appendix 7-1.

THE MANY ROLES OF THE APHASIOLOGIST

The clinical aphasiologist performs many of the same functions regardless of the professional setting in which he or she is employed. The most common functions of this clinician are identification and selection of clients; assessment; intervention; consultation and collaborative care; counseling; administration; quality assurance; contract negotiation; education; marketing; fundraising; advocacy; ethical decision-making; and research.

Identification and Selection of Clients

The ways in which patients are located or referred vary from setting to setting. In most instances, persons with aphasia are identified when a physician or another member of a rehabilitation team refers them to the aphasiologist. Such

referrals are dependent on team members' abilities to recognize the language impairment, and their interest in reporting the problem to the speech-language clinician.

In some residential settings, the clinician screens each individual who enters the facility. The purpose of screening is generally to identify those who have language, speech, and/or swallowing problems. Once persons with aphasia have been identified, a more detailed assessment is performed. Enrollment in a diagnostic and/or treatment program depends on many factors, including the patient's willingness and desire to participate; the attitudes and support of the patient's significant others; authorization from the patient's primary physician; the clinician's existing caseload demands; transportation to and from the clinical setting; and insurance coverage and other economic factors.

Assessment

Assessment and intervention are the most important functions of the aphasiologist. The purpose of assessment is to provide an in-depth description of each client's cognitive, linguistic, and communicative behavior, and to define the factors that should be taken into account in order to stimulate the patient's use of language. The diagnostic process, as well as some of the influences of health-care reform on the way we engage in the diagnostic process, are discussed in detail elsewhere in this text.

Intervention

Rehabilitation, ideally, is a complex, dynamic, comprehensive process of patient care, beginning at the time of onset of the trauma and continuing until the "maximum physical, psychological, social (language), and vocational functions for each individual have been achieved" (Sahs & Hartman, 1976, p. 205). The term "intervention" is frequently used to refer to the process of facilitating rehabilitation through skilled treatment, or therapy.

Through intervention, aphasiologists attempt to heighten each patient's potential to function maximally within his or her environment, to facilitate meaningful relationships, and to restore self-esteem, dignity, and independence. As we will consider in this chapter, many factors in the service-delivery arena may interfere with patients' access to intervention. Thus, the maximum benefits for which patients have potential are not always achieved. Persons with neurogenic communication disorders, like all persons with disabilities, should be treated by highly-qualified clinicians using the best techniques available to meet their holistic needs with quality and dignity.

Language intervention is also a complex, flexible, organized, goal-directed, dynamic process, aimed at restoring the individual's previously learned language through treatment and/or training. Intervention "must be individually

patterned, uniquely presented, and continuously tailored to signs of progress and signs of failure" (Darley, 1982, p. 238). It is a process that is designed to change communicative behavior, not just within the domain of the clinical setting, but in all communicative contexts and with all communicative partners.

Intervention is not confined to language and communication alone. The clinician helps patients to maintain and strengthen activities, participation in life, and social contacts; set and achieve life goals; gain a positive attitude; increase morale; gain insight into impairments; and develop feelings of acceptance, optimism, and emotional stability. Intervention is an innovative process that responds to the neurologic, linguistic, and social and life-participation goals and needs of each client, with a focus on the regaining of functional skills for communication in everyday life.

Due to increasing restrictions on frequency and duration of treatment for many patients requiring rehabilitation services, there is a growing need for stimulation and facilitation of communication outside the clinical environment from the earliest stages of treatment. Likewise, it is increasingly important to include caregivers and patients' significant others in direct treatment sessions. Numerous technologic tools are now available to supplement skilled treatment sessions (Katz & Hallowell, 1999) and by Katz (see Chapter 34). While such tools may help to enrich the intervention process, it is essential to recognize that their limitations, when used without a clinician, preclude their use as a solution to problem of reduced frequency and duration of skilled intervention.

Consultation and Collaborative Care

Most clinical aphasiologists function as members of rehabilitative assessment-intervention teams. In this capacity, they share knowledge and information with other professionals, such as occupational therapists, physical therapists, physicians, nurses, social workers, and dietitians, as well as with patients' family members. This necessitates team development and collaborative decision-making (see Chapter 8). Interdisciplinary consultation includes in-service training programs and presentations to professional groups. Team discussions may be related to the coordination or execution of clinical services; the case-management of specific clients; the nature of the patient's aphasia and other co-existing conditions; assessment and intervention related to medical, behavioral, and/or psychological problems; documentation of findings; insurance coverage; personal, occupational, and community activities; life participation; and discharge planning. True collaboration, in which the expertise of all team members is oriented toward holistically rehabilitating individuals to their fullest potential, improves case management through knowledge, understanding, and cooperation.

Referral for Additional Services and Resources

Given the common multiplicity of needs for medical, psychological, financial, legal, and social services among people with aphasia and their significant others, clinical aphasiologists often act as referral sources. It is important to have a deep well of information about specialists, community resources, and support services from which to draw when a patient or family member expresses a particular need. Many organizations worldwide have been designed to help connect people with aphasia to a range of support, networking, and training opportunities. Additionally, there are many centers for clinical treatment and social networking for people with aphasia. Still, access to such resources is limited or nonexistent in many geographic regions of the world. There remains a need not only to create more community resources, but also to assist people with aphasia and their families in identifying additional alternative resources at the local level. Local senior centers, lifelong learning institutes, exercise groups, support groups, respite programs, and elderhostel programs are some examples of resources that may not be designed specifically for people with aphasia, but that may offer wonderful opportunities for those affected by aphasia.

Many persons with aphasia and their significant others have Internet access; informing them of helpful links to sites offering support and information-exchange related to aphasia are often greatly appreciated. There is an ever-growing set of helpful Internet resources to aid clinicians, patients, and significant others make connections related to services, information, and support. The ASHA Web site has a continually updated list of such resources, and a simple Internet search results in numerous resources that may be helpful. Of course, it is important that users scrutinize carefully the validity and quality of Web-based materials.

Counseling

The role of counselor or adviser involves exchanging ideas or opinions and conducting discussions with the patient, members of the family, other professionals, or the community. The specific content of individual or group counseling depends on the individuals involved, but most often involves patients and their significant others. Topics such as the causes of stroke, the life-affecting impacts of stroke and aphasia, types of rehabilitation services available, and death and dying may be discussed.

Administration

Traditionally, administration or management has encompassed record keeping and report writing, scheduling clients, and ordering supplies. In the past, many aphasiologists practiced in clinical capacities with few other management

responsibilities. In most of today's service-delivery environments, though, clinicians play greatly expanded administrative roles. Even those without administrative or management titles per se are expected to engage in other activities that are not strictly clinical, such as marketing, advocacy, and quality assurance.

Documentation

Records and reports play a significant role in an aphasiology treatment program. The primary purposes for keeping records are to generate an account of the clinical services provided, to support the planning of future assessment and intervention goals, and to justify reimbursement for services provided. The system of record keeping chosen should be one that can be interpreted easily by other professionals. Some of the specific types of records and reports that may be used are assessment records, session plans (including goals, methods, type of therapy, and an evaluation of the client's responses), conference records, release-of-information forms, referral forms, master schedules, statistical summaries of cases, progress reports, and periodic disposition reports. The primary purpose of preparing reports is to disseminate and maintain information. Accurate, clear, and timely records and reports are essential to (1) providing continuity of service; (2) maintaining a cumulative account of each individual's assets, limitations, and progress in therapy; (3) evaluating the effectiveness, quality, efficiency, and productivity of clinicians and treatment programs; (4) monitoring consumer satisfaction; (5) developing and justifying programs; and (6) ensuring that clinicians and their employers are financially reimbursed for their services.

Thorough documentation is the vehicle that permits authorization (and sometimes pre- and re-authorization) for diagnosis and treatment, and that determines reimbursement by third-party payers (e.g., insurance companies, managed-care organizations, and federal health programs). Thus, clinical aphasiologists should be competent writers and should be well-trained in the fine art of clinical documentation. Speech-language documentation must contain (1) a complete history; (2) a clear statement of the problem; (3) a plan of action to address the problem, including short-term and long-term goals that are describable and quantifiable; (4) descriptions of tasks and modalities to be used in treatment; and (5) a prognostic statement and indication of expected results of intervention—preferably in terms of skills and abilities that facilitate functional behavior, independence, and improved quality of life. No matter how excellent the actual clinical services may be, clinicians and/or their employing agencies are regularly denied reimbursement from insurance companies or other third-party payers when documentation does not address each of these areas.

As treatment continues, progress should be recorded in detail. Changes in an individual's intellectual, emotional,

life-participation, and social status as they relate to communicative improvement should be described. Has motivation changed? Have there been changes in pre-existing conditions?

Documentation should be logical and sequential. Each report should be strongly tied to preceding and subsequent reports. Whenever possible, statements from patients and their families or significant others should be a component of progress notes or revisions of goals and procedures. Visual aids such as graphs and charts may add clarity to reports.

In most managed care contexts, and in contexts serving Medicare and Medicaid patients, standardized diagnostic and treatment reporting and billing forms are becoming the norm. Responses to these forms require clinicians to summarize vast amounts of information related to patient care in small designated spaces on pre-printed forms. In some cases clinicians from many disciplines are required to input their data on the same form. Such interdisciplinary coordination requires concerted effort to complete treatment and diagnostic records in a timely manner.

Aphasiologists, like clinicians in most health-care disciplines, may enjoy the advantages of new technologic developments that facilitate report writing and record keeping. For example, report writing templates may be generated through word-processing programs or commercially available programs. Further, in some settings, voice-activation report writing software now allows for hands-free dictation of reports, notes, and letters. Additionally, computerized versions of forms enable efficient form completion, cross-referencing with data base information, and easy transfer of information from one form to another. Some large hospitals and rehabilitation centers use report-writing software that links multiple workstations and integrates input from multiple disciplines. Such software may also be used to coordinate diagnostic, treatment, billing, and patient scheduling functions within and across disciplines (Hallowell & Katz, 1999).

Billing and Coding

Financial reimbursement from third-party payers depends on thoughtful, strategic billing practices. Clinicians are often responsible for the primary billing practices, including the tracking of time spent in treatment and diagnostic services, the coding of services according to coding schemes acceptable to each third-party payer, the completion of billing forms, and the submission of billing forms along with diagnostic and treatment reports to third-party payers. Even in those hospitals, rehabilitation centers, and other agencies that employ clerical professionals who are responsible for billing paperwork, clinicians must provide the factual input that will determine the content of billing records.

In most employment contexts, it is important that clinicians be familiar with numerical coding systems used by third-party payers and with related policies. The two coding systems most commonly used in speech-language pathology

are the International Classification of Diseases, 9th rev., Clinical Modification (ICD-9-CM; National Center for Health Statistics, 2006), and the Physicians Current Procedural Terminology, 4th ed. (CPTM; American Medical Association, 1999). Most public and private payers require ICD-9 codes for diagnoses and CPT codes for "procedures," or specific services rendered. These codes serve to standardize billing codes for uniformity among service providers and third-party payers.

ICD-9 diagnostic codes are used to classify medical diagnoses across disciplines and clinical settings. They are required by most insurance companies and by all programs of the U.S. Public Health Service and the Center for Medicare and Medicaid Services (CMS). ICD-9 codes consist of three digits. Sometimes, additional information is conveyed by adding two more digits to the right of a decimal point. A new edition of ICD codes, the ICD-10 codes, are in draft status and are under review by users and CMS at the time of publication of this text. The diagnostic codes currently in use may be obtained through CMS and are also available on the ASHA Web site.

CPT codes are used to standardize the coding of health-care services across disciplines and clinical settings. They consist of five digits. The codes are published annually by the American Medical Association (AMA), and are also available through the ASHA Web site. Numerous software packages and Internet resources are available for help in automation of billing and coding practices.

Appealing Denials for Treatment Authorization or Reimbursement

In many cases, requests for treatment authorization or for reimbursement of services already provided are denied by third-party payers. As managed care practices have expanded dramatically over the past few years, many agencies have seen their denial rates for evaluation and treatment authorizations grow significantly (Henri & Hallowell, 1999b). Typical reasons for which an insurance company may deny authorization or reimbursement include: (1) lack of a physician's order for services; (2) improper documentation or coding of diagnostic and/or treatment information; (3) failure to demonstrate that the patient has adequate rehabilitation potential to justify services; (4) failure to demonstrate the functional impacts that treatment will have on the functional communication, medical management, independence, and quality of life of the individual being served; (5) noncoverage of certain services by the patient's specific health care plan; and (6) exhaustion of services allowed by a given health care plan.

Whenever authorization or reimbursement is denied, clinicians may make an appeal to reverse the denial. In a majority of the cases reported in the United States, appeals for reimbursement are successful (Henri & Hallowell, 1999b). Documentation that supports a letter of appeal may

include a copy of written diagnostic or treatment authorization from the primary-care physician, progress notes, and discharge reports. The likelihood of success in the appeals process depends, in large part, on the quality of documentation, as well as in the persistence of the clinician or other professionals pursuing the appeal. Excellent documentation, and ongoing educational and advocacy efforts between clinicians and third-party payers, may help to reduce the likelihood of denials occurring in the first place.

If an appeal to overturn a denial for treatment authorization or reimbursement is unsuccessful, the clinician may be instrumental in having the patient or his or her significant other(s) file a complaint with the insurance company. Likewise, individuals with employer-sponsored insurance may file complaints with the human resources department of their employers. A more confrontational measure is to inform the third-party payer that a complaint will be filed with the state's insurance commissioner. It is important to avoid undermining relationships with insurers, though, and to maintain a cooperative, rather than adversarial, spirit throughout the process of reversing a denial whenever possible (Henri & Hallowell, 1999b).

Scheduling

Scheduling involves preparing a timed plan for the week, month, and/or year. Scheduling for the year involves accounting for legal holidays and professional conventions and conferences, and providing time for in-service training sessions and vacation time for staff members. In planning a weekly schedule, time must be reserved for traveling, holding conferences, writing reports, preparing sessions, coordinating activities, performing in-service education, and reading current professional literature. For most clinicians, the largest amount of time is ideally invested in patient assessment and intervention. Scheduling individual patients depends on such things as the patient's health and prognosis, transportation, clinicians' expertise, current clinical caseloads, insurance coverage, and additional financial considerations.

Ordering Supplies

Relevant equipment, materials, and supplies are often ordered by the clinician, depending on their perceived usefulness and the availability of funds for such purchases. Items that are frequently obtained include standard tests, textbooks, workbooks, prepared treatment materials, tape recorders and audiotapes, videotape recorders and videotapes, computers, software, and paper.

Negotiating Contracts with Third-Party Payers

To be listed on an insurance company's preferred-provider list, or to provide services for members of a preferred-provider plan, clinicians must have a contract with the cor-

responding insurance company. In many cases, professionals with administrative titles are the designated officials who engage in developing and negotiating the details of such contracts. Sometimes clinicians negotiate contracts, too, especially those who work in private practice, small speech-language hearing centers, community agencies, and university clinics (Henri, Hallowell, & Johnson, 1996).

Currently, many clinicians are keenly interested in joining specialty provider networks. Provider networks enable clinicians to team together, thus expanding patient and referral bases for network members, and decreasing the costs of marketing, billing, and other management functions through shared expenses (Davolt, 1999). Like contracting with HMOs, contracting with networks may be highly beneficial, and even necessary to some clinicians' and agencies' fiscal survival; but it involves complex professional risks, and requires keen business savvy on the part of clinicians. The employment of professional consultants for help in this arena is often well worth its cost.

Education

In the role of educator, the aphasiologist may supervise student-clinicians and paraprofessionals and/or teach in university training programs. The aphasiologist may also present in-service training to administrators, home-health aides, other health-care staff, and family members. Further, continuing self-education is essential to advanced professional competence. Reading professional journals and attending conferences, workshops, and courses helps to enrich professional development. Patient education may involve empowering individuals by informing them about the array of medical, communicative, activity, life-participation, environmental, and social choices available to them. The more individuals are involved in making decisions about their own care, the more positive and participatory they become. In addition, informing patients about their rights and discussing issues such as a positive outlook and its role in recovery, stress management, and self-esteem may be beneficial to treatment.

Ideally, the clinical aphasiologist also educates the public, fostering awareness of means of preventing stroke and traumatic brain injury. "Every year millions of people suffer and die of illnesses that could be cured or eliminated by altering patterns of personal behavior" (Ewart, 1991, p. 931). Clinicians may empower individuals for improvement by stimulating a sense of self-control, mastery, and power to effect change. Through education, they also encourage collective empowerment within the community, and development of strategies to promote better health patterns.

Marketing

Marketing is the process of defining what a potential customer wants or needs, producing that service, and letting

others know the service is for sale. It involves (1) detailed analysis of the customers' perceptions, wants, and needs; (2) analysis of the competition and other external factors that will affect service delivery; (3) development of products and services to address customers' wants and needs; (4) fostering an excellent local and regional reputation through assurance of top-quality service and demonstrable outcomes; (5) publicity and advertising (through Web sites, brochures, newsletters, education pamphlets, slide shows, and paid advertising in a variety of media); and (6) networking and successful collaboration with other health professionals.

In this era of health-care reform, few service-providing agencies, be they hospitals, long-term-care facilities, rehabilitation centers, not-for-profit clinics, home-health agencies, university- or college-based clinics, or private practices, have a steady flow of patients who can pay for diagnostic and treatment services. Service providers must now dedicate resources to marketing efforts to ensure that their agencies remain fiscally stable, that patients with communication disorders have access to treatment, and that communication-disorders professionals continue to be employed (ASHA, 1997; Cohn, 1994; Henri & Hallowell, 1997). Clinicians often participate in collaborative marketing efforts, including the development and dissemination of publicity materials, meetings with physicians and other referral sources, conferences with insurance-company representatives, and offering of in-services to the case managers and reviewers who make coverage and reimbursement decisions for managed-care organizations (MCOs).

Quality Assurance

Deep budget cuts and increased competitiveness require health-care professionals to deliver better products and services with greater efficiency. Quality is a competitive advantage. While quality-assurance programs were once considered to be in the domain of management staff, most service-providing agencies now depend on the contributions of all staff members in holistic, strategic quality-assurance efforts (Underhill, 1991). Total quality management (TQM) is a notion that has received a great deal of attention in all types of businesses throughout the world over the past three decades. It involves delivering a service or making a product, engaging employees in every process, assessing customer satisfaction, and modifying operations strategically based on outcomes and consumer feedback. The emphasis is on productivity, flexibility, efficiency, effective communication, and consumer-driven services.

TQM involves building quality into the whole of an organization, not just in specific aspects, components, or departments (Labovitz, 1991). Enterprises with successful TQM programs have well-defined objectives and guidelines for every participant, and are led by informed and active people. Ideally, these institutions invest in the notions that (1) it is

people who are critical to success, thus employees at all levels should be empowered; (2) customers must receive the best possible services; (3) excellence must be pursued in all areas of operation; and (4) strong investments in research and development are essential to quality, as are high readiness and receptiveness to change.

Regulatory agencies, including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), require accredited clinical facilities to demonstrate continuous quality-improvement programs (Roth, 1999). Regulatory agencies that accredit MCOs (e.g., the National Committee on Quality Assurance (NCQA) also require quality assurance programs on the part of MCOs (Goplerud, 2004). Such programs, generally employing multiple facets of TQM and related quality-management strategies, involve the ongoing and systematic monitoring, analysis, and improvement of services to yield improved patient outcomes. Although ASHA no longer certifies service-delivery programs, the association does offer specific guidelines for quality assurance (ASHA, 2005). Good communication is vital to the success of any total quality process (McLaurin & Bell, 1991; Varian, 1991).

Within health care in general and speech-language pathology in particular, there is a need to define what makes a TQM program. We must define our customers in very specific terms. Who are we serving? Insurance companies, facilities, the state, the patient? What are their specific needs? How can we become more responsive to these needs? What constitutes success in a TQM facility? What is our vision? What are our goals? To be excellent, we must stay close to our customers, learn their preferences, and cater to them (Peters & Waterman, 1982). We must assess consumer satisfaction and ask our patients how we can make their schedules more workable, how we can better use our facilities for their benefit, and how we can improve our human resources in order to be the preferred provider of cognitive, linguistic, and communicative services.

In the field of communication sciences and disorders we must create reliable and valid quality-assurance measures to assess patients' perceptions of the outcomes and efficacy of our treatments. In addition, we need to advocate for our professional integrity by promoting the importance of adequate professional training, certification, and licensure for professionals who work in the area of neurogenic communication disorders. Our clients have complex, multifaceted disabilities and deserve to interact with qualified professionals.

Health care and containment of health-care costs will continue to be a prime political issue in the upcoming decades. The winners in service-delivery competition "will not necessarily be the cheapest health care facilities, but those that meet customer needs by delivering quality care" (Labovitz, 1991, p. 46). It is important that we integrate TQM into our decisions regarding the kind of changes we believe are essential to the highest quality service.

Fundraising

Reduced rates for clinical services under managed care, in combination with reduced frequency and intensity of many covered services, is resulting in generally decreased revenues associated with clinical services. Thus, many service-providing agencies are increasingly reliant on finding additional means of financial support. Not-for-profit agencies, in particular, which are charged with providing services to clients regardless of their ability to pay, are dependent on alternative means of generating income to support clinical revenues. Many for-profit agencies have established their own not-for-profit foundations, or are partnering with existing foundations that help support the provision of services to persons whose access might otherwise be limited. Thus, clinicians are often involved in initiating or supporting fundraising efforts.

Fundraising efforts may include collaboration in developing fundraising materials; establishing and expanding a donor base of individuals, clients, foundations, and corporations that support the concerns of people with communication disorders; participating in annual fundraising campaigns and special events (e.g., benefit concerts, dinners, and sporting events); meeting with donors and potential donors about special clinical programs and needs; collaborating with fundraising professionals on planned-giving programs; and establishing partnerships with corporations and fraternal organizations (Henri & Hallowell, 1999a, 1999b).

Ethical Decision-Making

During the 21st century, health-care workers will increasingly be interacting with patients, family, and other health-care workers, and making decisions about the right to life, euthanasia, do-not-resuscitate (DNR) orders, the quality of life, and the right to health-care access. Agonizing questions we will have to face include: Who has the right to decide how long a patient lives? How much of our limited financial resources should be used to delay death? Should we provide rehabilitative services to people who are near death? How much emphasis should we give a patient's estimated prognosis when we decide whether or not to provide services?

In addition, clinicians face other conflicts of interest related to their own financial gains (Council on Ethical and Judicial Affairs, American Medical Association, 1995). During the past two decades, many rehabilitation companies in the United States have offered financial bonuses to clinicians based upon the amount of time they have engaged in billable service. Henri and Hallowell (1997) enumerate and describe the ways in which incentive systems may affect the quality and ethics of patient care by speech-language pathologists:

- Seeing high-fee patients too long or beyond the point of expecting further reasonable progress;
- Seeing low-fee patients too briefly or at such a frequency and intensity that progress is unlikely;

- Admitting patients to treatment who are unlikely to benefit from skilled therapy (i.e., patients who have limited rehabilitation potential) and overstating the likelihood of improvement to justify admitting persons to treatment;
- When documenting progress for billing, "stretching the truth" (e.g., misrepresenting actual progress or other forms of dishonesty);
- Misrepresenting the actual time spent in treatment; and
- Avoiding or limiting non-billable activities that are important to quality of service (e.g., in-services, informal discussions with team members, staff meetings).

Although an enormous amount of research across disciplines and industries documents the effectiveness of incentive systems, ethical implications of incentive systems are virtually ignored in most of the research literature. One study (Henri & Hallowell, 1997) suggests that students exiting graduate school and entering the clinical workforce are susceptible to such conflicts of interest, which appear to be related to the students' sense of financial need. The study also demonstrates that practicing clinicians across the country confront a multitude of ethical conflicts related not only to financial bonuses, but also to more dire personal needs. For example, an increasing number of clinicians are threatened with the loss of their jobs if they do not achieve a certain minimum level of billable clinical productivity per week. Consequently, many report a sense of ongoing ethical pressure in balancing their needs for job security with the ethical nature of treatment, billing, and caseload-management decisions. As recent worldwide trends in health-care restructuring have reduced financial gains through the provision of rehabilitation services (Katz et al., 2000), clinicians must be well prepared to face with solid moral fortitude personal conflicts of interest related to professional decisions.

Research

Some aphasiologists pursue careers in research at colleges, universities, or at private, state, or federal research agencies. A national shortage of doctoral-level personnel in communication sciences and disorders in the United States is now yielding rich opportunities for careers in higher education (Gallagher, 2006; Geffner, 1997). Furthermore, the need for faculty members who specialize in neurogenic communication disorders is greater than the need for those in other specialties within the profession. According to the results of annual surveys of graduate programs in communication sciences and disorders in the United States (Petrosino, Lieberman, & McNeil, 1997), the anticipated doctoral faculty openings in adult neurogenic disorders outnumbered those in every other specialty within speech-language pathology from 1991 through 1998. Again, in a survey completed in 2002, the number of new doctoral-program graduates in adult neurogenic disorders was far below the number needed to fill the corresponding

open positions (Shinn, Goldberg, Kimelman, & Messick, 2001). Adult neurogenic communication disorders continues to be the area of faculty specialty in greatest demand (Shinn et al., 2001).

Many clinicians with interests in scholarly work find personal and professional rewards in continuing their graduate and post-graduate training in research. For some seasoned clinicians, those interests lead to significant career changes as they return to school for doctoral study. Others know from the start of their graduate studies that they want to engage in academic careers, and thus continue their doctoral studies soon after their masters-level training.

Even clinicians who are not invested in research careers should be good consumers of and contributors to research. Minifie (1983) aptly claims that the destiny of our field is imminently tied to practitioners assuming a greater role in developing the clinical science, and that mediocrity comes from a division between clinical and research programs. Research is inseparable from clinical service.

There is a greater need now than in any time in the history of aphasiology to demonstrate the effectiveness of our interventions. It is essential to establish "how much and what kind of treatment is best and what changes constitute important treatment outcomes" (Thompson & Kearns, 1991, p. 52). As third-party payers are demanding published, empirically-based evidence of treatment efficacy and functional treatment outcomes to justify reimbursement for our services, every clinical aphasiologist has a responsibility to document his or her clinical successes and failures. Consequently, clinicians must be familiar with the techniques of scientific research design, measurement, and analysis, and with specific behavioral, cognitive, communicative, and/or linguistic models of intervention (Thompson & Kearns, 1991). Clinicians who are not well-versed in research design, and those whose schedules do not permit time to perform extensive literature reviews, collect data, and write for publication, may establish constructive partnerships with doctoral-level researchers in nearby academic institutions.

While the kind and quality of research that is undertaken depends on the availability of facilities and subjects and on the cooperative atmosphere provided by the administration and staff, it also largely depends on the commitment of the individual clinician to analyze the effectiveness of his or her work. An essential component of quality research is the creation of an environment that is conducive to risk-taking. Thus, the quality, motivation, and personal relationships of the research staff, and the style of management that is either supportive of creativity or critical of new ideas, will influence the quality of research that is conducted (Ringel, 1982).

Advocacy

Increasing competition for limited health-care resources requires that speech-language pathologists be active advo-

cates on behalf of their profession and their patients. Some specific means by which aphasiologists may advocate for their patients were discussed above in terms of appealing denials for authorization and reimbursement, marketing, quality assurance, education, negotiating contracts, and participating in research. Although it may seem obvious to the aphasiologist that speech and language services are essential to the total care of a patient, it is often necessary to demonstrate that fact to consumers and their significant others, colleagues in other disciplines, referral sources, insurance-company representatives, and legislators. Consumer advocacy is usually effective. However, consumers who have communication disorders, especially aphasia, are often unable to advocate independently for the services they need. It is important for the clinician to provide patients and their significant others the information necessary to be effective self-advocates. Aphasiologists may provide guidance concerning how to approach primary-care physicians and insurers, reverse prior authorization or treatment denials, write letters to legislators and insurance commissioners, or even testify before state and regional committees that monitor the performance of MCOs (Hallowell & Henri, in press; 1999b).

In the United States, numerous legislative advocacy campaigns to support the provision of services to persons with communication disorders are supported by ASHA, which provides free advocacy materials on the Internet and through mailings. Numerous state and local professional organizations also provide training and materials to support legislative advocacy. Although it is not often part of clinicians' job descriptions to be engaged in local, regional, and national advocacy, many clinicians feel compelled to do so, recognizing its importance. They may participate in letter-writing campaigns to legislators, election campaigns to support political representatives who support the provision of services to persons with communication disorders, and consumer education projects. Each individual's advocacy efforts contribute to the gains of all patients and professionals in our discipline.

LEGISLATIVE ISSUES AFFECTING SERVICE DELIVERY

Legislation Affecting Access to Care

In the United States, several pieces of federal and state legislation have been passed to ensure that persons of all ages with special conditions have access to adequate and appropriate levels of service. It is important for speech-language clinicians to be familiar with federal and state laws and rules and regulations that support access to special services. The Social Security Act, for example, contains several titles (i.e., chapters or subsections) that ensure reimbursement for speech-language pathology and audiology services (Hallowell & Henri, 2007). Those pertinent to serving adults with aphasia include Title 18 (Medicare), Title 19 (Medicaid),

Title 20 (the Social Services Subsidy, which supports social-work services that, in turn, may help families access speech-language pathology and audiology services). Many of these reimbursement mechanisms have mixed histories serving populations with chronic or degenerative conditions (Smith & Ashbaugh, 1995).

Several other pieces of federal legislation also support services to adults with aphasia. The Americans with Disabilities Act does not ensure funding, but may require employers to make available certain resources in cases where communication disorders have demonstrable impacts on an individual's ability to perform job duties. Other such federal acts include the Individuals with Disabilities Education Act, the primary funding vehicle for states' special-education programs, and the Rehabilitation Act, which funds rehabilitation services, including speech-language pathology and audiology, for persons ranging in age from 16 to 64 (Hallowell & Henri, 2007).

Legislation Affecting Patient Privacy

In the United States, the Health Insurance Portability and Accountability Act (HIPAA) requires that health plans standardize, streamline, and safeguard the transmission of individually identifiable health information among carriers and providers. All health-care professionals, including aphasiologists, and all support staff and student-clinicians in the U.S. are expected to be familiar with HIPAA regulations.

THE ECONOMICS OF LANGUAGE-INTERVENTION SERVICES

The delivery of diagnostic and intervention services is heavily influenced by economics. Professional clinicians are paid for the services they provide. Income generated through clinical services very rarely comes from fees paid by patients directly to providers. Rather, provider agencies are reimbursed by third-party payers. Third-party payers are usually insurance companies, federal health-care plans, or special not-for-profit foundations. Most often, clinicians receive salaries or hourly wages from their employers. Those who are self-employed generally pay themselves a fixed salary or a portion of the profits from their practice's annual revenues.

Third-Party Payers

In most countries, health-care services are covered through nationalized health programs. In the United States, however, individuals are insured primarily through private health-insurance programs, the majority through plans offered by employers as part of a benefits package. In many cases, those who are insured by their employers make some financial contribution to maintain their insurance plans. Often, employees have some choices regarding the type and

extent of medical coverage they would like, with less costly plans providing fewer medical benefits.

In addition to private insurance programs, there are two federal health programs that influence service delivery to adults in the United States: Medicare and Medicaid. Medicare provides coverage for speech and language pathologists' services to adults over 65 years of age and for persons under the age of 65 who have long-term disabilities (those lasting more than 2 years). Medicare plans are generally administered through private insurance companies that serve as interfaces between service providers and the Medicare program. Medicaid provides for services to persons who meet definable levels of low-income and specific asset standards. Medicaid programs are administered by individual states. Additionally, individuals who have served in the United States armed forces are eligible for health-care services provided through the Veterans Health Administration in the Department of Veterans Affairs (VA), most often at VA hospitals and clinics.

Reimbursement Schemes

Prior to about 1996, most insurance companies throughout the United States reimbursed service providers for specific services rendered and/or for units of time during which clinicians engaged in billable services with covered individuals. This reimbursement arrangement is known as "fee-for-service." Now, however, far-reaching measures known collectively as "managed care" have modified the traditional modes of reimbursement. Some of these managed-care modes have existed for a long time, especially in certain geographic pockets of the United States. They now characterize the majority of reimbursement arrangements in the United States. Examples of alternative reimbursement modes are discounted fee-for-service, case rate, per diem, and capitation. There are many permutations to each of these modes.

Discounted fee-for-service arrangements involve the establishment of reduced rates for patients who are members of a specific plan. In order to provide services to a plan's members, providers must agree to those rates. Third-party payers are billed for units of billable time or for specific services rendered.

In a *case rate* arrangement, the provider is paid a specific fee for treating a patient with a particular diagnosis, regardless of the duration of care or the number of services rendered. The case rate is based on actuarial analyses of the likely needs of patients according to their diagnoses. The standard Medicare diagnosis-related group (DRG) system and the new Medicare prospective-payment system (PPS) are examples of this type of arrangement.

In a *per diem* arrangement, the third-party payer pays the provider a specific amount of money for each day during which a patient is in the provider's care. The type and number of services does not generally influence the per diem rate.

Capitation involves a fixed amount of money that is paid to a provider, based on the number of people enrolled in a specific plan, not on the actual services rendered. Capitation rates are based on actuarial analyses of the likely needs of individuals who are insured through a specific plan. If those individuals require more services than are covered by the capitation revenue, then providers must absorb the remaining cost of caring for the enrolled individuals. Thus, capitation arrangements can be highly risky for providers. Still, capitation is a fast-growing type of payment system.

Managed Care

The rapid proliferation of managed-care practices in the United States is having a dramatic influence on virtually all aspects of service delivery to persons with aphasia and other communication disorders. Managed care has been defined in myriad ways in the health-care literature. Sometimes it is defined with a focus on managed-care's goals of preventing illness, maximizing health outcomes, coordinating care, and reducing unnecessary care (Henri & Hallowell, 1999b). Other definitions highlight specific cost-control and cost-cutting tactics that are characteristic of managed-care modes of service delivery. Regardless of the specific way one defines managed care, the three main goals most frequently stated are (1) assurance of the quality and coordination of care, (2) access to care for persons who need it, and (3) cost control (Henri & Hallowell, 1999b). Unfortunately, the health-care literature and the popular media are replete with accounts of how the overwhelming focus on cost control in managed care often leads to compromises in quality and access.

Because of great variability in managed-care proliferation according to geographic location within the country, and because of variability in the definition of what constitutes managed care, specific estimates of managed-care market penetration in the United States are variable. A majority of privately insured citizens receive service through a managed-care arrangement. Likewise, a large and growing proportion of Medicare and Medicaid patients receive federally sponsored benefits through managed-care plans. If one considers the cost-control mechanisms that are implemented across virtually all health-care contexts, the actual rate of managed-care penetration across the country is now near 100%. These cost-control mechanisms, enumerated by Henri and Hallowell (1999b), include:

- Increasingly stringent utilization review;
- Preadmission certification for hospital stays;
- Required pre-authorization for services;
- Negotiated reduced reimbursement rates;
- Designation of a restricted list of "preferred providers";
- Designation of physicians as "gatekeepers" of patients' health-care expenditure allotments;
- Salaried employment of physicians by payer organizations;

- Payment of incentives to physicians not to refer patients for specialty (e.g., rehabilitation) services;
- Use of red-flag diagnostic or treatment categories to deny reimbursement; and
- Restrictions on frequency, intensity, and duration of care (p. 4).

During the expansion of managed care in the U.S., there has been a general, parallel trend in health care restructuring all over the globe. Even in those countries that rely extensively on nationalized health-care systems, there have been upheavals in organizational structures and a proliferation of severe cost-cutting tactics in both federal and private programs (Katz et al., 2000).

Managed-Care Organizations

Managed-care organizations (MCOs) are insurance companies or programs that operate in managed-care modes. Given that the definition of managed care varies according to one's professional context and point of view, one might argue that the definition of an MCO does too. Generally, though, MCOs are characterized by (1) use of specific types of cost-saving reimbursement schemes, as described above; (2) promotion of health and wellness through preventive care and patient education; (3) concerted efforts to coordinate the type and number of services received by each enrollee; and (4) reduced enrollment fees for enrollees and/or the employers who pay for enrollees' insurance coverage.

There are many types of MCOs. The two most common examples are preferred-provider organizations and health-maintenance organizations. A preferred provider organization (PPO) is one that contracts with specific providers who agree to offer services to the PPO's enrollees at rates that are significantly below what the same providers would normally charge in a fee-for-service arrangement. Providers generally agree to reduced rates in the form of discounted fees-for-service, capitation schemes, case rates, or per diem allowances. Very low fees, usually in the form of co-payments, serve as an incentive for enrollees to use preferred providers. Members of a plan may use "out-of-network" providers, but at much higher rates and with greater restrictions on the type and extent of services allowable.

A health-maintenance organization (HMO) is a type of MCO in which comprehensive services are provided through one health-care facility or a network of facilities. Many of the clinicians who work for HMOs, including physicians, nurses, rehabilitation therapists, social workers, and others, are salaried by the HMO. They generally do not bill a third-party payer for services. Reimbursement schemes in HMOs are generally based on prospective payment models. The primary-care physician of each enrollee is considered a gatekeeper of all health-care resources, having the authority to determine the frequency, intensity, and

duration of any services allowable for each patient. Since the gatekeeper almost always receives financial rewards for spending less of the available financial resources on services to patients, he or she has inherent conflicts of interest related to the determination of services to be provided (Begley, 1987; Grey, 1990a, 1990b; Rodwin, 1995).

Consequences of Managed Care for Intervention in Aphasia

Restructuring of health-care systems to reduce costs has transferred control of the access to, and the duration of, care from clinicians to administrators. Although efforts to control rising health-care costs are laudable, such efforts often threaten patients' access to care and the quality of care they receive (Henri & Hallowell, 1996; Purtillo, 1995; Randall, 1994).

The key challenges to professional practitioners in neurogenic communication disorders are the same as those summarized by Henri and Hallowell (1999b) for the professions of speech-language pathology and audiology in general:

- Consumers' access to our services;
- The quality, intensity, duration, and frequency of care that we can provide;
- The fiscal stability of our service-providing agencies;
- The livelihood of our professionals;
- The maintenance of our professional integrity; and
- Problems of consumers' access to our services (p. 4).

Let us briefly review each of these key areas as they pertain to adults with neurogenic communication disorders.

Consumer Access

Consumers' access to diagnostic and treatment services is threatened by decreased referrals from managed-care's gatekeepers, usually physicians, who often receive financial incentives to decrease the amount of services offered. For persons with neurogenic disorders, managed care's emphasis on acute-care service-delivery models is particularly troublesome. One of the principal ways in which clinicians are held accountable for the outcomes of their services in such models is through the documentation of patients' ongoing improvements throughout treatment, with a logical point of discharge based on maximal progress (Henri & Hallowell, 1999b). Since elderly people and people with chronic health problems, degenerative conditions, and multiple disabilities often do not fit the acute-care patterns of quick and steady gains toward recovery and discharge, such individuals are experiencing more and more difficulty in receiving our services (Clement, Retchin, Brown, & Stegall, 1994; Fox, Wicks, & Newacheck, 1993; Oberlander, 1997; Smith & Ashbaugh, 1995). Furthermore, MCOs are less likely to provide full coverage for such persons (Inglehart, 1995). Restrictions on coverage for conditions diagnosed prior to

enrollment enable MCOs to reduce expenditures associated with the care of costly conditions (Clement, Retchin, Brown, & Stegall, 1994; Fisher, 1994; Hallowell & Henri, 2007; Henri & Hallowell, 1999a; Hiller & Lewis, 1995; Perkins, 1998).

Members of cultural and ethnic minorities and of low-income populations have restricted access to care as well (Daw, 2001; Hallowell & Henri, 2007; Leigh, 1994; Stenger, 1993), perhaps because they are less likely to have health-care coverage through employers, are less likely to be able to afford their own health-insurance coverage, and may be less likely to advocate for their own health-care needs (Henri & Hallowell, 1999b). Ironically, such individuals tend to have disproportionately greater needs for rehabilitation services (Screen & Anderson, 1994).

MCO clauses emphasizing the relatively new concept of "evidence-based medical necessity" further threaten patient access to speech-language services. Under such clauses, if providers cannot present a solid body of well-controlled research to support the effectiveness of any intervention administered, then they will not be reimbursed for providing that intervention. An additional repercussion of medical-necessity clauses is the emphasis on the importance of treatment of medical impairments rather than of disabling conditions that influence quality of life. A disconcerting example of this repercussion is that many clinicians are finding it easier to obtain authorization and reimbursement for dysphagia services than for language intervention. Given that many clinicians who treat aphasia also treat dysphagia, there is an alarming trend to prioritize treatment for swallowing problems over problems of communication (Hallowell & Clark, 2002).

Quality, Intensity, Duration, and Frequency of Care

Despite the supposed focus on "quality" in MCOs, several factors related to managed-care modes of delivery have eroded the quality of care clinicians can deliver. First, a prominent cost-containment feature of managed-care plans is the restriction on duration and frequency of treatments, which limits clinicians' abilities to foster significant functional gains, even in patients with good rehabilitation potential. Second, insurance companies are increasingly intervening in matters that traditionally have been in the hands of clinicians, such as treatment planning and discharge decision-making. This trend has led to decision-making that is more financially driven than clinically sound. Third, interruptions in the continuity of care have increased due to delays in authorization and re-authorization for services. Fourth, although the use of assistants and aides in the treatment of communication and swallowing disorders is relatively new in the United States, concerns about the overuse and misuse of these less expensive (but less qualified) personnel and the potential consequences for further reductions in the quality

and outcomes of care are growing (Hallowell & Henri, 2007).

Quality assurance is a stated aim in the literature of virtually every MCO. MCO-accrediting agencies, such as the NCQA, require that MCOs meet high standards of quality-assurance and quality-improvement practices. How can it be, then, that there is such a preponderance of complaints about managed care in the popular media, as well as evidence of decreasing quality in the research literature? One reason is that overall comparative standards among HMOs may be lower than standards under more traditional models. Another is that MCOs tend to minimize their quality under pressure to reduce their own administrative cost-improvement efforts. Recent research on the quality of health care suggests accreditation of HMOs may be misleading because a large proportion of enrollees who are not satisfied with their care withdraw from membership, thus eliminating their participation in consumer satisfaction surveys (Health Advocate, 1998).

Fiscal Stability of Service-Providing Agencies

Many of the features that characterize managed care threaten the fiscal stability of the agencies that support the delivery of care. Reduced reimbursement levels, increased reimbursement processing time, increases in the frequency of reimbursement denials, increased administrative costs, reductions in coverage, and reduced access for some patient populations are all factors that threaten agencies' clinical revenues. A recent surge in staffing reductions, modifications of salaried contracts to hourly contracts based on billable services, implementation of rigorous clinical-productivity standards, and dramatic dissolution of numerous rehabilitation companies and private practices is indicative of the current fiscal pressure on providers.

Because the majority of persons with aphasia are older than the age of 65, two of the most drastic threats to U.S. agencies that support intervention for aphasia have been Medicare's prospective-payment system (PPS), implemented in varied forms since 1983, and Medicare's payment cap for outpatient rehabilitation services, implemented in varied forms since 1999 (Moore, 1999). Both of these measures were implemented by the Center for Medicare and Medicaid Services.

Prospective-payment systems affect inpatient services in inpatient rehabilitation and long-term-care facilities in particular. Rather than being reimbursed for actual costs incurred, or for actual services rendered, facilities are paid a flat daily rate based on the conditions of individual residents. The rates are calculated with complex formulas involving resource-utilization group (RUG) classifications and case-mix data. RUG classifications are based on studies of the actual time clinicians from multiple disciplines spent caring for patients with a variety of conditions as assessed through

a standardized assessment scheme, known as the Minimum Data Set (MDS) (regularly updated). Case-mix data are based on RUG classifications of a facility's residents. Applying what is known as the "75% rule," CMS requires that at least 75% of patients admitted to inpatient rehabilitation hospitals have one of 13 qualifying diagnoses (updated from 10 in 2004). While the intent is reasonable to prevent rehabilitation centers from providing services that could be provided through less costly means in less-intensive care environments, the effect on quality of care is compromised. Having government fiscal policy rather than qualified medical providers determine which patients may receive which services is far from an optimal means of clinical decision-making. Worse, even when the latest CMS plan was first being phased in during 2005 (with only 50% compliance expected), patients had dramatically reduced access to rehabilitation hospitals (Moran Company, 2005).

Inpatient rehabilitation hospitals are vital to the restoration of health, independence, and functional abilities of many patients discharged from acute-care hospitals but not ready to return home. Patients who do not have one of the 13 allowable diagnoses now have longer acute-care stays, are transferred to nursing homes, or are discharged to their homes. Many nursing homes and home-health-care agencies do not have the equipment, staff, or expertise to address the medical or rehabilitation needs of patients with complex medical conditions, including cognitive and communicative disorders. Even the financial savings targeted through the CMS policy are not assured. The savings involved in reduced cost-of-care in the short term does not stem the long-term costly needs for care of patients who have not had appropriate care and rehabilitation to begin with (U.S. Government Accountability Office, 2005). Given the frequently complex medical conditions and the common need for intensive rehabilitation of persons with neurogenic communication disorders, the advocacy role of clinical aphasiologist's in light of such managed care trends is vital.

Medicare's payment cap for outpatient rehabilitation services (Medicare Part B) involves a limit (\$1,740 at the close of 2006) on payments for both speech-language pathology and physical therapy services, combined. Originally initiated in 1999, the cap dramatically reduces the frequency and duration of treatment that clinicians can provide, and requires clinicians across disciplines to make difficult and often arbitrary decisions about the priority of one treatment over another. Tremendous financial losses have consequently been experienced by long-term-care facilities and rehabilitation providers throughout the United States. The decrease in access to services for persons with neurogenic communication disorders has been equally, if not more, devastating. Following a strong advocacy campaign, this cap was temporarily rescinded in November 1999, but later reinstated. In 2006, an "exceptions" process was implemented, enabling speech-language pathologists to appeal for

additional reimbursable treatment based on documentation of a patient's need for additional services. It is incumbent upon clinical aphasiologists to provide sufficient and appropriate documentation to boost patient access to needed rehabilitation services for people with aphasia and related disorders.

Livelihood of Professionals

Given the financial losses to service-providing agencies discussed above, it is not surprising that clinicians, too, are experiencing the effects of managed care in terms of reduced salaries and employment opportunities. Restructuring, re-engineering, consolidation, and down-sizing movements in hospitals, speech and hearing centers, private practices, and rehabilitation companies have had direct and personal impacts on many speech-language clinicians (Henri & Hallowell, 1999b; 2007).

Professional Integrity

Under managed care, many insurance companies, as well as service-providing agencies, are attempting to reduce costs by addressing the expense of employing highly educated and skilled clinicians, such as fully certified and licensed speech-language pathologists. One way they may do this is to employ less costly assistants, technicians, and aides (ASHA, 1996a; Gerard, 1990; Holzemer, 1996). Another is to employ "multiskilled" or "transdisciplinary" professionals who are trained in a variety of medical and rehabilitative diagnostic and treatment methods that were once exclusively in the domain of specific clinical disciplines (ASHA, 1996c). Both of these strategies have resulted in a decrease in the level of skill, education, training, licensure, certification, and overall competence of clinical practitioners, and have yielded tremendous inconsistencies in the quality of care across treatment settings. Although there are merits to some of the arguments for the use of support and/or cross-trained personnel in some environments, it is essential that clinicians advocate for the integrity of their professions (Henri & Hallowell, 1999b), as well as for their specialized expertise in such areas as aphasiology.

Positive Impacts of Managed Care

Not all of managed-care's influences on services available to persons with neurogenic communication disorders are negative. Some of its touted virtues of prevention, cost-saving, accessibility, and accountability have, in fact, impacted our professional practices in positive ways.

Prevention, Access, and Cost

The emphasis of most MCOs on preventive care and health maintenance should ideally reduce the number of people who are affected by stroke, traumatic brain injury, infectious

processes, and so on, and thus may help to prevent some communication disorders. Additionally, the reduced cost of insurance coverage for most people who enroll in MCOs enhances the accessibility of coverage. While we lament the decline in revenues for our clinical services, we must also recognize that the continuous escalation of health-care costs from the 1960s through the early 1990s could not continue. Many practitioners and agencies representing the whole array of health-care disciplines are known to have abused the lucrative insurance-billing opportunities within the traditional indemnity fee-for-service modes of operation. Certainly, some reductions in reimbursement and coverage are truly outrageous, having no relevance to patients' actual needs or to actual expenses incurred in offering our services; the Medicare cap shared among speech-language pathologists and physical therapists is a good but unfortunate example. Even in the realm of aphasiology, there have been ongoing abuses of systems that allow for continuous high-cost hourly billing for frequent sessions, and long-lasting treatment programs that are not necessarily optimal in terms of achieving positive functional outcomes.

Accountability and Enhancement of Research

A related and critically important positive impact of health-care restructuring is that it demands increased accountability of clinicians, service-providing agencies, and clinical professions. Scientific evidence of our treatment efficacy and treatment outcomes is being far more carefully scrutinized than ever. This scrutiny has increased awareness of our great need for a richer empirical base of research with which to justify our interventions. Thus, we have been driven to improve the quantity and quality of clinical research in our discipline (Boston, 1994; Sarno, 1998).

Another facet of our heightened accountability is that clinicians are now required to ensure that services provided address important life-affecting changes in clients and patients, and that those services are necessary. Clinicians were once typically trained to think of treatment in terms of clinical performance-based objectives (e.g., those pertaining to grammatical structures, articulator placement, or speech sound discrimination), remote from practical communication in real-world contexts. Now we have been challenged to reformulate our diagnostic and treatment methods to better address "functional outcomes," a concept that is addressed repeatedly in this book.

It is troublesome that the new evidence-based medical-necessity clauses of some MCOs impose unreasonable restrictions on the types of evidence required to justify treatments. It is also troublesome that such clauses often encourage denial of the communicative, cognitive, and psychosocial needs of patients, in favor of the treatment of physical impairments that are not always as life-affecting. Still, clinicians in the past were probably far too liberal in providing

services that were not necessarily based in solid scientific research and theory. Further, the resources they had in the treatment-outcomes and efficacy literature to support their treatment approaches were lacking.

The fact that third-party payers and government-sponsored health-care plans now require solid evidence to justify reimbursement has stimulated concerted research and publication efforts on the part of our professional organizations, researchers, and clinicians. Some university research and teaching programs in communication sciences and disorders have reorganized research priorities over the past 10 years, such that clinical research is valued in academic cultures more than it had been previously. Likewise, private, state, and federal funding opportunities for research involving treatment outcomes and treatment efficacy have increased. The continued expansion of controlled research regarding our clinical practices will undoubtedly help us not only justify our services, but also learn better ways to diagnose, treat, and make valid prognostic statements about neurogenic communication disorders.

One additional benefit of managed care, reported by health-care administrators, is that clinical professionals are increasingly aware of the financial impact of their individual and agency-wide services on the financial well-being of their employing agencies. In contexts in which clinicians once performed clinical duties without engaging in the monitoring of clinical revenues, clinicians now frequently play a vital role in business and financial-planning teamwork within their agencies. This change appears to have increased clinicians' sense of ownership for their agencies' operations. Likewise, employers report being impressed with the improved business savvy of their clinical employees (Henri & Hallowell, 1997, 1999b).

Gender Influences on Salary and Status

Wage rates are influenced primarily by the gender composition of specific occupations; low salary and low status are linked to the preponderance of women in a profession (U.S. Government Accountability Office, 2003). Women consistently make less money than men in almost every industry (Bayard, Hellerstein, Newmark, & Troske, 2003; Isaacs, 1995; Schwartz, 1988; Signer, 1988). According to a recent Department of Labor report, women's median weekly full-time wage and salary earnings in 2001 were about 75% of those of men with the same experience (U.S. Government Accountability Office, 2003). Since women make up 75% of the health-care work force, salaries are low throughout the health-care professions.

Not surprisingly, there is also a strong relationship between gender and status. The health-care labor force is notorious for its hierarchical status and power differences between high-ranking and low-ranking workers. For example, despite the long-time predominance of women (over

90%) in the field of communication sciences and disorders (ASHA, 2006), men have continued to represent the majority of directors and heads of programs in the field (c.f., Signer, 1988).

Because women sometimes contribute only secondarily to income, they may not assert their right to a salary commensurate with their training and professional status. The lower salaries in our profession are also tied to inadequate marketing of our scope of practice and the perceived value of our services (Holley, 1988).

THE ULTIMATE EXCELLENT APHASIOLOGIST

What constitutes the ultimate excellent clinical aphasiologist? What factors characterize the very best clinicians? There certainly are not definitive answers to these questions, as the skills and qualities needed for excellence differ according to the contexts in which we work, the patients and colleagues with whom we work, and the nature of our specific professional responsibilities. One must recognize that the degree of excellence perceived is relative to the person who perceives it. A list of prescriptive features indicating what constitutes the "best" aphasiologist may not be appropriate, as diversity in expertise, skills, knowledge, effect, and culture among clinicians is certainly desirable. Still, there are numerous ideal characteristics that we might all aspire to possess.

The excellent aphasiologist is competent. Competent clinicians have a graduate education, national and regional certification in speech-language pathology (in the United States, this means a Certificate of Clinical Competence (CCC) granted by ASHA and, where appropriate, a state license as a speech-language pathologist). They have clinical-practice experience under the supervision and mentorship of seasoned excellent aphasiologists (Kovach & Moore, 1992). They also demonstrate outstanding oral and written communication skills; use only high-caliber assessment and intervention techniques; foster maximum self-determination on the part of patients (Cormier & Cormier, 1991); maintain an effective climate that contributes positively to the therapeutic relationship (Rogers, 1969); provide inspiration, motivation, encouragement, and leadership to patients and their significant others as well as to colleagues; are flexible and adapt well to change; and integrate the personal, scientific, and artistic parts of themselves to achieve a balance of interpersonal, intellectual, and technical competence.

The excellent aphasiologist is knowledgeable. Knowledgeable clinicians are able to reason scientifically, incorporate new findings, and generate new applications. They use knowledge effectively and think and learn independently. They are committed to interdisciplinary study, and have formal and informal training in the arts and sciences, including not only speech-language pathology and audiology, but also cognitive sciences, psychology, linguistics,

education, medicine (especially neurology), statistics, computer science, manual communication and other modern languages, business and health administration, economics, gerontology, sociology, anthropology, music, and counseling. They have training and experience in the effective management of communication problems resulting not only from stroke, but also those associated with traumatic brain injury, dementia, movement disorders, infectious processes, neoplasms, and confusional states. Likewise, knowledgeable clinicians are familiar with multiple aspects of aging, and are abreast of the latest research regarding “normal” versus “disordered” aspects of language, conversational discourse, speech, voice, and hearing (Worrall & Hickson, 2003). Their knowledge base is constantly expanding as they read the current professional literature, take advantage of continuing-education opportunities, and learn from their colleagues and patients. They have a profound sense of inquiry, and are open to questioning and exploration (Rogers, 1969). They complement their knowledge with keen insight in managing simple and complex cases.

The excellent aphasiologist is sensitive to issues of gender, age, culture, race, sexual orientation, and socioeconomic status. Sensitive clinicians appreciate multiculturalism and multilingualism, and familiarize themselves with, and celebrate, differences and similarities among their patients and colleagues. Some have been raised in bilingual or multilingual environments. Others strive to learn additional languages in order to expand opportunities for communication and, when possible, to provide services in more than one language. They are aware of the relative lack of persons from culturally diverse populations in the profession of communication sciences and disorders and support strategic efforts to recruit, educate, mentor, support, and retain multicultural clinicians (Wallace & Freeman, 1991). Sensitive clinicians are aware of biases—their own and those of others—and examine the basis for any unreasoned distortion of judgment. They strive to resolve their own prejudices through education, exposure, and sensitivity training.

The excellent aphasiologist is ethical. Ethical clinicians are aware of conflicts of interest and work to resolve personal wants and needs without compromising the appropriateness of their actions (Hirsch, 1994). They are unfailingly honest. They follow their professional codes of ethics, obey all laws, and adhere to their own personal solid moral codes.

The excellent aphasiologist is professional. His or her primary goal is high-quality, first-rate patient care. Effective clinicians have a rationale for everything they do, and communicate that rationale, whenever possible, to patients and the patients’ clinicians from other disciplines. They foster responsible participation in the selection of goals, in ways of reaching those goals, and in the development of appropriate attitudes and skills, such as personal responsibility for learning and improvement. They critique, assess, monitor, and

edit their own behavior. They interact effectively with the entire rehabilitation team. They treat colleagues with respect, courtesy, fairness, and good faith (Cormier & Cormier, 1991). They maintain records and reports accurately and completely and keep them up-to-date. They consistently protect clients’ privacy and confidentiality, initiate proper referrals and recommendations, and exhibit proper follow-through. They have definite but malleable professional and personal goals and defined ways of reaching those goals.

The excellent aphasiologist is warm, caring, patient, empathetic, and compassionate. The ultimate excellent clinical aphasiologist is sensitive to client-centered and significant-other-centered needs in providing maximally effective services. His or her empathetic and compassionate nature helps to foster feelings of comfort, safety, and confidence among patients, significant others, and collaborating professionals. He or she addresses current events in clients’ and families’ lives, honors each significant other, listens thoughtfully to their needs, and tailors sessions to meet those needs (Brown, 2005). He or she has effective listening skills (Brownell, 2002). He or she is aware of nonverbal communication messages and is skilled in interpreting them.

The excellent aphasiologist is a thoughtful, motivated, interesting person. Excellent clinicians fit Ringel’s definition of “gifted scientists” who are “individualistic, open-minded, freedom-loving, highly motivated, fiercely independent, imaginative, nonconformist and usually critical of the status quo” (Ringel, 1982, p. 401). They are also genuinely motivated to help others (Minifie, 1983), and have a terrific sense of humor, a love of people, a commitment to service, and a passion for patient and professional advocacy. They have weaknesses and failures, and acknowledge and grow through them with grace. Although aware of their assets, they are humble.

The excellent aphasiologist is emotionally healthy. Healthy clinicians serve as role models to clinicians in training, colleagues, consumers, and others in terms of health maintenance, stress management, life-style balance, and self-esteem. They have familiarized themselves with books on healthy interpersonal interaction and intimacy, and understand the fundamentals of interpersonal relationships, which include communication, active listening, previous familial patterning, emotional expression, and the development of compassion and understanding for another. They continue to learn how to cultivate healthy relationships and to love and be loved unconditionally. They avoid professional burnout, actively balancing their psychological resources with the demands of their jobs.

FUTURE TRENDS

Demographic trends will certainly continue to play an important role in aphasia intervention. With post-World War generations growing older and living longer than ever

before, and with fewer children being born, attention to issues affecting older adults is steadily growing. Public and private retirement and medical programs will necessarily evolve with increasing focus on the elderly over the next few decades (Mechanic, 1999). The aging of the population brings with it increased risks for catastrophic disease, illness, and disability (Kaplan, Haan, & Wallace, 1999), including adult aphasia. Enhanced consumer education and new methods to prevent stroke and traumatic brain injury will help address these risks.

Other demographic trends, such as the growth of racial, ethnic, and linguistic minority populations in the United States, will continue to stimulate our constructive actions to meet the needs of the members of such populations. Increases in certain patient populations, such as those with HIV/AIDS, in our caseloads (ASHA, 1989; ASHA Committee on Quality Assurance, 1990; Flower & Sooy, 1987; Larsen, 1998) will require that we engage in ongoing research pertaining to relatively new areas of clinical practice.

As new formulae for practice under changing modes of service delivery continue to evolve, we will continue to see further positive effects on our professions, such as more efficient and increasingly outcomes-focused treatments, new types of employment opportunities, and improved interdisciplinary teamwork in the coordination of patient care, co-treatment, and discharge planning. At the same time, we are likely to see more women in leadership roles.

Over the next few decades, we will draw on the evolving empirical research base to enhance our methods for improving our patients' quality of life, independence, and medical management. We will take advantage of technologic advancements that will influence virtually every one of our many professional roles. We will also continue to adapt constructively to reduced patient access, both through advocacy for improved access and through the use of alternative models of intervention and caregiver training.

As the research base on treatment efficacy, cost-effectiveness, and outcomes continues to grow, we will become increasingly sophisticated about the appropriate patterns of practice associated with patients' specific diagnostic characteristics. More and more clinical agencies will implement "clinical pathways," or optimal plans for diagnostic and treatment services that take into account the nature and severity of patients' deficits and time post-onset. Likewise, guidelines concerning the common best practices given a patient's diagnosis, such as ASHA's "Preferred Practice Patterns" (ASHA 1993, 1996b), will undoubtedly continue to be refined.

The specialty of neurogenic communication disorders will benefit from clinicians who are dedicated to fostering all of the characteristics that constitute the "ultimate excellent aphasiologist." The active role that aphasiologists play as advocates for our clients and profession is critical to maximizing our effectiveness.

KEY POINTS

1. Throughout the world, changes in health-care policy, reimbursement schemes, national health plans, political climates, insurance mechanisms, clinical licensure, and professional training are having dramatic impacts on access to patients and the services we deliver to them.
2. Gerontologic issues that affect aphasia intervention include the rapid growth of the aging population worldwide, the extension of life expectancy, and the fact that women live an average of 7 years longer than men. Multiple dimensions of age-related health concerns are discussed, including chronological, biological, and behavioral age and successful ageing and wellness. Ageism is seen as the systematic stereotyping and discriminating against people because of age. The cultural roots and harmful impact of ageism, internalized ageism, and ageism and Civil Rights are explored. Gender and ageism, or the fact that a good deal of age-related discrimination targets older women, and the financial aspects of aging, are explored.
3. Speech-language pathologists rehabilitate patients with aphasia in a variety of contexts such as hospitals, rehabilitation centers, skilled-nursing facilities, nursing homes, clinics, private offices, and the patient's own home. In addition, "telehealth," or the use of electronic communications technologies, may provide and/or support health-care services.
4. The clinical aphasiologist performs many of the same functions regardless of professional setting, such as the identification and selection of clients; assessment; intervention; consultation and collaborative care; counseling; administration; quality assurance; contract negotiation; education; marketing; fundraising; advocacy; ethical decision-making; and research.
5. Legislative issues affecting service delivery in the United States include several pieces of legislation to ensure that persons of all ages with special conditions have access to adequate and appropriate levels of service. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) requires that health plans standardize, streamline, and safeguard the transmission of individually identifiable health information among carriers and providers.
6. The delivery of diagnostic and intervention services is heavily influenced by economics. In the U.S., recent impacts of managed care in the private sector and

evolving federal health policies are significantly impacting the practice of aphasiology. For example, in the U.S., individuals are insured primarily through private health insurance programs, the majority through plans offered by employers as part of a benefits package. In addition to private insurance programs, two federal health programs, Medicare and Medicaid, influence service delivery to adults in the United States. Managed-care practice is having a dramatic influence on service delivery. The three main goals most frequently stated are assurance of the quality and coordination of care, access to care for persons who need it, and cost control. Specific cost-control mechanisms are discussed. Unfortunately, the literature is replete with accounts of how the overwhelming focus on cost control in managed care often leads to compromises in quality and access.

7. Managed care organizations (MCOs) are insurance companies or programs that operate in managed-care modes and are characterized by the use of specific types of cost-saving reimbursement schemes, the promotion of health and wellness through preventive care and education; a concerted effort to coordinate the type and number of services received by each enrollee; and reduced enrollment fees for enrollees and/or the employers who pay for enrollees' insurance coverage. There are many types of MCOs. The two most common examples are preferred-provider organizations (PPOs) and health-maintenance organizations (HMOs).
8. Restructuring of health-care systems to reduce costs has transferred control of the access to, and duration of, care from clinicians to administrators. Although efforts to control rising health-care costs are laudable, such efforts often threaten patients' access to care and the quality of care they receive.
9. Key challenges to professional practice in neurogenic communication disorders are consumers' access to our services; the quality, intensity, duration, and frequency of care that we can provide; the fiscal stability of our service-providing agencies; the livelihood of our professionals; the maintenance of our professional integrity; and problems of consumers' access to our services.
10. The ultimate excellent aphasiologist is seen as one who is competent, knowledgeable, ethical, professional, warm, caring, patient, empathetic, and compassionate, and a thoughtful, motivated, interesting person who is emotionally healthy.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Compare and contrast the type of collaborative care and teamwork in which aphasiologists are likely to be engaged within their varied employment contexts.
2. For each of the varied employment contexts, consider which of the many roles of the aphasiologist are most emphasized.
3. Discuss the ways in which employment in each of the different service delivery contexts might affect the quality of life of clinicians.
4. Develop a Web page, flier, or brochure to provide information about community resources available to people with aphasia and their significant others in your local community. Be sure to think broadly about the types of referrals for information, support, and clinical-care options from which your patients might benefit.
5. Imagine that you are team-teaching a graduate course on neurogenic communication disorders and that you have agreed to teach the component addressing the importance and relevance of gerontology to aphasia intervention. Outline the key topics that you would cover in your component on the course. Given time constraints, which topics would you prioritize as most important?
6. Develop a position statement for aphasiologists stating how changing the way that older women are viewed and valued may reduce the prejudice experienced by female patients.
7. In what ways is excellence in documentation critical to the success of the aphasiologist?
8. Describe the ways in which recent service-delivery trends have influenced where (in what type of service-delivery context) persons with neurogenic communication disorders receive treatment.
9. How do reductions in stays in acute-care hospitals impact what the speech-language clinician accomplishes in the acute care context?
10. How do reductions in the frequency and duration of treatment programs for patients with aphasia influence intervention?
11. List specific ways in which aphasiologists may engage actively in quality assurance, marketing, contract negotiation, and fundraising.
12. Describe what you think are the most critical ethical issues for aphasiologists. What might be done to alleviate some of the ethical dilemmas and conflicts of interest that clinicians face in the workplace?
13. In what ways might the full-time clinician without doctoral training participate in research?
14. Make an outline of both positive and negative service-delivery trends that are influencing intervention for adults with aphasia and related disorders. For each of the negative trends, list and discuss specific ways in

which you may act strategically as an advocate to lessen the negative effects for your patients and your profession. List and discuss the specific ways in which you might capitalize on each of the positive trends to improve service for your patients.

15. Consider this hypothetical case: You are an SLP who is treating Mr. Comet, a 48-year-old man who recently suffered a CVA. He is enrolled in an HMO. Mr. Comet's physician, his primary medical provider, has a contract with the patient's HMO. She had authorized one evaluation and six treatment sessions to address speech and language problems secondary to the CVA. You have exhausted those authorized sessions. Now the physician refuses to authorize any further treatment from your discipline. You have ample evidence that Mr. Comet's communication deficits are having a significant impact on his safety, his medical management, his ability to live independently, and his quality of life. You are confident that he is an appropriate candidate for treatment and that you have effective strategies to implement in a treatment program for him. What specific steps will you take to advocate effectively for Mr. Comet's continued access to your services?
16. How would you describe the ultimate excellent clinical aphasiologist? What are your own strengths and weaknesses relative to your view of the ideal clinician?

Chapter 8

Teams and Partnerships in Aphasia Intervention

Lee Ann C. Golper

OBJECTIVES

The objectives of this chapter are (1) to define and examine typical team organization designs found in health care delivery; (2) to review basic elements in group processes that lead to successful teams and some of the potential barriers to developing effective teams; (3) to consider how the team designs may differ depending upon the setting and how priorities and the primary decision-makers change across the continuum of recovery from aphasia; (4) to examine related issues, including collaborative evaluations, documentation, outcomes studies, family and patient education, professional education, and research; and (5) to suggest that the overriding aim of the rehabilitation team throughout the recovery continuum with adult aphasia should be directed at educating and empowering patients and families to become collaborative partners, to make use of community and national resources, and ultimately to lead their own “team aphasia.”

IT TAKES A VILLAGE

In almost every service arena throughout the world—from emergency rooms to community mental-health clinics—team intervention with a patient-centered emphasis has long been recognized as the optimal approach to health-services delivery (Billups, 1987; Cifu & Stewart, 1999; Collins, Moore, Mitchell, & Alpress, 1999; Davis, Cornman, Lane, & Patton, 2005; Gibbon, 1999; Heikkila, Korpelainen, Turkka, Lallanranta, & Summala, 1999; Hogh et al., 1999; Lott, Hennes, & Dick, 1999; Rosin et al., 1996). This approach necessitates bringing together the knowledge and skills of individuals from many disciplines in order to ensure that complex problems receive the comprehensive attention they require (Allen, Holm, & Scheifelbusch, 1978). As individuals with aphasia move from their hospital beds to their homes, their concerns often shift from surviving the acute event to issues related to finances or changes in their family dynamics. No one discipline can

encompass the whole life-changing condition known as “aphasia.” It takes a village. Developing collaborations with others is particularly important throughout the recovery continuum following the onset of aphasia since many patients with aphasia have medical, physical, psychosocial, emotional, recreational, vocational, and financial concerns that may or may not be directly complicated by their communication impairment. Indeed, such issues can supersede the language deficits. Those of us who work with individuals who have communication disorders have long been proponents of family-centered team intervention (Rosin et al., 1996). We rarely evaluate or treat any type of communication disorder without having some amount of collaboration with the patients’ families and with other disciplines. Unfortunately, evidence-based guidelines help us determine how to optimally integrate patients and families into the health-care team are largely lacking (D’Amour, Ferrada-Videla, Rodriguez, & Beaulieu, 2005).

WHAT IS A TEAM?

Teams are groups of people collaborating in some way to reach a common goal. Teams can be made up of two people or fifty people. They can have face-to-face meetings or use more indirect communication methods. They can be a formal, structured hierarchy, or a loosely organized group of peers. Usually, teams have at least one designated leader. Teams may have leaders who are authoritarian, controlling the team’s actions, or have leaders who function more as facilitators, advising from the sidelines. They may be made up of people from a single discipline or multiple disciplines and can have professional and nonprofessional members. They can be designed to include the patient and family as active participants or can be restricted to an exclusive panel of specialist-consultants. Teams can have smaller teams within them, such as the nursing care team within the rehabilitation care team. Whatever the composition, structure, or purpose, it is important to remember that teams are human enterprises. Teams are made up of people and personalities and they are often “caldrons of bubbling emotions.” (Goleman, 1998, p. 101). No team looks or functions exactly like any other. Appreciating that there is no ideal blueprint for teams and

that the team design can vary depending on the setting, let's examine a couple of typical models for team processes in health services delivery.

MODELS

The models of team processes most commonly found in health care delivery are either *multidisciplinary* or *interdisciplinary* teams. In education, particularly early intervention, *transdisciplinary* teams are more common. These team models mainly differ in their role delineations and communication processes. Occasionally, the terms multidisciplinary, interdisciplinary, and transdisciplinary seem to be used interchangeably. Thus, it may be helpful to consider the differences between them. In a multidisciplinary model, specialists with clearly defined roles work side by side, each addressing different problems, or different aspects of a given problem. Multidisciplinary teams are probably a good way to characterize how disciplines typically function in an acute care setting, such as on an inpatient medicine or surgery unit. In that setting, various disciplines have defined roles and work cooperatively together, but for the most part they work in parallel, rather than in partnership, with one another. In multidisciplinary teams, individual members bring discipline-specific skills, and the members' responsibilities are clearly defined and understood (Tuchman, 1996). Opportunities for communication between and among the disciplines may be cursory, and shared goals may be lacking (Allen et al., 1978).

Interdisciplinary teams are, by contrast, intended to be interactive and highly collaborative. There is greater emphasis on communication processes in interdisciplinary teams as compared with multidisciplinary teams (Tuchman, 1996). True interdisciplinary teams allow for at least some amount of blurring between traditional professional boundaries. In interdisciplinary teams, different professional disciplines not only work together in a cooperative manner, they also collaborate in partnerships to implement the treatment procedures. In an interdisciplinary format, goals are discussed as "our goals," rather than "OT goals" or "PT goals."

There is very good evidence to suggest that the most effective model for rehabilitation-services teams is an interdisciplinary design. In their review of 79 studies looking at factors affecting outcomes in stroke, Cifu and Stewart (1999) examined the effects of interdisciplinary versus multidisciplinary teams on patient outcomes. They conducted a meta-analysis of 11 well-defined Level I studies, including eight studies in which patients were randomized to either a multidisciplinary medical stroke unit or an interdisciplinary rehabilitation unit. These analyses demonstrate that interdisciplinary team intervention is associated with decreased mortality, improved functional outcomes, shorter lengths of stays, and decreased costs (Cifu & Stewart, 1999). It may be that a key feature to successful outcomes in stroke rehabilitation is not so much having several different disciplines

involved in patient care but, rather, establishing good communication and intervention partnerships.

Teams that are truly transdisciplinary tend to be more common in early childhood intervention settings (Rosin et al., 1996). In these settings team members have had specific transdisciplinary orientation and training and are encouraged to practice *role release*. Role release refers to the elimination of traditional professional boundaries in intervention practices (Tuchman, 1996). A transdisciplinary approach to intervention requires incorporating the knowledge and skills from many discipline areas into one multi-skilled practice (Allen et al., 1978). Transdisciplinary teams are most advantageous when intervention requires interfacing a number of related professional disciplines. Although true transdisciplinary teams are rare in hospitals and other health care settings, the transdisciplinary team model is promoted by the Individuals with Disabilities Education Act (IDEA) of 1990, PL 101-476 (Rosin, 1996).

In health-services settings issues such as clinical privileges and licensure restrictions may interfere with forming transdisciplinary teams. In addition, there may be resistance from staff who are not in favor of "cross-training." There was a movement in health service delivery in the past toward encouraging *cross-training* between disciplines and *multi-skilling* within disciplines. Cross-training refers to situations in which staff members are trained to do all or parts of each other's jobs. Cross-training discourages "that's not my job" thinking and encourages staff to feel a part of a team process. For example, ward clerks may be cross-trained with patient-transport personnel so they can cover for each other when needed. Multi-skilling implies having skills that exceed the boundaries of the traditional scopes of practice within a given discipline (Brown & Handlesman, 2006). An example would be training a speech-language pathologist to draw blood, perform range-of-motion exercises, or take blood pressures. Multi-skilling is sometimes viewed as creating minimally skilled technicians with specific skill sets across several areas but without the depth of knowledge needed to make independent decisions. Cross-training and multi-skilling, unfortunately, are concepts that developed in an attempt to save costs. Thus, the notions of cross-training and multi-skilled staff are sometimes viewed with skepticism among licensed professionals and have fallen out of favor in recent years.

TEAM PROCESSES

Group Communication

Much of what we call "interdisciplinary patient care" is just group problem-solving to develop partnerships in interventions through good communication. The key element is communication. Eliciting group problem-solving and group actions involves more than getting together people who have mutually supportive "roles and goals" in patient care.

How well a group of people work together to help one another help patients and their families depends largely on how well communication is managed within the team. Groups of people work together most effectively when two basic elements are in place: (1) group communication processes that encourage interactions, cooperation, and mutual respect, and (2) focused activities aimed at meeting specific objectives or performance measures (Manion, Lorimer, & Leander, 1996).

Researchers looking at small group communication in health-care settings have found the communication characteristics will vary along a continuum, depending upon the nature and purpose of the group (Northouse & Northouse, 1998). Our behavior and the manner in which we participate in groups shifts when the focus of the group is more toward *content-oriented* activities as opposed to *process-oriented* activities (Loomis, 1979). A content-oriented activity is one that is directed toward some *objective* (e.g., discharge planning) or some *performance measure* (e.g., improved functional rating scores). Team activities that are skewed toward content over process are common in health care settings, where everyone feels pressured to make an economic use of time, or in situations where weekly patient care team conferences are viewed by the participants as merely a mandated necessity. Typically, content-oriented patient care teams spend little time in idle chatting or group process, but move directly to the objectives of the meeting. In these settings, reporting information to the group to ensure everyone has a general notion about what the various disciplines are doing with the patient is essentially the extent of the communication. There is not much attention paid to processes that promote good interactions among team members. At meetings that are highly content-oriented, the team members might make their reports in turn, take their respective notes, and then move on to the next task. When communication is focused more on tasks, without attending to group participation, it is difficult to engender good interactive collaborations within the team.

At the other end of the continuum, process-oriented communication is directed toward developing relationships, cooperation, or mutual goals. Process-oriented communication includes group activities such as sharing feelings, brainstorming solutions, supporting one another, and building alliances. Communication itself may be the main purpose. Therapy groups, such as aphasia group therapy or various support groups, are good examples of groups engaged mostly in process-oriented activities.

Interdisciplinary teams need to strike a balance between content and process. Although interdisciplinary patient-care teams are not “support groups,” intervention plans often require negotiations between or among disciplines. Consequently, it is important to incorporate process-oriented communication into the group’s activities, even when time is limited and several tasks must be accomplished in a short amount of time. In interdisciplinary management, trust and collabora-

tion are essential. Developing good communication processes at the outset of team development tends to discourage polarities. The team members may refer to these activities, affectionately, as “sharing and caring.” Time spent building and maintaining mutual trust and open communication between team members is absolutely essential to a successful interdisciplinary team.

CREATING A COHESIVE TEAM

Developing Cohesion

One of the ways corporations and other groups develop a sense of cohesion within a team is to do things like take periodic retreats or engage in similar activities to promote good interpersonal relationships. Team retreats can be anything from wilderness-survival treks to an afternoon away from the office. Usually, retreats are intended to accomplish both group relationship building and goal setting. Managers and group-process facilitators also use devices like personality inventories, such as the Meyers-Briggs Inventory (Meyers-Briggs & Briggs, 1980) as a way for the group members to identify and inventory their individual work styles and consider how these styles differ from one another. Another method to aid in developing group cooperation and reliance is to involve the members in problem-solving games that require teamwork for solutions. Here is an example: A group of health-care providers is divided into teams of four members and each team is given five sheets of standard, 8½" × 11" paper. Each team is then asked to solve this problem, “Imagine that the carpet in this room is a raging river and each of your pieces of paper is a stepping stone. Using only your five ‘stepping stone’ sheets of paper, how can all the members of your team cross the river?” Since just laying down the five sheets of paper end to end would not allow the group to reach the other side of the room, the solution to the problem requires teamwork. The four-member teams solve the problem and cross the room by laying down the sheets of paper ahead of them in a row; and as each member moves forward one step, the last sheet rotates from the member at the tail of the line to the member at the front to take the next step. Thus, each team member moves forward until everyone has reached the opposite “shore.” These activities are intended to convey a simple message about teamwork, which is plan together, work together, look out for one another, and we will get to the goal.

In most health care teams, retreats, personality assessments, and group problem-solving games may not be very practical, but there are less elaborate ways to create a sense of membership and trust within the group. Simply engaging in “ice breakers” during the formative team meetings may be sufficient. For example, have members tell the group something about themselves, like: What is the one junk food they would want to have if stranded on a desert island? What was

their greatest achievement in high school? What is one of their most embarrassing moments? Just taking a few minutes to get the group talking to one another and revealing personal information helps to set aside the roles and goals of the team to create a degree of familiarity and comfort among team members and improve interactions in patient care.

Effective Team Leaders

What makes a good leader? There are volumes of answers to that question in management texts and articles, but the general consensus is that effective leaders have an ability (either innate or acquired) to get others to focus their energies on a goal. That ability is not necessarily endowed by status, degrees, or intelligence. Some have suggested the most important characteristic of a good leader is “emotional intelligence” (Goleman, 1998). Goleman lists five components of emotional intelligence that he believed were more important to effective leadership than the individual’s intelligence, technical skills, and other cognitive abilities. These traits include *self-awareness* (the ability to recognize your own mood, emotions, and drives); *self-regulation* (the ability to control impulses and moods); *motivation* (having a passion for work beyond money or status); *empathy* (the ability to understand the emotions of others); and *social skill* (a special proficiency in managing interpersonal relationships). Golper and Brown (2004) remind us that leaders have empowerment that can come from a variety of sources. Some leaders draw on the power inherent in their position; that is, empowerment comes from the title of their position (chair, manager, supervisor, director). Some leaders use rewards or coercion (punishment) to exert power. Power can also come from having expertise in a given area. Having knowledge and skills in a particular area of practice can provide an avenue for empowerment in a leadership role. Managers who have experience and expertise in their clinical area lend themselves well to leadership roles in health care. The final source of power is personal power. Personal power in leadership comes from the charisma of the individual and his or her communication skills and general “likeability,” which engenders trust in the individual’s decision-making and empowers his or her leadership.

BARRIERS TO COMMUNICATION

We have made a case for infusing non-task-directed communication (“sharing and caring”) processes into team meetings as helpful when developing a cohesive interdisciplinary team. What are some of the barriers to maintaining good communication? Aside from time—never having enough of it to maintain good group-communication processes—a couple of factors inherent to medical settings specifically can present problems. First is the traditional top-down professional hierarchies that exist in health service delivery, with physicians sitting at the capstone of the pyramid

(Northouse & Northouse, 1998). The second relates to the ethnocentrism and fears of encroachment that exist between professions (Ducanis & Golin, 1979).

Decision-Makers Versus Leaders

Physicians

When physicians are a part of the health-service team, they often assume a de facto leadership of the group because they are the primary decision-makers in the health care world. That primacy is appropriate in hospitals during the acute and subacute phase of recovery, where concerns center mainly on the medical status of the patient. But when medical issues are no longer a major concern, the physician’s hold on the decision-making processes ought to diminish. Unfortunately, for several reasons related to medical and legal responsibilities and their “gatekeeping” role in health care coverage plans, physicians maintain decision-making power even when they are no longer directly treating the patients.

Throughout the continuum of care, physicians are expected to take the ultimate legal responsibility for patient-care decisions. Additionally, the adult aphasic patient’s primary-care physicians are usually the “gatekeepers” for insurance-coverage decisions, or are required to “certify” or “authorize” the need for rehabilitation services on behalf of the payer, such as Medicare. Because these payer groups nearly always require a physician’s order for a patient to receive covered therapy services by a non-physician, physicians continue to be the decision-makers long after the medical issues have resolved. Even when the team members consider themselves to work on a par with one another, or when a non-physician heads up the team, typically the only member empowered to authorize the care plan is the physician. And, even though facility policies may say something like “the values, goals, and wishes of the patient and families must be addressed in the care plan,” in practice, the values, goals, and wishes of the person writing the orders can intrude. How physicians view their role with relation to the team can help or hinder good group cohesion and communication; any positive or negative attitudes the physician has toward the effectiveness of rehabilitation will also be a factor.

Professional Ethnocentrism

Good interdisciplinary teams are those with members who appreciate and respect the competencies of other disciplines (Sampson & Marthas, 1977). Mutual respect is the cornerstone of successful partnerships with other disciplines. Most of us bring fairly ingrained notions about our professional boundaries, and we often have prejudices about the training and professional standards of others. To work together collaboratively, we may have to reexamine and relinquish some of the notions established during our professional training.

Just like developing good group-communication processes, breaking down professional ethnocentrism may require specific attention. Ducanis and Golin (1979) discuss the problems with interprofessional ethnocentrism as a major obstacle to interdisciplinary teams. They suggested teams engage in an explicit examination of attitudes and develop an ongoing dialogue aimed at maintaining good relationships. They designed an instrument referred to as the “Interprofessional Perception Scale,” which requires members of different disciplines to examine their interprofessional attitudes. A modification of this scale has been applied in investigation of attitudes within the rehabilitation teams in the Department of Veterans Affairs medical centers (Strasser, Stanley, Falconer, Herrin, & Bowen, 2002). Another modification of Ducanis and Golin’s (1979) original instrument is the Revised Interprofessional Attitude Scale (RIPS) described by Skoloda and Angelini (1998). Essentially, this instrument in its various forms allows members of different professional groups (such as physical therapy, speech-language pathology, nursing, respiratory therapy, etc.) to assess their preconceived notions of another professional group by responding to a list of subjective statements and relating them to that group. These include statements such as, for example, “physical therapists are well trained,” “physical therapists have good relations with my profession,” “physical therapists are very defensive about their professional prerogatives,” and so forth (Ducanis & Golin, 1979, p. 34). The members of the various professional groups represented on the team, other than the target group (in this example, physical therapists), indicate whether each statement is “true” or “false.” In addition, they indicate how they think members of the target group (physical therapy) would answer about themselves, and then how the members of that profession would say the other professional-group respondents answered. What Ducanis and Golan are suggesting is that it is important to acknowledge our prejudices and appreciate that we all have preconceived attitudes, not necessarily justified by fact or experience, and that these attitudes can hinder the development of open communication, mutual trust, and cooperation in teams. Interdisciplinary teams function best when each member discipline appreciates not only their own strengths and limitations but also appreciates the contributions other disciplines bring (Allen et al., 1978).

Communication Patterns

In their review of group process in the health professions, Sampson and Marthas (1977) found three types of communication channels to be common in health services. The most common type of communication pattern was referred to as the “chain structure,” in which communication occurs up and down a line in some established professional hierarchy. In this structure the physician is at the top of the chain and ward clerks, therapy aides, and patient care technicians

are at the bottom. This type of communication structure discourages much direct contact with decision-makers. The second pattern is referred to as the “wheel structure,” in which information is fed to a central person, typically the unit’s head nurse or the physician. In this structure, the central conduit of information (a nurse, social worker, physician, or ward clerk) is the only person to have the whole picture at any one time. The wheel structure is probably a good way to describe much of the communication that occurs with multidisciplinary teams. Last is the “circle structure,” in which messages flow within a connected circle of disciplines. This pattern is most consistent with the type of communication needed to maintain effective interdisciplinary and transdisciplinary teams.

Weak Links and Poor Team Processes

There are several other potential barriers to successful communication and team intervention. Specifically, since teams are made up of human beings, individual members will vary in their ability to be open, receptive, cooperative, and professionally dedicated to the goals of the team. Therefore, there will probably be at least one or two “weak links” in any team. For example, if the speech-language pathologist (SLP) collaborates with the recreational therapist to work on functional-communication abilities during recreation activities, but the recreation therapist is the sort of employee who frequently calls in sick, the SLP will have difficulty implementing his or her goals effectively. Weak links deplete the energies of the group and create resentments. Poor team processes can also present problems. Other examples of poor processes include planning meetings at times when key members cannot be present, or trying to cover too much at one meeting. Not having adequate background information provided to team members before a meeting can lead to inefficiencies. Teams may be too large or too small for the demands placed on them. Teams can have the wrong mix of members or may not have the right combination of expertise and shared responsibilities. Teams also need to be designed to shift activities among members fluidly and to adjust to changes in workload and priorities (Sampson & Marthas, 1977). When process problems are apparent, it may be a good idea to charter a team just to figure out what’s wrong with the team. By using tools from a “continuous quality improvement” (CQI) or a “total quality improvement” (TQI) problem-solving approach, the team can identify and correct process problems.

WHO ARE YOUR PARTNERS?

The Patient’s Primary Physician

Patients with aphasia may have various physician-specialists involved in their care. Their primary-care physician could

be an internist (specialist in internal diseases), neurologist (specialist in diseases of the nervous system), cardiologist (specialist in diseases of the heart and vascular system), physical medicine and rehabilitation physician, also called a physiatrist (specialist in rehabilitation medicine), neurosurgeon (specialist in neurologic surgery), geriatrician (specialist in geriatric medicine), family practice physician, general practitioner, or some other physician coming from a general or specialized area of medicine or surgery. Even though the interests, background, and training of physicians will vary, they bring to the interdisciplinary team a comprehensive knowledge of diseases, disease processes, and disease treatment. They understand how biologic functions and diseases involving one organ system can impair another. They can interpret laboratory data and other findings. They can determine when findings are within normal limits or are abnormal for a given individual. They prescribe drugs and perform invasive procedures for which there may be some risk of injury to the patient. In most situations physicians are given the medical-legal responsibility for care decisions, as well as financial-oversight authority. Physicians may have a good or a not-so-good grasp of the linguistic and other cognitive problems the patient with aphasia has, and they may have a good or a not-so-good sense of the psychosocial issues the adult individual with aphasia and his or her family are likely to face. There is very little in medical training that specifically prepares physicians to characterize the psycholinguistic deficits, quality-of-life changes, or the functional-communication handicap brought on by aphasia. Although the physician may know the patient and family well (which is perhaps not as likely in today's health-care delivery systems as it was previously), he or she may not have spent any time in conversation with the family about what their priorities are, much less in conversation with the patient with aphasia. The physician is the team member best prepared to identify and manage the medically related issues. Physicians will rely on the other specialists, such as speech-language pathologists, to characterize and plan remediation in the arenas in which the patient's physician lacks sufficient familiarity.

Nurses

Nurses come in a lot of varieties. Some may have postgraduate degrees in some specialty area (doctorates, masters degrees, or advanced-practice degrees). They may be Registered Nurses (RNs) with or without bachelors degrees. They may be Licensed Practical Nurses (LPNs), or nurses' aides, personal-care aides, or personal care technicians. Rehabilitation nurses have specific training and expertise in developing and implementing a rehabilitation nursing-care plan. Depending upon where they fit in the hierarchy of skills and training, as well as which state they are licensed in, nursing staff are the professionals who will administer the

prescribed medications and perform medical procedures according to the physician's order or oversight. They maintain ongoing monitoring of the patient's vital signs and the patient's general mental and physical status. They also ensure that all of the patient's basic-care needs (nutrition, hydration, elimination, comfort, hygiene, and so forth) are met. In an inpatient facility, nurses have the most ongoing and frequent contact with the patients and families. As a group, nurses are with patients more than any other member of the team, 24 hours a day. Nurses are also trained and skilled in teaching the patient and family to manage their own care, and they are especially good at reinforcing both the team's instructions to the patient and family and the team's goals of functional independence.

Case-Managers and Medical Social Workers

Case-managers are usually nurses and most often are RNs. In general, case-managers are interested in ensuring that the requirements of the patient's health care coverage are met (insurance, managed-care, Medicare, etc.). If coverage requires a certain number of hours or minutes of therapy per week, or that the patient is seen "daily," meaning 7 days a week, the case-manager makes sure the therapy team can provide that level of service. When the speech-language pathologist sees a therapy need that exceeds the patient's insurance coverage, the case manager can be a very helpful advocate for the patient and the team.

Medical social workers sometimes have responsibilities in case management. Usually, however, their primary roles are (1) to provide counseling to patients and families for the psychosocial issues that arise, (2) to provide assistance with practical matters, such as financial concerns, and (3) to arrange for discharges appropriate to the needs of the patient and the family. The medical social worker is often the first person the speech-language pathologist will turn to when family adjustment and coping problems are apparent, or when financial assistance is needed.

Pharmacists

Not all facilities or settings will have pharmacists as participants on their care teams. Hospitals are probably the places where pharmacists are most likely to be involved as formal members of unit teams. In hospitals, pharmacists routinely participate in care-planning meetings and ward rounds. Pharmacists have a key role in determining appropriate therapeutic drug dosages for individual patients based on age, gender, weight, and other medical conditions. They monitor for errors in medication orders, for potential drug complications and side effects, and for polypharmacy effects (taking too many drugs and potentially causing negative interaction effects). They participate in teaching the patient and family self-management of medications, and can work

with the speech-language pathologist to address safe self-medication.

Dietitians

Inpatient facilities typically have a dietitian or dietary technician attached to their care team. They follow the patient's nutrition and hydration status, monitoring parameters such as body weight, renal chemistry panels, serum albumin, daily intake of food and water, and general appetite. They also monitor the patient's alertness and well-being. The speech-language pathologist may work with the dietitian, particularly if the patient with aphasia has a concomitant problem managing oral intake, or if there are other issues related more directly to the aphasia, such as difficulties ordering preferred items from the facility menu.

Psychologists

Neuropsychologists, geropsychologists, or general clinical psychologists may be a part of the core care team, or may be consultants to the team. In comprehensive rehabilitation facilities, psychologists are an integral part of the rehabilitation team. In units such as head injury programs, where cognitive and behavioral issues tend to be principal concerns, psychologists may be the team leaders. Psychologists conduct and participate in the team assessments of cognitive, emotional, and behavioral areas. They collaborate with the team to design and implement the cognitive, emotional, and behavioral therapies. They work with families and, when needed, collaborate with medical social workers to link families and patients to community mental health services. Depending upon the individual's training and specialty area, the psychologist can be a very close partner with the speech-language pathologist in developing a profile of the cognitive and other deficits and collaborating on interpretations of test findings.

Recreation Therapy

Rehabilitation units and other facilities, such as skilled-nursing units, are usually required to have someone on staff to conduct a recreation and resident activities program. These individuals may have Bachelor or associate degrees in recreation therapy or may be Certified Activities Directors, who may not have completed professional degrees but have completed a course and passed a state-certifying examination in this area. These individuals are responsible for planning and scheduling the daily-activity calendar of patients. Speech-language pathologists will work closely with the recreation-therapy staff to ensure that the patients can engage as fully as possible in the unit's recreation activities, without experiencing a communication disadvantage. Recreation therapy is more than just keeping patients busy. Recreation-therapy

groups can be the first place where the patient with aphasia and the family resume shared activities; thus, these groups offer excellent opportunities for partnerships with the speech-language pathologist. By engaging patients together with their families in recreation activities that do not require much language facility (such as playing cards or dominoes) the team can demonstrate to the family the patient's residual non-language abilities. By involving patients with aphasia in recreation tasks that have some demand for communication (targeted to be just within the patient's ability range) the speech-language pathologist can demonstrate the value of applying the communication-facilitating strategies they are developing in therapy to everyday social activities.

Occupational Therapists and Physical Therapists

Occupational therapists (OTs) and physical therapists (PTs) have uniquely different professional preparation and perspectives on rehabilitation, but also have some overlapping areas in their scopes of practice. This sometimes leads the general public and health-care personnel to refer to all therapies (including speech-language therapy) as "Physical Therapy." In general, occupational therapists are concerned with the patient's functional daily-living abilities, safety, and independence in self-care and related areas. OTs ensure that patients can take care of their grooming and hygiene, can don and doff clothes, and can functionally transfer in and out of a wheelchair, in and out of bed, in and out of a tub or shower, and so on, for optimal independence and self-care. Most OTs have experience in the assessment and treatment of perceptual-motor abilities and the visuospatial abilities and visuo-perceptual abilities associated with brain injuries. Some OTs have had specialized training in "Low Vision Rehab" with patients who have visuosensory losses. They are a valuable partner for the speech-language pathologist in designing a plan for improving a patient's functional impairments involving visual, visuo-perceptual, visuomotor, visual recognition, or perceptual-motor deficits, as with conditions such as apraxias and neglect syndromes, or with visual-field cuts. OTs also are very adept at designing or providing assistive devices to improve functional independence. In some settings, OTs may be involved in kitchen and recreation evaluations, or they may be involved in an assessment of the patient's ability to return safely to driving. Many of these areas are going to be crucial for the patient to return to a maximal level of independence. The speech-language pathologist and OT often work in partnership when communication problems interact with other functional losses, or to combine the objectives of both therapies into treatment sessions. For example, the OT might be asked to have the patient point to the items of clothing he or she names before beginning the dressing routine.

Physical therapists (PTs) have a key role with stroke rehabilitation whenever weakness, incoordination, or balance

problems are present. For the most part PTs are focused on the patient's mobility, strength, balance, transfers, endurance, range of movement, and exercise or activity tolerance. PTs and OTs may also be involved in other areas of rehabilitation, such as splinting, cardiac rehabilitation, or bladder-containment control. Physical therapists, like all other members of the team, are concerned with maximizing functional independence. Physical therapy addresses not only the neuromuscular weakness, coordination, and balance problems found in patients with neurologic damage, but also the associated functional living problems. For example, the goal of physical therapy may be something like "the patient will walk 50 feet without assistance," but in addition, "the patient will be able to carry a basket of clothes the distance from his bedroom to the laundry room." Speech-language pathologists might partner with the PT to incorporate functional language-facilitating activities into the physical therapist's directions and requests. Similarly, the SLP might incorporate a PT objective into therapy sessions, such as asking the patient to transfer from the bed to a chair before beginning therapy.

Speech-Language Pathologist

The speech-language pathologist (SLP) brings to the team knowledge and skills in the evaluation and remediation of the aphasic person's communication and related cognitive impairments. This text provides a comprehensive review of the breadth of the SLP's expertise in aphasia intervention. The SLP is the member of the team who provides theory-driven and evidence-based language intervention. The SLP evaluation usually includes a psycholinguistic assessment of the patient's language deficits, and an assessment of related cognitive impairments. Test findings, along with all of the evaluations, behavioral data, and observational input provided by other members of the care team—in collaboration with the patient and family in identifying the communication goals—forms the basis of the SLP's intervention program.

Support Personnel

In rehabilitation, it is increasingly common to find support personnel. Certified Occupational Therapy Assistants (COTAs), Physical Therapist Assistants (PTAs), Speech-Language Pathology Assistants (SLP-As), and trained volunteers may be a part of the team, working under the supervision of the licensed/certified professional therapists. In several states these individuals have to have met qualifying examinations to be licensed in their discipline area after completing required education and training (usually either a bachelors degree or an associates degree). The requirements and standards vary by state and by discipline. For example, in Tennessee, the basic requirement for Speech-Language Pathology Assistants is a high-school diploma or equivalent.

Therapy assistants usually are restricted by the State Boards of Examiners to the implementation of treatment procedures only under specific conditions, including under the supervision and direction of professional therapists. Therapy assistants sometimes are viewed as "therapy extenders"—implementing the plans that are established by the physical therapists, occupational therapists, or speech-language pathologists; payers typically do not reimburse services provided by assistants. Evidence supports the role of trained and supervised nonlicensed individuals, such as assistants and volunteers, in aphasia intervention (Kagan, Black, Duchan, Simmons-Mackie, & Square, 2001; Marshall et al., 1989; Paul & Sparks, 2006; Wertz et al., 1986). Assistants and aides do not conduct new patient evaluations, make differential diagnoses, or design the treatment plans. Therapy assistants have to demonstrate specific competencies before they can treat patients independently. In addition to assistants, therapy aides, or "rehab techs," are fairly common in rehabilitation settings. These individuals may be students or others without degrees in rehabilitation therapy specialties but with specific training to lend help to the therapists and assistants in patient care and other clinical duties (e.g., setting up equipment).

Other Allied Professionals

Professionals from a variety of disciplines, such as audiologists, biomedical engineers, assistive technologists, vocational counselors, and chaplains, may be members of the health-care team with adults with aphasia. If the patient has a hearing impairment, the audiologist can become a central member of the team. If the patient requires special adaptive equipment or augmentative communication systems or equipment for other purposes, the assistive technologist (AT) will help the team select the instruments and design the access switches. If there is potential for the adult with aphasia to return to a previous vocation, similar vocation, or even a new vocation, a rehabilitation vocation counselor is the individual best equipped to direct the patient and family toward potential alternatives. When the patient and family have spiritual needs that require specialized attention, a member of the facility's pastoral care or chaplaincy service will help the team address those concerns.

TEAMS ACROSS THE CONTINUUM

Changing Priorities

As persons with aphasia move from the crisis of the acute event through various care settings, and eventually, hopefully, reentering their home life and community, there will be shifts in primary concerns and priorities for intervention, and correspondingly there will be changes in the major decision-makers.

TABLE 8-1

Shifts in Priorities Across Settings and the Recovery Continuum with Adults with Aphasia

Setting	Typical Priorities
Acute-care	1. Physiologic and medical stability 2. Emotional issues 3. Physical limitations 4. Communicative and other cognitive limitations 5. Discharge plan
Subacute nursing	1. Physiologic and medical status 2. Physical limitations 3. Communicative and other cognitive limitations 4. Functional independence 5. Discharge plan
Inpatient rehabilitation	1. Communication and other cognitive limitations 2. Physical limitations 3. Functional independence 4. Psychosocial and emotional issues 5. Discharge plan
Outpatient rehabilitation	1. Functional independence 2. Communication and other cognitive limitations 3. Physical limitations 4. Psychosocial and emotional issues 5. Financial and vocational issues
Home-health-care	1. Functional independence 2. Communication and other cognitive limitations 3. Physical limitations 4. Financial and vocational issues 5. Psychosocial and emotional issues
Home and community reentry	1. Psychosocial and emotional issues 2. Financial and vocational issues 3. Functional independence 4. Physical limitations 5. Communication and other cognitive limitations

Table 8-1 illustrates how priorities can change across settings and through the continuum of recovery with adult aphasia. Team designs and the primacy of different individuals in the hierarchy of decision-making will also change (Table 8-2). Obviously, these scenarios are intended to illustrate a point. Not every facility, setting, or individual patient will necessarily follow this pattern. Shifts in priorities, team designs, and decision-makers across the recovery continuum are considered here merely to emphasize that intervention extends beyond any one setting or team. Intervention rolls through many settings, from the hospital bed to the nursing

home or rehabilitation facility, from outpatient therapy to home-health-care, from the rehabilitation team to independent living. In fairly short order the support systems provided by the multidisciplinary or interdisciplinary teams will end. Patients and families need to be prepared for the time when decision-making responsibilities will fall squarely on their shoulders. As soon as the patient's medical condition has stabilized and the patient enters rehabilitation, the overarching goal of all of the rehabilitation professionals they encounter should be directed toward functional independence and encouraging the patient with aphasia, with his or her family, to take control of their own lives.

Changing Rehabilitation Outcome Goals

As illustrated by a schema described by Sundance and Cope (1995), rehabilitation outcome goals move through a continuum as the patient progresses from a destabilized state during the acute phase up through later phases of community reintegration and productive activity. These authors conceptualized the continuum of treatment to span the following stages.

Level 0 = Physiologic Instability. The acute onset of illness in which medical stabilization is the main concern and diagnostic evaluations are completed.

Level I = Physiologic Stability. Limited attention is given to functional rehabilitation restoration; medical stabilization continues to be addressed.

Level II = Physiologic Maintenance. Rehabilitation primarily is aimed at establishing adequate and safe systems of nutrition and hydration, and prevention of complications, such as aspiration pneumonia, skin breakdown, joint-mobilization problems, and bowel- and bladder-control problems. Secondly, rehabilitation at this phase will be aimed at communication, self-care, mobilization, and cognitive and behavioral issues, depending on the patient's responsiveness.

Level III = Primary Functional Goals. Functional-deficit-specific goals are established to facilitate discharge to home or to improve residential integration.

Level IV = Advanced Functional Goals. Rehabilitation is directed toward community reintegration.

Level V = Productive Activity. Rehabilitation outcomes are directed at returning the adult with aphasia adult to productive activities within his or her level of ability (Landrum, Schmidt, & McLean, 1995; Paradigm Health Corporation, 1993; Sundance & Cope, 1995).

Changing Settings

Acute Care Setting

Initially, the team's efforts are directed toward moving the patient out of physiologic instability toward a level of

TABLE 8-2

Team Designs and Decision-Makers Across Settings and the Recovery Continuum with Adults with Aphasia

Setting	Team Design	Primary Decision-Makers
Acute-care Subacute unit	Multidisciplinary Interdisciplinary	1. Physician 1. Physician 2. Patient-care team 3. Patient and family
Inpatient rehabilitation	Interdisciplinary	1. Physician 2. Rehabilitation team 3. Patient and family
Outpatient rehabilitation	Multidisciplinary Community support networks and partnerships	1. Physician 2. Rehabilitation team 3. Patient and family
Home-health-care	Multidisciplinary Community support networks and partnerships	1. Physician 2. Home-health rehabilitation team 3. Patient and family
Home and community reentry	Community support networks and partnerships	1. Patient and family

physiologic stability and maintenance (Sundance & Cope, 1995). In the acute setting, the first priorities are (1) ensuring the patient survives the acute event with minimal residual neurologic damage and (2) diminishing the risks for complications. Some patients are ready to participate in rehabilitation services within a few days of the acute event and onset of aphasia. Unfortunately, most acute-stroke clinical care pathways anticipate discharge in 3 to 5 days from admission, making interdisciplinary team rehabilitation virtually impossible. With just a few days' involvement with the patient before discharge, the team's emphasis tends to be on patient and family education and appropriate discharge planning. As is the case with nearly any hospitalization with an acute event, the aphasic person's family is under tremendous emotional stress. They may not be in the best frame of mind to absorb new information or make decisions. The family will, however, be sensitive to the verbal messages, body language, and attitudes of all the team members participating in caring for the patient. It is especially important that family and patients be approached with a professional, supportive, and reassuring attitude (van Vendendaal, Grinspin, & Andriaanse, 1996). Education and verbal messages need to be brief and consistent. Information needs to guide, and not overwhelm. The family should not be expected to fully grasp the consequences of the neurologic damage, so a supercilious lecture on recovery from aphasia full of grim predictions intended to correct the family's "unrealistic expectations" is completely inappropriate and unnecessary at this point. The messages must be accurate but also hopeful.

As we suggested earlier, unless the patient is admitted to an acute "stroke unit," where an interdisciplinary team is in place, the typical model for team care in an acute setting is more likely to look like a multidisciplinary than interdisciplinary model. Consequently, care planning discussions, if they take place at all, focus on sharing assessment findings with other team members, and making discharge recommendations to the physician and medical social worker. Group discussions of observations of the patient are an important part of decision-making during this time. Often, the patient's responsiveness will vary during the day, so team discussions of observations on cognitive and communicative status will help the speech-language pathologist gauge the reliability of communication assessments. Finally, because the patient and family are under stress, it may be better to channel information through as few people as possible, principally through the physician, the primary nurse, or the social worker, and allow them to work with the family. Other professionals should be available to address their particular concerns; however, it is important for the team to keep messages consistent and to not overwhelm the patient or family.

Subacute Nursing Setting

Usually, after the medical and acute physiologic conditions have stabilized, patients are transferred to some kind of subacute setting, where physiologic maintenance may still be the main outcome goal. These settings can be a skilled nursing facility, recuperative care unit, transitional care unit, or the like. Prevention of complications continues to be a

concern along with communication, cognitive and emotional issues, mobility, and independence. Emotional issues, such as anxiety and depression on the part of the family, continue to be major concern, and the psychosocial effects of the aphasia and other impairments will begin to be felt by the patient and the family. Psychosocial concerns can include such things as changes in body image and losses in the level of independence; uncertainties about the future and the recovery processes; frustration with communication and impaired movement; emotional lability; changes in family dynamics and a sense of a lack of control over events happening to them; irritability; self-centeredness; unrealistic expectations or denial; and dependency (Churchill, 1993; Flick, 1999). Patients also may display post-stroke depression and anxiety. These emotional problems usually respond to a combination of medication and reassurance. At the subacute phase, the patient's residual physical impairments, if any, often are more of a concern to the family and the patient than communication and other cognitive impairments, possibly because mobility is linked to independence. Integral to improving the patient's psychosocial and emotional status is the implementation of rehabilitation for physical, self-care, and cognitive/communicative problems. If the patient's physical tolerance and cognitive status allow, the earliest possible involvement in rehabilitation should be encouraged (Flick, 1999). Intervention at this phase usually takes place in a residential-program setting where teams tend to be interdisciplinary (Cifu & Stewart, 1999). It is important that everyone working with the patient and family have the same goals in mind and that no one professional group exerts ownership over their goals or procedures. Although different members of the team have a slightly different center of concern, the entire team is responsible for achieving the intervention goals. When possible, intervention procedures are shared and implemented in partnerships between team and family members.

Inpatient Rehabilitation Setting

Some patients transfer directly to a rehabilitation facility from their acute-care ward, and some continue rehabilitation in a skilled nursing facility or following a stay in a subacute nursing unit. Typically, once the patient reaches the rehabilitation setting the major medical issues have resolved and some of the acute emotional reactions and psychosocial issues have become slightly less of a priority than the residual effects of the stroke (such as hemiparesis, aphasia, and other cognitive problems). There may be significant, chronic medical issues to consider, such as pain management, depression, blood pressure management, blood-coagulation management, seizure control, or incontinence, but the patient is typically believed to be generally medically stable. Typically, on an inpatient rehabilitation unit the family sees the patient working for several hours a day with a

team of experts attempting to maximize the patient's functional status. Also, most likely, the patient has experienced some amount of recovery at this point. In such settings, the family and the patient are usually highly confident that some improvement will result; consequently, concerns about psychosocial and emotional issues may temporarily be set aside, or at least become less severe. In a rehabilitation setting there is a "full-court press" to address the specific deficit-effects of the stroke. Aggressive speech-language therapy for the aphasia will be implemented, in addition to 3 or 4 hours daily of occupational and physical therapy. The focus on everyone's part is placed on maximizing the patient's abilities to return either to his or her home or to a residential facility, with the overriding goal of maximizing independence. Again, inpatient team intervention tends to be interdisciplinary, and collaborative goals are emphasized. Because all the intensive therapy and team activity leads to an expectation for positive results, one of the problems that arises with the inpatient rehabilitation setting is that patients and families may see the end of rehabilitation as the end of recovery (Flick, 1999). Therefore, psychological stresses may begin to emerge at about the time the inpatient rehabilitation stay is nearing its end. The end of formal treatment can signal a concern for "is this as good as it gets?," which creates anxiety for both the family and the patient.

Outpatient Rehabilitation Setting

In this setting daily contact with non-therapist, allied disciplines such as pharmacists, social workers, dietitians, nurses, and even physicians is not typical. Therapists from different disciplines may work in the same clinic area, but the team-intervention model is more likely to be closer to the multidisciplinary design. Much like the hierarchy of concerns when patients enter inpatient rehabilitation facilities, the interventions in outpatient rehabilitation settings are impairment-specific, for the most part. However, the overriding goal to improve self-care and independence for home and community integration and toward some resumption of productive activity is still primary. Because the patient is typically coming to therapy from home at this juncture, psychosocial, emotional, financial, and vocational concerns may be uppermost on the minds of the patient and family. In this setting especially, caregivers are likely to express frustration with communicating with the person with aphasia in addition to sadness over the loss of companionship. Issues such as lifestyle changes, social isolation, and financial difficulties may surface after the patient goes home (Flick, 1999); thus, these should be addressed as part of the outpatient rehabilitation program. Since this arena of treatment can tend to be more multidisciplinary than interdisciplinary, due mostly to difficulties with scheduling collaborative therapies and the unavailability of support professionals, a mechanism to address these special issues easily may be lacking. Explicit

referrals to a psychologist and other professionals will need to be set up. Similar to a home health based setting, encouraging the patient and family to link with community support networks well ahead of the completion of formal outpatient therapy is essential.

RELATED ISSUES

Team Evaluations and Team Treatments

One of the frequent concerns expressed when team evaluations and treatments are considered is the belief that “only one discipline can bill for this time.” That may be the case in any fee-for-service visits, where charges are made per procedure and payers usually will not pay for two procedure charges in the same unit of time. Other types of reimbursement schemes, however, might support collaborative interdisciplinary team evaluations and treatment. For example, when a pre-established payment is made for a certain amount of treatment time (as with Medicare’s DRGs or prospective-payment system for Part A coverage, or with inpatient insurance per diem), there are no payer restrictions on having more than one discipline involved in a given evaluation or therapy session. The issue may be provider costs. The facility may resist having more people involved in patient care than are necessary. Increased staff time translates to increased costs to the provider facility; therefore, it may be necessary to justify collaborative evaluations and interventions and nonbillable staff time (such as team meetings) as a facility cost *savings*. Collaborative evaluations may accomplish a more comprehensive assessment in a shorter time frame than evaluations that are done independently. In the earlier discussion of “who are your partners,” several examples of collaborative evaluations and interventions were mentioned. It’s a bit like the parable of the seven blind men and the elephant, in which a different interpretation emerges depending upon which part of the elephant you are touching. Team evaluations with more than one discipline participating can yield a much better composite picture than independent assessments.

Collaborative interventions can reduce redundancies, reduce the time taken for communications, and more efficiently ease transfers and discharges, which reduce the lengths of stays. Reducing the lengths of stays often saves costs to the facility; it has the added benefit of reducing the risks of nosocomial infections and other hospital stay related complications.

Documentation

Documentation is another important area for collaboration. Some of the current practices in health care in the U.S. today strongly encourage multidisciplinary documentation. For example, Clinical Care Pathways may be used to guide

day-to-day care plans, particularly in inpatient facilities. The documentation for these pathways flows across multiple disciplines, and some of the care objectives may be shared between or among disciplines (e.g., patient education) (Ignatavicius & Housman, 1995). To be in compliance with the standards of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (JCAHO, 2006) or CARE, the Commission on Accreditation of Rehabilitation Facilities (CARE, 2005), it is expected that family and patient education be conducted in a multidisciplinary manner.

Clinical Preparation and Research

Training programs and research are ripe for interdisciplinary collaborations. Emphasis on interdisciplinary education and collaboration in patient care is primarily evident in literature coming out of Canada and the United Kingdom (Cook, 2005; D’Amour et al., 2005; Gibbon, 1999). The time to initiate good interdisciplinary relations to prevent potential problems related to professional ethnocentrism, discussed earlier, is during the professional clinical preparation. It is important that students have a good exposure to different team interventions as a part of their professional training. Collaborative research also has exciting possibilities. When different disciplines collaborate in research we discover a new way of looking at old notions, and test the extent to which our data apply to other areas.

COMMUNITY AND NATIONAL SUPPORT NETWORKS AND PARTNERSHIPS

Every adult with aphasia who completes formal therapy under the care of either an array of disciplines or just a few eventually reaches an outcome: the rest of life. In outcome-oriented rehabilitation (Landrum et al., 1995; Schmidt, 1999), the intervention services of the health care delivery team are, from the initiation of care, conceptualized, organized, and delivered with an eye on the quality of the rest of life for that person. Landrum et al. (1995) and Schmidt (1999) observe that all too often the team fails to consider until the end of the patient’s stay the resources the patient and family have available to them, much less how to incorporate those resources and social support networks into their future.

Schmidt (1999) suggests the following resources should be identified with the patient and family very early in the continuum of rehabilitation therapy services: (1) *Health services funding resources* (what will the insurance coverage provide for this person to support his or her needs now and in the future?); (2) *financial resources* (what are the additional financial resources available to this patient and family?); (3) *family resources* (what are the caregiver and other resources available to this family unit?); and (4) *community*

resources (what community and social support services are available to this family?). It is important that every member of the rehabilitation team understand the global impact that aphasia and other problems resulting from brain damage will have on the individual and the family unit. The intervention team should anticipate and incorporate that perspective into each phase of therapy. The team needs to be focused on the future and also keep the patient and family focused on the future. Schmidt (1999) suggests starting with the end-point and aligning expectations throughout the continuum of recovery. The team should be supportive and should encourage and empower aphasic adults and their families to use their available resources to reintegrate into their homes and communities and return to productive activity. One of the projects for the team can be to help the family develop an individualized resource directory for community services. This can include such things as elder care services, day treatment programs, Meals on Wheels, community- or university-based aphasia therapy programs, church activities, support groups, recreation opportunities, and the like. The team can also help the patient and family plan post therapy goals, such as continuing language-reinforcing tasks at home (e.g., word-processor letters, reading selected sections of the newspaper) and family or community activities (e.g., attending a reunion, participating in a church project). These kinds of planned activities may help to carry forward formal treatment into functional living in the future.

The outcome of *survival* following a major neurologic event, such as a stroke, is, literally, life. After formal therapy ends, the patient and the family may need to maintain contact with a support team, and that should not be discouraged. However, one of the overarching goals of rehabilitation should be to identify the potential risks and concerns prior to the end of treatment and help the patient and family establish the community support networks they will need and to then be prepared to lead their own “team aphasia.”

National Support Groups

The National Stroke Association (NSA)

The National Stroke Association (NSA) was founded in 1984 as a nonprofit organization dedicated to educating survivors of stroke, their families, health-care professionals, and the general public about stroke. The NSA's focus is on reducing the incidence and impact of stroke through activities related to prevention, medical care, research, resocialization, and rehabilitation. This organization develops and distributes educational materials and publishes a magazine, *Stroke Smart*, and a journal. The NSA provides guidance in developing stroke clubs and stroke support groups; operates a Stroke Center Network program and encourages conducting clinical trials in the prevention and management of stroke and its consequences.

The National Aphasia Association

The National Aphasia Association (NAA) is a nonprofit organization governed by a Board of Directors made up of individuals with professional interests in aphasia (speech-language pathologists, physiatrists, neurologists) and individuals with aphasia and their co-survivors. This organization was charted in nearly two decades ago, and has continued to advocate for and serve the interests of individuals with aphasia and their co-survivors, through its “hot line,” Web site, and published materials, including *The Aphasia Handbook* (Sarno & Peters, 2005), and by sponsoring conferences, such as its “Speaking Out” conferences held biennially. The NAA's mission is “to educate the public to know that the word aphasia describes an impairment of the ability to communicate, not an impairment of intellect. The NAA makes people with aphasia, their families, support systems, and health care professionals aware of resources to recover lost skills to the extent possible, to compensate for skills that will not be recovered and to minimize the psychosocial impact of the language impairment” (www.aphasia.org). To that end, the NAA has developed and endorsed the adoption of the Aphasia Bill of Rights (www.aphasia.org), which states: people with aphasia have the right to:

1. Be told, as soon as it is determined, preferably by a qualified speech-language pathologist (SLP), both orally and in writing, that they have “aphasia” and given an explanation of the meaning of aphasia.
2. Be provided, upon release from the hospital, with written documentation that “aphasia” is part of their diagnosis.
3. Be told, both orally and in writing, that there are local resources available to them, including Aphasia Community Groups in their areas, as well as national organizations such as the National Aphasia Association (NAA).
4. Have access to outpatient therapy to the extent deemed appropriate by a qualified speech-language pathologist (SLP).
5. Give their informed consent in any research project in which they are participating.
6. Demand that accrediting health-care agencies and health care facilities establish requirements for and competency in caring for people with aphasia.

SUMMARY

This chapter examined concepts in team collaborations mainly within the context of therapeutic interventions for aphasia in health care facilities and other rehabilitation settings. The notion of team intervention is extended to family-centered partnerships as early as possible and throughout the continuum of care and into community-supported partnerships after formal therapy has ended. In an examination

of the differences between *interdisciplinary*, *multidisciplinary*, and *transdisciplinary* teams in health care settings, the importance of good communication is stressed. We have also emphasized how becoming comfortable with a certain amount of blurring of professional scopes of practice may be necessary for the success of interdisciplinary teams. In team dynamics, there needs to be a balance of both content (activities, goals, and products) and process (communication, affiliation, and collaboration). We considered how team processes may be hindered by a number of factors that can be barriers to communication. We looked at how professional hierarchies in health care settings tend to place the physician in the role of primary decision-maker, especially in the more acute phases of care. We considered how the structure of teams tends to vary in different settings, and how the priorities and primary decision-makers might shift over the recovery continuum. The principal goal of this chapter is to emphasize the value of team collaborations and partnerships, both in the formal rehabilitation program itself and in the transition to the home and community. We suggest that one of the overarching goals of therapy should be to empower patients and families to become independent decision-makers. When therapy has ended, the leaders in “team aphasia” are ultimately the patient and the family.

FUTURE TRENDS

Teams and family-centered and community partnerships have an important future in patient care in all arenas, but especially in aphasia intervention. An interdisciplinary team approach is supported by research examining evidence-based treatment (Cifu & Stewart, 1999). Team intervention is also strongly encouraged by legislative and certifying bodies (CARF, 2005; JCAHO, 2006; Rosin et al., 1996), by third-party payers, and as a standard of care preferred by providers (Davis et al., 2005; Gibbon, 1999; Malone & McPherson, 2004; Strasser et al., 2005). All of the current trends and influences in health care delivery today suggest the “lone professional” practice is diminishing and collaborations in patient care are here to stay.

KEY POINTS

1. No team will look or function exactly like any other, but health-care teams in general tend to be organized as multidisciplinary, interdisciplinary, and transdisciplinary models.
2. Multidisciplinary teams are common in inpatient settings. Interdisciplinary teams, common in rehabilitation settings, share common goals. Transdisciplinary

teams, a model applied in early intervention, require “role release,” and less distinctive discipline-specific boundaries.

3. Group communication, creating cohesion, and establishing effective leadership are key elements to successful team processes.
4. Professional ethnocentrism can influence how we perceive other professions and diminish the team’s ability to work collaboratively and effectively.
5. There are a number of challenges to interdisciplinary team management, including problems with conducting “billable” team evaluations and implementing interdisciplinary team documentation.
6. Presuming our ultimate goal is to bring about the best quality of life after the onset of aphasia, the patient and family are, ultimately, the most important members of the health care team; thus, one objective of management throughout the continuum is to prepare the family to lead “team aphasia” after therapy has ended.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. What are the advantages and disadvantages of having more than one discipline involved in intervention in patients with aphasia?
2. What are the similarities and differences between multidisciplinary, interdisciplinary, and transdisciplinary teams?
3. Which professional group tends to be the decision-makers in health care in the U.S., and why?
4. What do case-managers and social workers bring to the team?
5. How might teams differ in the acute phase of rehabilitation as compared with the subacute and chronic phases of recovery?
6. During which time frames are patients and families most likely to become more concerned about psychosocial and financial issues than medical issues?
7. List the ways team intervention is encouraged by trends and influences in health service delivery.
8. What is the evidence in support of the benefit of team-based, collaborative services for patients with aphasia?
9. Describe some specific objectives teams might incorporate into the therapy plan to empower patients and families ultimately to take control of “team aphasia” after formal rehabilitation has ended.

Chapter 9

Issues in Assessment and Treatment for Bilingual and Culturally Diverse Patients

Patricia M. Roberts

OBJECTIVES

The goals of this chapter are as follows:

1. To highlight how culture may influence the clinical process, and to provide references and a framework for detailed study of this area;
2. To provide a brief overview of the key terminology and concepts in bilingualism and bilingual aphasia;
3. To summarize some of the findings from psycholinguistic studies that are most relevant for clinical work with bilingual adults with aphasia;
4. To outline issues in the assessment and treatment of bilingual aphasia. These include test reliability and interpretation; available tests in different languages; patterns of impairment and recovery; setting treatment goals; choice of language(s) for treatment; use of interpreters; and generalization across languages.

In all areas, the goal is to highlight key issues. A single chapter cannot provide a comprehensive literature review on each topic. The focus is on issues most closely linked to clinical work and on issues that have received little attention in the speech pathology literature to date. In some cases, only recent work is cited. In these recent studies and review articles, the reader will find additional references. While language and culture are closely related, the challenges they present to clinicians working with clients with aphasia are quite different. Therefore, in this chapter they will be considered separately.

As awareness of the needs of patients from various cultural and linguistic backgrounds has grown, so has the awareness that clinicians require specific types of knowledge to work with these types of patients. This knowledge draws on at least three fields: (1) bilingualism, (2) culture, and (3) comparative aphasiology. Studies of bilingualism/multilingualism examine how people learn and use two or more lan-

guages or dialects, often comparing their performance to that of unilingual speakers. The literature on culture and cultural diversity examines the customs, beliefs, and behaviors of different groups defined by race, national origin, socioeconomic status (SES), or other common factor, and their impact on the clinical process or outcome. Comparative aphasiology refers to the study of aphasia in different languages. All three fields are relevant to the study of culturally and linguistically diverse (CLD) patients. A specialty within the CLD field is CLD neurogenetics, or multicultural neurogenetics, which focuses on neurogenic communication disorders. This chapter addresses CLD issues in aphasia, those relating to culture and also to bilingualism.

Some authors now use the term “multilingual” to mean speakers of two or more languages. In some studies, the authors fail to provide sufficient information and readers do not know whether the participants were bilingual (two languages) or multilingual (more than two). In the present chapter, we have used one or the other, as seemed appropriate, but the line between the two remains fuzzy. New studies are now probing for potential differences between bilinguals and multilinguals (Dewaele, 2001; Goral, Levy, Obler, & Cohen, 2006; Goral & Obler, in press; Lemhöfer, Dijkstra, & Michel, 2004).

Prior to 1990, bilingual aphasia is rarely mentioned in English textbooks, and cultural issues, if mentioned at all, are given little attention. Yet, “bilingualism, far from being exceptional, is a problem which affects the majority of the world’s population” (Mackey, 1967, p. 11).¹ Paradis echoed this view, within a clinical perspective: “Bilingualism is not just a rare, occasional occurrence in the language/speech pathology clinic, but a phenomenon every clinic must be prepared to cope with” (1995c, p. 219).

In recent years, there has been a growing recognition in the English-language aphasiology literature of the importance of addressing the needs of patients from all linguistic and cultural backgrounds. This may reflect both greater

¹In the French version of the same paper, Mackey refers to bilingualism as a “phenomenon.” The English wording may or may not express his intended meaning and serves as an example of the potential for distortions of meaning that can occur in translation!

awareness of indigenous minority populations in many countries and the growing numbers of non-native English speakers in countries such as the United States, the United Kingdom, Canada, and Australia. Policy statements by several influential bodies have drawn attention to CLD issues (ASHA, 1985, 1989, 1991; Australian Association of Speech and Hearing, 1994; Australian Institute of Multicultural Affairs, 1985; Cole, 1989; Martin et al., 1998). Professional associations have prepared guidelines or standards for clinicians working with CLD populations (e.g., ASHA, 2004; Crago & Westernoff, 1997). Publications in medicine and (neuro)psychology have also called for more study of CLD groups (e.g., Ardila, 1995; Frayne, Burns, Hardt, Rosen, & Moskowitz, 1996; National Institutes of Health, 1990; NIDCD, 1992).

In the 1980s and 1990s researchers found that language and cultural background have an impact on performance on some neuropsychological tests (Ellis, 1992; Mungas, 1996; Puente & McCaffrey, 1992). In the same period, it became clear that aphasia in languages other than English and aphasia in bilinguals presented features not addressed in the English aphasiology literature.

CULTURE

Avoiding Stereotypes while Recognizing Differences

According to Grosjean (1982): “anthropologists commonly agree that culture consists of a number of components: the human’s way of maintaining life, and perpetuating the species, along with habits, customs, ideas, sentiments, social arrangements, and objects. Culture is the way of life of a people or a society, including its rules of behavior; its economic, social and political systems; its language; its religious beliefs; its laws; and so on. Culture is acquired, socially transmitted, and communicated in large part by language.” (p. 157).

Cultural background can influence many aspects of communication. Figure 9-1 illustrates how cultural factors, domains/topics, pragmatics, and linguistic knowledge all combine to produce communication. The items within each ring are examples of relevant factors, not a complete list. Depending on the communicative situation, the importance of each ring may grow or shrink. For example, asking someone what time it is has far less cultural content than asking someone out for dinner.

Most discussions of culture focus at a macro level. That is, they look at cultures as a whole. There are many books that describe various cultures, to assist health-care workers and/or teachers in working with people from these cultures (for example: Asante & Gudykunst, 1989; Battle, 1998; Brislin, 1994; Brislin, Cushner, Cherrie, & Yong, 1986; Fawcett & Carino, 1987; Galens, Sheets, & Young, 1995; Goldstein, 2000; Lynch & Hanson, 1992). These books describe various societies or cultural groups in terms of specific characteristics, often prefaced by a historical sketch of how a particular group came to

live in a given country or region. Most sketches include information on (1) health and wellness; (2) disability; (3) family structure and roles within the family; (4) how status is determined; (5) time; (6) religion; (7) food preferences and customs; (8) the language(s) and dialect(s) spoken and some of their key characteristics; and (9) nonverbal aspects of communication.

There are many sources of information on different cultures, and many different cultures that could be relevant for readers in different settings. Therefore, specific cultural profiles will not be presented here. Instead, the following section offers some caveats and comments for clinicians to consider as they read these cultural guidebooks.

The problem with brief cultural sketches is that they tend not to recognize individual variations. Therefore, they can easily create or reinforce ethnic and racial stereotypes. One author, for example, describes the Japanese immigrant family as characterized by interdependency, hierarchical relationships, and empathy, and contrasts this with Anglo-American families which, the author implies, do not share these characteristics (Tempo & Saito, 1996). But not all Anglo-American families are the same. Another cultural guide states that some devout Muslims do not plan more than a few weeks ahead because they believe that only Allah knows the future (Davis, Gentry, & Hubbard-Wiley, 1998). There is no indication of how many Muslims might share this fatalistic approach. Nor does the author remind us that some people of other faiths share a similar fatalistic view of the future. Such inaccurate, sweeping generalizations do little to help us understand each other.

A different approach to culture can help to minimize stereotyping. Gollnick and Chin (1990) suggest viewing individuals as coming from individual (micro) cultures within a broader (macro) culture. This view encourages clinicians to look beyond race or ethnicity to see what factors influence a specific patient’s behavior. The microculture variables Gollnick and Chin identify are (1) ethnic or national origin; (2) religion; (3) gender/sex; (4) age; (5) exceptionality; (6) urban-suburban-rural; (7) geographic region; and (8) social class. These eight factors and the individual patient’s views and behavior can help us to look beyond ethnic groups and see that, despite their different race and nationality, a 55-year-old Chinese lawyer from Hong Kong may have more in common with a 52-year-old Anglo architect from Chicago than he does with a 22-year-old Hong Kong street vendor. A number of authors have reminded us of the importance of individual differences within cultural groups (e.g., Kayser, 1998; Pontón & Ardila, 1999; Wallace, 1997) but this point is often neglected. We must be particularly careful to guard against cultural stereotypes and generalizations when a patient’s appearance (skin color, hair, features) identifies them as having a specific background.

The descriptions in many books stress the differences between CLD groups and the so-called mainstream culture. While these differences can be important, we must not lose sight of the many similarities across cultures, and of individ-

Figure 9–1. Communication within a cultural context.

ual variability within each cultural group. Holland and Penn (1995) describe Native American and African views in which disability is due to evil spirits. These views may lead some patients and families to reject rehabilitation efforts. The cases are used to support Holland and Penn's recommendation that treatment "should [not] be imposed upon patients whose cultural belief systems do not recognize therapy as a need" (p. 154). This is true, not only for CLD patients but for all patients. Some white, middle-class, Anglo-Saxon clients also reject therapy. What are often cited as "cultural variables" apply to all patients. They are factors clinicians can use to assess their possible impact on the clinical process. They allow us to tailor the assessment and treatment to meet the individual needs of each patient, not only those labeled CLD.

Acculturation is another factor in working with CLD patients. Acculturation refers to the process by which people

from one cultural background adopt the cultural values and practices of a different culture. Usually, it applies to immigrants adopting the prevailing culture of their new country. Some authors propose seeing people as being on a continuum of acculturation or a series of levels of acculturation (Langdon, 1992b; Marin, 1992; Valle, 1994). Culture is a multilayered, multifaceted thing. A given person may be at a different level of acculturation in different areas of their lives, adopting "mainstream" values and habits around work and retaining more customs and values from their national group around religious or family matters. Within the same family, different members may be at different levels of acculturation. For some adults, proficiency in the mainstream language correlates strongly with their level of acculturation (Burr & Mutchler, 2003; Kang, 2006).

Finally, many immigrants, especially those who have chosen to leave their country of birth, reject aspects of its

prevailing culture and embrace the values of their new country. Thus, knowing that someone is a recent immigrant from Haïti, Pakistan, or Russia does not mean that they share the prevailing religious, political, or family values of those countries. This is demonstrated in a study by Erickson, Devlieger, and Sung (1999). Thirty young women, all born in Korea but living in the United States, identified many folk beliefs about illness and disability as being typical of Korean culture. However, their own beliefs closely matched those of the mainstream American culture.

It is important for clinicians working with CLD clients to read about and learn about the cultural backgrounds of their patients. These descriptions provide tools for problem-solving and clues about what to watch for in our interactions. These descriptions suggest questions: Why is this client late? Does the patient want a relative to be in the room during our sessions? Should I shake hands with family members? Can the patient attend an appointment on Friday? However, descriptions about racial, linguistic, or political groups cannot be used to predict what any individual may believe or do.

The Need for Data

Many recommendations in the CLD literature are based on the author's clinical experience, or their opinion. While some provide valuable insights, others are incorrect. For example, one writer stated that the phrase "no if's and's or but's" probably cannot be translated into any other language (Teng, 1996, p. 78). It is possible to translate this into a number of languages (French is one), though it would not necessarily have the status of a fixed expression as it does in English. Many recommendations in the CLD literature are untested. Suggestions such as "Better clinical results may be obtained if music consistent with the African-American culture is played while the client waits" (Terrell, Battle, & Grantham, 1998, p. 37) need to be tested. The clinician should also weigh the possible benefits of suggested changes in the clinical environment or clinical process in relation to their cost, and try to separate politically motivated claims and recommendations from those that have a clinical, patient-focused foundation. Clinicians will find valuable information in journals such as the *Journal of Cross-cultural Psychology* and the *Journal of Cross-cultural Gerontology*, as well as in books written for health-care providers (e.g., Paniagua, 2005). There are also studies and books on areas now called "ethnogerontology" and "gerontolinguistics" (e.g., de Bot & Makoni, 2005). These are relevant to aphasia, given the age of many adults with aphasia.

Clinical Chameleons?

In some cases, a center may serve a single client group, such as Hispanic, African-American, or Chinese. This makes it possible to link the clinical environment to that culture (e.g.,

decor, music, clinical tools). In many cities, however, a clinic serves clients from different cultures. This makes it impossible to tailor the environment to any one group. It also means that the clinician and the client will often not be from the same linguistic or cultural background. Therefore, compromises will have to be made.

To work with CLD clients, clinicians should be as knowledgeable as possible about customs and views that may affect the clinical process. It is possible to change many aspects of our testing and treatment. Possible changes include using appropriate greetings, having other family members attend with the patient, asking the appropriate person in the family group when decisions must be made, asking indirect questions, and allowing more or less time for informal conversation as part of each appointment. It is also possible to learn to interpret signals such as eye contact or punctuality within a range of cultural contexts. It is not possible, however, for a clinician to fully master all the culture-specific behaviors needed in a setting where a wide range of people are seen. Inevitably, when clinical services are offered by a professional who does not share the patient's macro- or microcultural background, some things may seem "foreign." The client, family, and clinician can all work to avoid misunderstandings. The clinician can do this by stating explicitly what the assessment or treatment involves; what role the patient, family, and clinician will each play; asking the patient and family what is important to them (as we do with any patient, but recognizing that for CLD patients the answers may vary more); and giving choices where it is possible to do so. If read with a critical eye, the literature on different cultures provides a starting point for clinical problem-solving. It provides the clinician with tools for his or her work with patients from different backgrounds. It does not and cannot provide step-by-step instructions or rules for any given type of patient.

BILINGUALISM

Debates about Defining Bilingualism

The word "bilingual" has different meanings for different people. In fact, Hakuta has said that the difficulty defining bilingualism makes it "fruitless to estimate the proportion of the world's population that is bilingual" (Hakuta, 1986, p. 4). Other authors have stated that at least half the world's population is bilingual (Grosjean, 1997; Harris & Nelson, 1992). Perhaps surprisingly, in bilingualism research, there is no consensus about the definition of "bilingual." In some studies, the bilingual subjects are in the process of learning a second language, while in others, the subjects have spoken both languages well since early childhood (see Edwards, 2006, for an entertaining discussion of the problem of defining bilingualism).

The lack of consensus about the definition of the word *bilingualism* leads to differences in how the term is used. For

some authors, one can speak two languages but not be bilingual if the second language (L2) is a “foreign” language that is not needed for day-to-day life (Baker, 1993; Duncan, 1989; Grosjean, 1992; Paradis, 1997). Thus, Americans who speak French are seen as bilingual by some authors (Frenck-Mestre & Pynte, 1997), but would be called L2 speakers by others. For other authors (see Baetens Beardsmore, 1982), bilingualism is defined in terms of language use, not in terms of knowledge. The problem in basing definitions in bilingualism on patterns of use is that these can change, while the level of knowledge of the language does not. For example, if a bilingual speaker moved from Texas, where she regularly used English and Spanish, to South Dakota, where she only spoke English, would she stop being bilingual a week after she moved? A month after?

This lack of consensus about what *bilingual* means is important to keep in mind when interpreting and comparing studies, and when deciding to whom the results of a particular study apply. If the participants were in the process of learning a second language, the results may or may not apply to proficient L2 speakers, even though they may all be called bilingual.

Most authors, especially in studies of adult bilinguals, define bilingualism in terms of level of linguistic knowledge. They see bilingualism as a continuum, not a bilingual/unilingual dichotomy (Hakuta, 1986; Paradis, 1998). Many studies refer to more-fluent or less-fluent bilinguals or compare groups with different levels of bilingualism. Furthermore, the bilingualism continuum is multidimensional. A person may have different levels of proficiency in the different language modalities (auditory and written comprehension, verbal expression, and written expression) and in different linguistic components (morphology, syntax, phonology, lexical semantics). Although some authors have viewed “true” bilinguals as those who have equal proficiency in their two languages, such people are the exception, if they exist at all. Even people who appear to have native or near-native proficiency in their second language display subtle differences in their performance on both production and comprehension tasks (Cutler, Mehler, Norris, & Segui, 1992; Hyltenstam, 1992) because each language may influence the other in speech perception (Flege, MacKay, & Meador, 1999; Levey, 2004), vocabulary (Bettoni, 1991; Chitiri & Willows, 1997), and syntax (Dijkstra et al., 2005; Frenck-Mestre & Pynte, 1997; Grosjean & Py, 1991; Hohenstein, Eisenberg, & Naigles, 2006; Kilborn, 1992; MacWhinney, 2002; Oesch-Serra, 1992; Pavlenko, 2000; Pavlenko & Jarvis, 2002; Salamoura & Williams, 2006; Van Hell & Dijkstra, 2002; Van Wijnendaele & Brysbaert, 2002). Bilingualism creates a unique speaker-hearer, unlike a unilingual speaker of either language (Fishman, 1965; Grosjean, 1989, 1998; Hyltenstam, 1992; Selinker, 1992). The most obvious lexical changes occur when words from L2 become accepted as words within L1. In North America, for example, English

terms such as “modem” or “back-up” are often used in Spanish or French conversations about computers. Several models attempt to explain this cross-language interference, including Selinker’s interlanguage, the competition model of MacWhinney and Bates (1989), and models derived from Levelt’s work. The key point for clinicians to remember about these studies is that, while there is still debate about how and why the interference between languages occurs, it is clear that it does occur for phonology, lexical items, and syntax, and in both comprehension and production. So clinicians should expect to see features of one language in the other, even in neurologically intact adults. For some patients, this makes it difficult to know what is a symptom of the aphasia and what reflects normal language patterns. The processing strategy some patients use for a particular task may not be the one the clinician is targeting.

People rarely experience all activities and all types of interactions in both their languages. Therefore, their vocabulary, use of idioms, and mastery of formal and informal registers is rarely equivalent in the two languages. There are domains of use such as family, religion, and work, each with its own vocabulary and linguistic patterns (Baker, 1995; Fishman, 1965; Miller, 1984; Reyes, 1998). Someone who uses only one language at work may not know work-related vocabulary in his other language. Grosjean (1997, 1998) has termed this the **complementarity principle**—each language is used for certain purposes in specific situations and vocabulary and other types of knowledge only exist in both or all languages if that individual has needed to use both languages in a particular context.

Another feature of bilingualism is its instability over time. A person’s level of bilingualism may increase or decrease with use or disuse. Language **attrition**—also called language loss—is a common process (Seliger & Vago, 1991). Attrition may affect different language modalities and linguistic components differently. Expressive use of vocabulary is particularly vulnerable to forgetting (Weltens & Grendel, 1993), while comprehension is less so. The type and degree of attrition vary, in ways not yet well-documented or understood, with the age of acquisition, amount of use, and level of proficiency attained in each language and not simply with years of residency in a particular country (Bahrick, Hall, Goggin, Bahrick, & Berger, 1994; Bettoni, 1991; Goral, 2004; Montrul, 2002). Some aspects of linguistic knowledge that may be particularly vulnerable to attrition are infrequently used words, distinctions that exist in the weakening language but not in the increasingly dominant language, bound items (as opposed to free), and irregularities (Seliger & Vago, 1991; Sharwood Smith, 1989; Weltens & Grendel, 1993). Because of language attrition, a person’s first language (L1) or native language is not always their stronger language.

In considering how to define bilingualism, it is important to acknowledge **dialects**. There is no standard for determining at what point a dialect is different enough from its base

language to become a language in its own right. Some pairs of languages are more similar and more mutually intelligible than are some language/dialect pairs. In some cases, a speaker of two dialects of the same language may be seen as bilingual, especially when the dialects are not mutually intelligible, as is the case for some dialects of Italian, Arabic, and Chinese, for example. Some authors consider speakers of African-American English and standard English to be bilingual (de Bot & Makoni, 2005), while most do not.

Another factor to keep in mind is that, in regions with a history of extensive interaction between speakers of different languages, the languages themselves change. For example, there are different “world Englishes” learned by native English speakers in Singapore, Hawaii, India, Canada, and Scotland. Within the United States and the United Kingdom, there are also many varieties of English spoken, often linked to regional, racial, or socioeconomic differences. The same is true of Spanish, French, and Arabic, all of which have creole, pidgin, and regional varieties. Clinical assessments must measure language abilities in relation to the patient’s dialect.

Code-switching is one feature of how some bilinguals communicate. Code-switching is the use of a word, phrase, or sentence in one language when speaking another. It is sometimes used when the speaker does not know how to say what he wants to in the language being spoken or when one language has a word or phrase which expresses his or her intended meaning better than the other. Code-switching is also triggered by the topic, by shared group membership or experiences, and by other factors. Code-switching occurs more often in some speakers and some groups than in others, and follows different patterns (Jacobson, 1998, 2001; Myers-Scotton, 2005; Myers-Scotton & Jake, 2001). Aphasia may lead to an increase in code-switching (Hyltenstam, 1992). Selinker and Seliger (1972, 1992) coined the term **interlanguage** to refer to the influence of one language on another. Interlanguage refers to errors made by L2 speakers that can be linked to the influence of their L1 (for a review of interlanguage during acquisition, and how interlanguage becomes permanent, see Gass & Selinker, 1994). The most well-known examples of interlanguage are perhaps in pronunciation. For example, some Spanish-speakers roll their R’s when speaking English, and some native Chinese speakers substitute /r/ for /l/.

Types of Bilingualism

Many typologies of bilingualism have been proposed. Overly simple models such as the compound/coordinate/subordinate distinction (for overviews see Baetens Beardsmore, 1982, or Hamers & Blanc, 1989) have been discarded by most researchers (Durgunoglu & Roediger, 1987; Grosjean, 1998; Kirsner, Lalor, & Hird, 1993; Paradis, 1995a). Recent studies also suggest that different types of

lexical representations may exist for different types of words, with concrete nouns, for example, sharing more of the elements of their representations than other types of words (Costa, 2005; de Groot, 1993). Most studies group their subjects by age of acquisition of the two languages and by level of proficiency in each language because these two factors influence performance on a wide range of tasks. In clinical work, too, when and how well patients learned their languages are key factors.

Various models of how the two languages are organized and processed have been proposed (Cenoz, Hufeisen, & Jessner, 2003; de Bot, 1992; de Bot & Schreuder, 1993; Dijkstra & Van Heuven, 2002; Green, 1998; Grosjean, 1997; Kroll & de Groot, 1997, 2005; MacWhinney, 2002; Paradis, 1997, 2004). Experimental evidence is still being gathered on these models. It seems clear, however, that the question “do bilinguals store their languages in one system or two?” is overly simple. Research is now focused on the types and strengths of links between languages, the processing strategies used during comprehension and production, and whether these links and strategies vary with level of proficiency in each language, the type of word, the degree of similarity between the two languages, and other factors. Although each model has studies supporting it (and others potentially contradicting it), there is now substantial converging evidence that the two languages are connected. This finding has direct consequences for clinical work, as described below.

Age of Acquisition

Recent work shows sensitive periods of varying length for optimal acquisition of different language components, such as syntax and phonology. During these sensitive periods, children can acquire native-like proficiency in a second language (L2), although not all of them will reach this high level (Pallier, Bosch, & Sebastián-Galles, 1997). Language-learning is still possible later, but more conscious effort is required and the L2 is more likely to show the influence of L1, in at least some linguistic components (Harley & Wang, 1997; Hurford, 1991; Scovel, 1989).

On a clinical level, this means that the later a patient began to learn a given language, the more imperfect their mastery of that language is likely to be. We can expect to see more interlanguage, more influence of L1 on L2, in late learners. However, individual differences in language-learning ability and patterns of use of each language over time will influence the level of proficiency attained.

Localization of Languages in Bilinguals

Localization of language in multilingual speakers has been studied in a series of cases (see Abutalebi, Cappa, & Perani, 2005, for a recent review). It is now clear that functions that

are in the left hemisphere of unilinguals are also in the left hemisphere of bilinguals (Paradis, 1990, 1998). This is apparently the case even for tone languages such as Chinese and Thai (Gandour, 1998; Naeser & Chan, 1980). Damage to the left hemisphere affects linguistic tones, which serve a lexical role. Comprehension and production of tones are dissociable (Gandour, 1998; Packard, 1986), just as comprehension and expression for non-tonal elements can be.

Subcortical aphasia similar to that reported in unilinguals has been documented following lesions in the left putamen, left caudate nucleus, internal capsule, and thalamus in several Italian patients (Abutalebi, Miozzo, & Cappa, 2000; Aglioti & Fabbro, 1993; Fabbro & Paradis, 1995; Moretti, Torre, Antonello, Cazzato, & Bava, 2003). There are also cases of subcortical, bilingual aphasia in Mandarin, Cantonese, and Thai (Gandour, 1998). Some authors have linked subcortical lesions, including those in the left caudate nucleus, to control of selecting and switching appropriately between languages (Abutalebi, Miozzo, & Cappa, 2000; Crinion et al., 2006).

Initial PET studies of English/French bilingual adults who learned French at an average age of 7 years found that the two languages activate overlapping regions in the left hemisphere (Klein, Zatorre, Milner, Meyer, & Evans, 1994, 1995). "Within- and across- language searches [synonym generation, translation of single words] involve similar distributed networks even when there are differences in the accuracy and latencies across the tasks, strongly suggesting that word generation in the two languages makes demands on overlapping neural substrates (Klein et al., 1995, p. 31). Hernandez, Dapretto, Mazziotta, and Bookheimer (2001) found no difference in the left-hemisphere areas activated during a naming task in English and Spanish in proficient bilinguals. Translation from L1 (English) to L2 (French) activated the putamen, but backward translation (L2 to L1) did not (Klein et al., 1995).

A similar but not identical result is reported by Kim, Relkin, Lee, and Hirsch (1997) using 12 adults who spoke six different pairs of languages. Using fMRI, they found overlapping areas of activation for L1 and L2 in Wernicke's area for all subjects. For the six early bilinguals, the two languages also activated similar regions in and near Broca's area. Less overlap in Broca's area was observed for the six subjects who began L2 acquisition later (mean age 11). Also using fMRI, Chee, Tan, and Thiel (1999) found that single-word production in Mandarin/English bilingual adults activated the same regions within the left hemisphere in both languages. This was true for early bilinguals (began L2 by age 6) and for late bilinguals (began L2 after age 12).

Somewhat different patterns of results have also been found. Chee, Soon, and Lee (2003) found some overlapping areas of activation but also differences in activation in the L prefrontal and L temporal regions during a word repetition task (fMRI) by 22 English-Chinese bilinguals. Halsband,

Krause, Sipilae, Teraes, & Laihininen (2002) studied Finnish-English bilingual men with PET scans. During a memory task for pairs of words, the two languages activated some different regions around Broca's area, the left angular and supramarginal gyri, and the cerebellum. Perani and colleagues (2003) tested two groups of men (all very proficient bilinguals) who spoke either primarily Spanish ($n = 6$) or primarily Catalan ($n = 5$) in their daily lives. There were differences in activation in the left frontal and parietal temporal lobes during a verbal-fluency task for the two groups. Perani and colleagues interpret these differences as being due to a combination of exposure to L2 and to age of acquisition. However, the verbal-fluency task activates a wide range of areas, in both hemispheres; the groups were small, and relatively diverse in their patterns of language use; and no mention is made of knowledge of additional languages. Therefore, other explanations for the results cannot be ruled out.

There are fewer fMRI studies of comprehension tasks. Perani and colleagues used a receptive language task in a series of studies. Using French/English and Italian/English bilingual adults, these studies have shown that the left-hemisphere areas activated when listening to stories in L1 and L2 vary with the age of acquisition and with the level of proficiency in L2 (Dehaene et al., 1997; Perani et al., 1996; Perani et al., 1998).

In at least one study there is evidence that learning a second language can increase gray-matter density in the left hemisphere (left inferior parietal cortex), and that these changes correlate with both age of L2 acquisition and overall proficiency in L2 (Mechelli et al., 2004). Activation of overlapping areas during language tasks does not mean that the same neuronal networks are involved in both languages. Clinically, there is evidence that the vocabulary or the syntax of only one language may be available at certain times, suggesting that different languages draw on different micro-anatomical regions or circuits. This variability is similar to what we see in unilingual patients who can produce some words or sentence types (inconsistently from day to day) but not others.

We are only beginning to map the localization of the bilingual's two languages. The range of tasks used in the brain-mapping studies to date is limited. Few language pairs, and relatively few individuals, have been studied with fMRI and PET. Individual differences in anatomy and localization may be incorrectly interpreted (Dehaene et al., 1997; Steinmetz & Seitz, 1991). Most studies that compare areas activated in two or more languages fail to consider what the difference in activation might have been if participants were retested in the same language. Mahendra, Plante, Magloire, Milman, and Trouard (2003) draw attention to this point in a study that found that the degree of non-overlap for participants' L1 and L2 was no greater than what they call the "run-to-run variability" inherent in fMRI testing. Most studies fail to provide adequate descriptions of the participants'

language history and proficiency to allow comparisons across studies. The linguistic demands and neurologic activity associated with the experimental task(s) in unilingual speakers are still being identified and debated (Grosjean, Li, Münte, & Rodríguez-Fornells, 2003; Dijkstra & Van Heuven, 2006). Van Lancker Sidtis goes so far as to say that in fMRI studies “the cognitive meaning of the signal remains uncertain” (2006, p. 285). How neural representation of the two languages relates to symptoms, prognosis, or rehabilitation for aphasia has not yet been addressed.

Functional Links Between Languages

Understanding how languages are stored neuroanatomically is important. Just as important for clinical work is understanding how the two languages are functionally connected. What are the links or relationships between languages that may be exploited in treatment?

In exploring how the two languages are organized, researchers have studied cross-language priming (facilitation) and cross-language interference. These studies use single words, usually nouns. Therefore, the results apply to part of the bilingual lexicon, and not necessarily to other aspects of language. Nonetheless, dozens of studies show that reading or hearing a word in one language can facilitate or interfere with responses in another language. The tasks studied include reading aloud, lexical decision, translating single words, and categorizing words (Altarriba, 1992; Chen, 1992; Costa, Miozzo, & Caramazza, 1999; de Groot, Borgwaldt, Bos, & Van den Eijnden, 2002; Lemhöfer & Dijkstra, 2004; Snodgrass, 1993; Van Hell & de Groot, 1998). In most studies, the priming or interference is stronger in one direction than the other. The strength and the direction of between-language effects are influenced by factors such as the length of time (in milliseconds) between the prime and the target, the level of proficiency of the subjects in each language, age of acquisition, and the stimuli used. All of these factors, except the first, come into play in clinical work.

In addition to the usual factors that make stimuli easier or harder, such as frequency or length of the words, factors specific to bilinguals have been identified. First, the number of “**neighbors**” (words with similar spelling and/or pronunciation) in one language affects lexical decision speed in the other language (Grainger & Dijkstra, 1992). Second, the similarity of the words in each language is a factor. Synonyms with a very similar form in different languages are called “cognates” (e.g. lemon and limòn). Several studies show that priming between languages is greater for cognates than for non-cognates (see above reviews) and processing of cognates is faster and/or more accurate than it is for non-cognates (Lemhöfer & Dijkstra, 2004). Naming of cognates is more accurate than non-cognates for both normal adults and those with aphasia (Ferrand & Humphreys, 1996;

Kohnert, 2004; Roberts & Deslauriers, 1999; Sanchez-Casas & García-Albea, 2005; Stadie, Springer, de Bleser, & Burk, 1995), but individual patients do not necessarily achieve higher scores on cognate words than on non-cognates for all tasks (Goral et al., 2006).

Clinically, these findings suggest that cues in one language may assist word-finding in the other, that interference across languages should be monitored, and that in selecting stimuli, the clinician should be aware of possible cross-language phenomena, including the bilingual neighborhood effect and the influence of cognates.

The literature on culture and on bilingualism has implications for clinical work. The remainder of this chapter will outline these, and examine the challenges facing clinicians who assess and treat bilingual aphasia.

ISSUES IN ASSESSING BILINGUAL APHASIA

To plan appropriate treatment, one must conduct a valid, comprehensive, and reliable assessment. This is difficult to do in bilingual aphasia. There are problems related to culture, level of bilingualism, available tests, interpreters, and test-retest reliability, as outlined below. The assessment of bilingual patients also includes determining the impact of the aphasia on each language.

Culture

Cultural factors can influence the level of cooperation with the assessment. These factors may include the perceived appropriateness of the clinician’s age, gender, race, body language, tone of voice, or dress. How the testing tasks are presented (direct versus indirect commands), the patient’s understanding of why he or she is being tested, and what is expected of him or her are also important.

Prior to the assessment, the clinician should learn enough about a patient’s background to know which aspects of the clinical process might be problematic. For inpatients, it is often helpful to observe the patient and family, and to consult with the social worker and nurses to learn more about the macro- and microcultural history of the patient and about the patient’s and family’s reaction to the communication disorder. During the assessment and treatment, give the patient and family members choices, when possible, based on cultural factors.

The assessment is a cyclical process of observing, then interpreting, the client’s behavior. Before interpreting behaviors, especially apparently negative ones, consider all possible reasons for the behavior, including cultural ones. Being late may indicate a lack of motivation, transportation problems, anxiety about coming to the clinic, executive-function problems, or simply a different view of time. Other behaviors that are easily misunderstood include eye contact, greetings, notifying the clinic to cancel an appointment,

asking or not asking questions, indicating yes/no, accepting or refusing food, giving/receiving gifts, gestures, choice of topics for conversation, and being active or passive in the treatment process.

Dealing with CLD patients and families can be a wonderful experience. Flexibility, a nonjudgmental view, and good clinical problem-solving skills are essential qualities. Cheng (1996) emphasizes how difficult intercultural communication is, and how easily misunderstandings can occur. But working with CLD clients can, with a little flexibility on all sides, work well. Published case summaries demonstrate this (Holland & Penn, 1995; Wallace, 1997; Whitworth & Sjardin, 1993). For aphasia assessment and treatment to work, the clinician need not master all aspects of the patient's culture. The clinician and the patient do not have to be from the same culture. Our goals should be to understand the aspects of each patient's beliefs, values, and communication style that will have the most impact on the clinical process. We can then be creative in developing ways of interacting that the patient finds culturally acceptable, while still allowing the clinician to offer assessment and treatment that are clinically appropriate. This goal applies to all patients no matter what their language, cultural background, race, or ethnic origins.

Level of Bilingualism

Decisions about testing and treatment must take into account the patient's premorbid level of bilingualism. The psycholinguistic studies of bilingualism show that the speed and accuracy on many language tasks, the effects of cues, and the amount of interference between languages are all influenced by the level of proficiency in each language. Unfortunately, it is impossible to know precisely what the patient's premorbid abilities were. Using the psycholinguistic literature as a guide, one can use four types of information to arrive at an estimate.

1. Self-ratings: Adults can rate their abilities in each language for various types of tasks (Albert & Obler, 1978; Hamers & Blanc, 1989, 2000) with reasonable levels of accuracy. Some authors use a five-point or seven-point scale, obtaining separate ratings for each language (Langdon, Wiig, & Nielsen, 2005). Others ask subjects to directly compare their abilities in each language (de Groot & Poot, 1997; Roberts & Le Dorze, 1997, 1998). Both types of self-rating correlate with group performance on a number of tasks used in clinical work, including verbal fluency (Lafaury & Roberts, 1998; Langdon et al., 2005; Roberts & Le Dorze, 1997) and picture naming (Kohnert, Hernandez, & Bates, 1998; Roberts & Bois, 1999).

One group study has used self-rating of premorbid abilities by adults with aphasia (Roberts & Le Dorze, 1998). While this identified groups of balanced bilin-

guals, how well self-ratings correlate with individual performance on a given task or aphasia test has not been adequately examined.

2. Ratings by family members: Information provided by the patient can be supplemented by asking the family to assess the patient's level of bilingualism. Ratings of the patient's abilities may be influenced by the family member's own level of bilingualism. To obtain an accurate view, ask more than one person, and take their own bilingualism into account in interpreting their ratings. A wife who speaks little English may overestimate her husband's abilities. A child who grew up speaking English may be very critical of an immigrant parent's less-than-perfect abilities.

In trying to establish the patient's premorbid level of bilingualism, it is best to avoid the use of the word "bilingual." For many people, bilingual means perfect and equal proficiency in both languages. When asked if the patient is bilingual, they will say "No," and the patient will be incorrectly identified thereafter as unilingual. It is important to ask sufficiently detailed questions before deciding on a rating, and to ask the questions in terms the patient and family can understand. Instead of "How was his auditory comprehension in ____," ask "Could he understand the news on the radio? people talking at work? people who spoke quickly? people with different accents? . . ."

3. Patterns of use for each language: Knowing which language was used in which situation helps to determine the importance of each language for the patient, what language(s) will be needed poststroke, and what vocabulary may be used for which types of treatment tasks.

Baker (1995) has shown the importance of assessing domains of use. In a study of 72 immigrants from six different countries, most of whom had lived in Australia for over 10 years, there was a wide range of patterns of use of L1 and English. Length of residence in Australia and even level of ability in English did not correlate with patterns of use. Subjects identified 10 domains of use: family, friends, shopping, religion, medical, dealing with tradespeople, hobbies, business/work, dealing with the legal/government system, and public transportation. Within these domains, 38 specific tasks were identified. Baker's list of tasks makes a good starting point for a language-use questionnaire.

4. Acquisition history: Knowing how and at what age the patient was exposed to each language may suggest treatment approaches. For example, one might refer to "grammar rules" or the names of verb tenses if English (L2) was learned in a classroom but not if it was acquired informally. The acquisition history and patterns of use both provide indirect evidence about level of proficiency. Early acquisition and extensive use across different domains often suggest a high level of

proficiency. If there are discrepancies between the family's assessment of the patient's abilities, and the patient's use of his languages, these can be explored. For example, if the family or patient claim that the patient "spoke ___ perfectly before his stroke," but this language was rarely used, this discrepancy should be explored, especially given the potential attrition of little-used languages.

Information on language proficiency, use, and acquisition is important in deciding what areas to assess, interpreting the results (separating premorbid characteristics from the effects of the aphasia), and in planning treatment (see Roberts & Shenker (in press) for a language-history questionnaire covering all three of these dimensions). For example, if a patient says "now talk hard - no talk good," this could indicate nonfluent aphasia or could be close to his prestroke level of English. Only by gathering information about the patient's premorbid bilingualism can the clinician estimate their poststroke language impairment and plan appropriate treatment. This information, however, does not allow us to predict patterns of impairment (L1 vs. L2) or recovery, nor to establish a prognosis specifically focused on the bilingualism. "No correlation has been found between pattern of recovery and neurological, etiological, experimental or linguistic parameters: not site, size or origin of lesion, type or severity of aphasia, type of bilingualism, language structure type, or factors related to acquisition or habitual use" (Paradis, 1995b, p. 211).

Using Interpreters

When a patient must be assessed or treated in a language that the clinician does not master (see ASHA 1989 guidelines for the level of proficiency needed for clinical work), an interpreter can be used. Interpreters should be used only if there is no speech-language pathologist (SLP) available who speaks the patient's language(s). This is because of the disadvantages associated with using interpreters. These include difficulties locating an interpreter who is able to spend the time required and who is able to fit into the constraints of the patient's schedule, and the time needed to train interpreters in test administration, interviewing, and therapy techniques. Even with training, interpreters may inadvertently alter the test stimuli or protocol or fail to convey relevant details of the patient's response. Because the SLP does not speak the language being tested, he or she may not always be aware that this has happened. Furthermore, the clinician cannot be certain that the interpreter is reporting all the relevant aspects of the patient's performance, such as the nature of errors. There may be direct costs for the interpreter's time, which are not covered by health insurance.

When demand justifies it, a clinic may hire interpreters for specific languages as full- or part-time staff. Before

working with interpreters—either volunteers or paid staff—clinicians should familiarize themselves with the process, its requirements, its pitfalls, its limitations, and any relevant legal restrictions or policies (Gentile, Ozolins, & Vasilakakos, 1996; Kayser, 1995; Langdon, 1992a; Langdon & Cheng, 2002; Martin et al., 1998).

When a professional interpreter or aide trained to fill this role is not available, members of the patient's community or family can be used if they are trained by the SLP for this role. Family members who have close ties to the patient may find it distressing to see the full extent of the deficits exposed. They may also be more inclined to provide cues or assistance to the patient. Friends or members of the patient's religious or community groups can often be more detached. The person chosen as interpreter must also be acceptable to the patient, available for the time needed to complete the assessment, and available for regular treatment sessions.

Given the time and expense required, and given the problems in achieving reliable results in assessment, is it worth using an interpreter? The consensus in the current literature is that patients must be assessed in all languages they use on a regular basis, or for a specific purpose. Without this assessment, the diagnosis, as well as the treatment goals set for the patient, may be inappropriate. The resources and policies of each clinic will determine whether this standard is reached for all patients.

Testing in Various Languages

To adequately assess patients with bilingual aphasia, we need a range of tests that are reliable and valid with demonstrated sensitivity (to detect changes over time and to discriminate between levels of impairment), and with norms for specific groups. Such tests should be as free of cultural bias as possible. Unfortunately, we do not yet have such a range of tests.

It is important to remember that the basic principles of test design (validity, reliability, adequacy of norms, etc.) apply to all aphasia tests, including translations of existing tests that attempt to meet the needs of CLD patients. The (American) Agency for Health Care Research and Quality has identified the need for development of better tests for communication disorders, stating: "With the increasing cultural, linguistic, and racial diversity of the U.S. population, the applicability of assessment instruments to individuals who are members of different subpopulations is of crucial importance to clinical diagnosis and the process of disability determination. Despite the existence of a large number of speech and language assessment instruments, we still lack appropriate instruments for reliably and validly assessing speech and language in many subgroups defined in terms of language, dialect, or cultural differences. Thus, future research funding and priorities should be directed at addressing these serious deficiencies." (2002) (<http://www.ahrq.gov/clinic/epcsums/spdissum.htm>)

Many clinics and many published studies use in-house translations of published tests (e.g., Radanovic, Mansur, & Scaff, 2004). Thus, studies are published that present data on tests such as the BDAE or the WAB but with no reference for the test in the language of the study. This state of affairs is due partly to the reluctance of publishing houses to accept tests that will have relatively small potential markets. Clinicians and researchers have little choice but to develop their own tests, or their own translations of published tests. However, too often, clinicians and authors then use these tests to compare the severity of the aphasia across languages or to measure improvement over time. Without even basic reliability, validity, and sensitivity data on these instruments, there is no way to interpret the obtained scores, beyond a very general patterns such as “seemed to do well on these tasks” or “low score on this set of items.” It is inappropriate to use them to diagnose aphasia or to identify a type of aphasia. On the other hand, faced with the need to assess patients, clinicians may have little choice, particularly in countries where no one has developed aphasia tests in the range of languages needed for patients in that country.

Published Tests in Various Languages

To assess the patient's or family's perception of the impact of the aphasia on the patient's communication, the ASHA Functional Assessment of Communication Skills (FACS; Frattali, Thompson, Holland, Wohl, & Ferketic, 1995) may be used. Its test items are designed to be suitable for use with patients from a wide range of cultural backgrounds. It falls to the individual clinician, however, to translate the questions, with the potential for poor translations and changes in meaning or nuance across the different languages.

To assess the linguistic abilities of bilingual patients, clinicians in North America have limited choices: the Boston Diagnostic Aphasia Examination, the Bilingual Aphasia Test, the Multilingual Aphasia Examination, and the Aachen Aphasia Test all have published versions in various languages. In-house translations of these and other tests are often available in clinics that see patients from different language backgrounds. In all cases (published or unpublished tests), clinicians need to be aware of the widely varying reliability and validity of these tests.

The Boston Diagnostic Aphasia Examination (BDAE)

The BDAE is widely used in English. Its revised versions have provided additional normative data (Goodglass, Kaplan, & Barresi, 2000). Nonetheless, it is not necessarily an ideal test in its design and performance and was judged unsatisfactory on psychometric grounds in a recent review (<http://www.ahrq.gov/clinic/epcsu/su/spdisum.htm>). Spanish versions have been published over the past 15 years by Editorial Medical Panamericana in Argentina and by Masson in

Spain, but its availability has varied. It is currently available from <http://www.medicapanamericana.com/>.

A French version of the BDAE, published in 2005, is available from ECPA (Editions du Centre de Psychologie Appliquée, a section within Harcourt Assessment/The Psychological Corporation). The manual provides information on a normative sample of 207 adults.

The Bilingual Aphasia Test

The Bilingual Aphasia Test (BAT) developed by Paradis and his colleagues is specifically designed for bilinguals. It exists in over 60 languages, and tests all language modalities. It also has a section that tests translation abilities between more than 100 pairs of languages. Detailed descriptions of the BAT's rationale, development, and administration instructions are available in English (Paradis & Libben, 1987; Paradis, 2004) and in Spanish (Paradis & Libben, 1993). No longer commercially published, it is available directly from its author (see Appendix 9-1).

Each version of the BAT uses vocabulary and pictures that the authors consider culturally appropriate. The content is modified somewhat to assess different features in different languages. Each version has been “normed” on a sample of native speakers of each language; however, published normative data for most languages are not available in English-language journals (or in the other languages included in data bases such as PsychInfo and Medline).

According to Paradis and Libben (1987), normal speakers of each language, or L2 speakers with 400 or more hours of instruction, should score 100% on most subtests. However, two studies of Spanish-English bilingual speakers in Texas and in Florida suggest that this may not be the case. In one study, a group of 14 Spanish-English bilingual adults (mean education 14.5 years, Cuban background) did not score within the expected range for normals on six of 24 subtests in Spanish (L1) and on two subtests in English (L2) (Manuel-Dupont, Ardila, Rosselli, & Puente, 1992). Similar results are reported by Muñoz and Marquardt (in press) with a group of 22 Spanish-English bilingual older adults. The mean group scores were below 70% on 54 items of the short version of the BAT, 22 on the Spanish section of the test. There are no studies documenting the equivalent difficulty of various versions of the test in different languages or its test-retest reliability.

The Multilingual Aphasia Examination

This test, despite its name, is available only in Spanish (MAE-S) (Rey & Benton, 1991) and English (MAE-E) (Benton, Hamsher, & Sivan, 1994; Rey, Feldman, Rivas-Vazquez, Levin, & Benton, 1999). Its manual and a series of publications provide data on its reliability, discrimination, sensitivity, and split-half performance with children (Schum, Sivan, & Benton, 1989) and with English-speaking adults

(Elias, Elias, D'Agostino, Silbershatz, & Wolf, 1997; Ivnik et al., 1996; Schum & Sivan, 1997). The Spanish version was standardized on 234 North American Spanish speakers (Spreeen & Strauss, 1998). There are also a number of studies of its psychometric properties in Spanish (e.g., Rey et al., 2001).

The Aachen Aphasia Test

The AAT is not familiar to most clinicians in North America, but it has demonstrated validity and reliability, including test-retest reliability. Published versions exist in German (Huber, Poeck, Weniger, & Willmes, 1983; see www.testzentrale.de), Dutch (Graetz, de Bleser, & Willmes, 1992), and Italian (Luzzatti, Willmes, & de Bleser, 1992, 1996) (see www.osnet.it). An experimental version in English was developed and its properties found to be satisfactory (Miller, Willmes, & de Bleser, 2000), but the English version has not been published. There is also an unpublished Portuguese version of the test. The equivalence of this test across languages and, therefore, its suitability for use with bilingual adults remain untested. However, the results of each patient can be converted to stanine scores, T-scores, and to percentile ranks, allowing comparison of each patient to the (unilingual) normative sample the test was based on, for each language.

Tests in Other Languages and Dialects

Clinicians assessing aphasia in unilingual patients can draw on a wide range of tests, some aimed at detecting mild impairments, others at severe ones. Some tests assess a specific aspect of language, such as reading, in detail. No such range of tests exists for bilingual aphasia. However, there are tests developed in different languages, some of which have versions in more than one language. A list of a number of these tests, and studies reporting results obtained with unpublished, experimental versions, was included in the previous version of the current chapter (Roberts, 2001). However, many of these tests are not available commercially, were never published, and/or go out-of-print rapidly, making it difficult to compile an accurate listing at any point in time.

To use tests designed for one group to assess members of another group (for example, a test from Italy to test Italian-English speaking immigrants in North America or Australia), clinicians need studies of their reliability and validity (Ardila, 1995; Baker, 1993). A number of studies have been done; they illustrate how complex this area is and how much is yet to be done. The following (incomplete) review highlights some of the issues.

Armstrong, Borthwick, Bayles, and Tomoeda (1996) found that the Arizona Battery for Communication Disorders in Dementia (Bayles & Tomoeda, 1991) is suitable for use with speakers of British English. The authors do not

recommend changing any stimulus items. They recommend using the American norms.

There are many studies on the Boston Naming Test (BNT) (Kaplan, Goodglass, & Weintraub, 1983) in various languages (see Roberts & Kiran, 2007). In Spanish and French versions of the BNT, the item difficulty is not the same as in the English version (Roberts, Garcia, Desrochers, & Hernandez, 2002).

When the BNT is used in English with different cultural groups, results are mixed. Worrall, Yiu, Hickson, and Barrett (1995) found two of the 60 items are not familiar to Australians, but Tallberg (2005) found no items had to be removed for cultural reasons for Swedish adults. A Greek version of the test has, apparently, retained all 60 items (Tsolaki, Tsantali, Lekka, Kiosseoglu, & Kazis, 2003). The Korean "BNT" has so many changed items that it no longer resembles the original test (Kim & Na, 1999). In each case, authors used different definitions of "culturally appropriate," further complicating comparisons across these and other studies.

The unmodified BNT was sensitive to age and education in English-speaking Australian subjects (Worrall et al., 1995) and in 45 unilingual French Canadian subjects (Doucet & Roberts, 1999). Scores differed significantly with age, education, and gender in elderly Dutch-speaking Belgians (many of whom were likely to be multilingual, although this is not noted) (Mariën, Mampaey, Vervaeke, Scaerens, & De Deyn (1998). In Swedish-speaking adults, Tallberg (2005) found a significant effect for education. This suggests that despite cultural factors and problems with name-agreement for some stimuli, the test is fairly robust. However, studies of bilingual adults (Kohnert et al., 1998; Roberts et al., 2002) show that the unilingual norms clearly do not apply. Thus, different cut-off scores must be established for different age and education levels within each linguistic group.

Of those studies of African-American performance on the BNT, some have shown no difference in BNT scores across races when age and education are controlled (Henderson, Frank, Pigatt, Abramson, & Houston, 1998). Other studies find that African-Americans score below Caucasians (e.g., Lichtenberg, Ross, & Christensen, 1994). However, small sample size and failure to control for or to report education limit the usefulness of these findings.

There are fewer studies of other tests, but some work has been done. Molrine and Pierce (1998) found that on the Boston Diagnostic Aphasia Examination (BDAE) (Goodglass & Kaplan, 1983) the Western Aphasia Battery (WAB) (Kertesz, 1982), and the Minnesota Test for Differential Diagnosis of Aphasia (MTDDA) (Schuell, 1965), the scores of African-Americans were below those of Caucasian-Americans ($n = 24$ of each) on only three of 26 subtests of expressive language. For upper-SES subjects, these were Animal Naming (BDAE, WAB), and paragraph

retelling (MTDDA), and, for middle-SES, word reading (BDAE). With 12 subjects for each SES level and only a single category used in the verbal-fluency test (Animal Naming), these results are preliminary. Huntress (1979), quoted in Wallace & Tonkovich, 1997, p. 153) found statistically significant but not clinically significant differences in performance on the MTDDA in a group of 15 African-Americans, matched for age, education, and income to a group of white subjects. If credit had been given for responses that were correct, but given in nonstandard English, the scores for the African-American group would have been higher. Thus, this study also suggests that test performance can be very similar across CLD groups.

More studies of CLD test performance are needed, with complete data on the age, education, and language history of participants. This information is essential to allow readers to know to whom the results of a particular study may apply and to permit comparison across studies and appropriate generalization of the findings. The studies done to date illustrate that the answer to the question “can existing tests be used with CLD populations?” is complex. We cannot reject all tests initially normed on white, middle-class, native English speakers as unsuitable for use with other groups. Some tests, and many subtests in existing batteries, are proving to be appropriate. Other tests need specific stimuli, or scoring procedures, changed. Still others may prove entirely inappropriate. Through rigorous validation and normative studies, we will learn which is which.

Informal Assessments and In-House Translations

Until we have more data and more norms for various patient groups, clinicians will continue their current practice of using their own translations of published tests or in-house translations of various tasks on CLD patients, without norms to guide them. The use of nonstandardized evaluation tools is widespread (Katz et al., 2000) and is not limited to CLD patients. Clinical judgment is an important component in interpreting these results. There are, however, pitfalls associated with using ad hoc translations of subtests or tasks.

Tasks can change in nature and in difficulty when they are translated. For example, counting and reciting the months of the year are different tasks in English, but not in Mandarin (Chinese), since the months are called “one-month, two-month, three-month . . .” (Naeser & Chan, 1980). Spelling is a challenge, and a very familiar task in English, but not in Spanish or Italian because of their highly regular phoneme-grapheme correspondence (Ardila, 1998). Spelling, of course, exists only in languages that use an alphabet-based writing system. In naming, or auditory discrimination tasks, nouns that are high-frequency and short in one language can be low-frequency and multisyllabic in another language, changing several dimensions of the task. For bilinguals, frequency of use may be much more idiosyn-

cratic and less predictable than in unilinguals. At least one study has found that the frequency effects so well documented in unilinguals may be absent for bilingual speakers (Lehtonen & Laine, 2003). Because knowledge is dependent on domains of use, we cannot assume that all bilinguals know “simple” vocabulary in both languages. Name agreement is lower for bilingual speakers than for unilingual speakers (Goggin, Estrada, & Villarreal, 1994; Roberts et al., 2002), which may have implications for how naming and other lexical retrieval tasks are scored. In an innovative study, Croft, Marshall, and Pring (2006) devised a naming test for Bengali-English bilingual aphasic adults by selecting 30 pictures out of a possible of 150 based on naming-latency and name-agreement data obtained from a control group of 20 nonaphasic members of the same community. In a sense, they used the patients’ cultural peers as context for assessing and interpreting the naming deficits of their six patients, given the unavailability of a published naming test for Bengali-English speakers in England.

A further challenge in assessing CLD patients is that some symptoms of aphasia vary across languages (Menn, 2001). This has been shown in syntactic deficits (Bates & Wulfeck, 1989; Bates, Wulfeck, & MacWhinney, 1991; Menn, 1989; Menn & Obler, 1990; Menn, O’Connor, Obler, & Holland, 1995; Nilipour & Paradis, 1995; Sasanuma, 1986) and for deep and surface dyslexia (Ardila, 1998; Luzzatti, Laiacina, Allamano, De Tanti, & Inzaghi, 1998; Sasanuma, 1986).

The noun/verb dissociation, commonly seen in aphasia in English and several European languages, is difficult to assess in Chinese, where many words are noun-verb compounds (Bates, Chen, Tzeng, Li, & Opie, 1991; Chen & Bates, 1998; Law & Leung, 2000). There are also studies of reading deficits that suggest that the frequency and/or the types of errors vary across languages, making the deep-dyslexia and surface-dyslexia patterns described for English inapplicable to some other languages (Ardila, 1998; Ferreres & Miravalles, 1995; Sasanuma, 1986). Other studies report patterns similar to those reported in English-speaking patients (Weekes et al., 1998), including acquired dyslexia (Torraldo, Cattani, Zonca, Saletta, & Luzzatti, 2006). These studies demonstrate that one cannot apply all English-based definitions of symptoms or syndromes to other languages. Some apply, some do not. Assessment results must be interpreted with caution, and must take into account the features of the patient’s (other) language or dialect. For bilinguals, competition between the processing strategies or the elements of the two languages and interlanguage must both be considered when determining what is a clinical symptom and what is a premorbid feature of bilingualism. There are also error types that are possible in some languages but not in others (correct phonemes, but incorrect tones; wrong gender or case for nouns; creating a false cognate word to cover a word-finding problem). Symptom lists generated to

describe one language do not address many possible symptoms in other languages.

Test-Retest Reliability

When a patient is tested twice or more, once in each language, the question of test-retest (TRT) reliability arises. To interpret possible between-language differences, we need to know the normal variability on retesting within a single language. On the BNT, most unilingual English speakers scored within 1 point on retesting, but some changed by 3 or 4 points (Roberts et al., 2002). On the Graded Naming Test, Roberts (2003) found less individual variability and a group mean improvement of 1 point (out of a score of 30). Roberts and Le Dorze (1994) have shown that on semantic verbal fluency, individual scores may increase or decrease by more than 30%. Brookshire and Nicholas (1994) found significant variability on retesting using the picture-description task from the BDAE. More accurate scores and less TRT variability are obtained when results of several connected-speech tasks or several verbal-fluency categories are combined (Brookshire & Nicholas, 1994; Monsch et al., 1992). Until there are more data on the variability of individual scores within a given language, clinicians should be cautious in interpreting different scores between languages (see Roberts (1998) and Roberts and Kiran (2007) for more on this). Interpretation/comparison of scores on different languages is particularly difficult when using tests with unknown test-retest reliability for individual scores, and tests with no published norms, or norms based on samples with different educational, age, and cultural/linguistic backgrounds than the patient being tested.

Clinicians can sample or test some tasks twice in each language for each patient to provide an indication of within-language variability that can guide the interpretation of between-language differences. Using the complete test, not the shortened version, a longer sample, and more exemplars in informal evaluations will often yield more reliable results.

The Test Mess

There is a lack of culturally and psycholinguistically appropriate, rigorous tests of aphasia in the range of languages spoken by people living in many countries, including the U.S., Canada, the U.K., and India. Some have even speculated that it may be impossible to devise any kind of meaningful norms, given the impact of language proficiency and dialect on each individual's (prestroke) performance. The individual variability that is part and parcel of bilingualism combines with the idiosyncrasies of the aphasia each patient experiences. One possible (pessimistic) conclusion is that it will be impossible to develop rigorous tests for bilingual adults with aphasia. The best we can hope for is to develop a range of tasks that allows clinicians to explore various language functions, without seeking to draw strong conclusions

about the severity of the aphasia or to classify it. On the other hand, governments, insurance companies, and employers raise the need to identify, accurately diagnose, and quantify the language impairment in order to support funding for therapy and disability claims. The calls for evidence-based practice (EBP) motivate clinicians to base their therapy on the most valid (accurate) test results possible. Thus, a debate is going on between the optimists, who argue that psychometrically sound tests are possible, at least for large subgroups of bilingual individuals, if we, as a profession, invest the time to develop and assess them adequately, and the pessimists, who argue that the combined complexities of bilingualism and aphasia make it unrealistic to attempt to develop such tests.

Patterns of Impairment and Recovery in Bilingual Aphasia

One purpose of the assessment is to determine the impact of the aphasia on each language. The patterns of impairment and recovery in bilingual aphasia have been described in individual, usually exceptional, patients since the 19th century (Paradis, 1983). Paradis has identified and labeled these patterns (Paradis, 1989, 1993a, 1998; Paradis & Libben, 1987). To facilitate clinical use of these patterns, I have modified Paradis' list somewhat, separating impairment from recovery, and expanding and commenting on the definitions.

Reported Types of Impairment in Bilingual Aphasia

1. **Parallel impairment:** the two languages are impaired in the same manner and to the same degree. Parallel impairment is determined in relation to premorbid proficiency. If the patient mastered both languages equally premorbidly, the level of ability will be equal post-onset. If one language was stronger than the other, it remains so in cases of parallel impairment. Because aphasia can affect some aspects of language more than others (comprehension vs. expression, or oral vs. written language), the most accurate way to use this label is to rate each modality separately. There may be parallel impairment in auditory comprehension, but differential impairment in reading comprehension, for example.
2. **Differential impairment:** one language is more severely damaged by the aphasia than the other one. Thus, a difference in proficiency may exist between languages that were approximately equal premorbidly. Or, a premorbid difference may have been erased by the stroke. For example, Spanish may have been stronger than English prestroke, but poststroke, the two are equal. This is not parallel impairment, because the aphasia has had a greater impact on Spanish.
3. **Differential aphasia:** this refers to the type of aphasia, not to the degree of deficit. Differential aphasia exists

when symptoms differ across languages. In a case reported by Albert and Obler (1978), a multilingual patient appeared to have Broca's aphasia in one language and Wernicke's aphasia in another. Chengappa, Bhat, and Padakannaya (2004), using in-house translations of the WAB, found their 70-year-old patient had global aphasia in Hindi and Kannada, and Wernicke's aphasia in English and Tamil. The validity of published reports of differential aphasia has been questioned (Dronkers, Yamasaki, Webster Ross, & White, 1995; Paradis, 1997, 1998).

4. Blended or mixed pattern: "patients systematically mix or blend features of their languages at any or all levels of linguistic structure (i.e., phonological, morphological, syntactic, lexical and semantic) inappropriately" (Paradis, 1989, p. 117). In these cases, it is as if the patient no longer recognizes what words or features belong in each language, and blends both languages. The patient uses this blended language even when speaking to unilinguals. This is not the same as code-switching or mixing, which is normal behavior in many bilinguals when speaking to another bilingual. Initially called "mixed impairment," Paradis now labels this as blending (1998), to avoid possible confusion with mixed aphasia.
5. Selective aphasia: only one language is affected; the other remains at its premorbid level (Paradis & Goldblum, 1989).

Reported Types of Recovery in Bilingual Aphasia

1. Parallel recovery: both languages improve at the same rate and to the same degree, relative to premorbid levels.
2. Differential recovery: one language recovers better than the other.
3. Successive recovery: "one language does not begin to reappear until another has been maximally recovered" (Paradis, 1989, p. 117). In practice, one cannot determine when maximum recovery has been reached, but the label of successive recovery applies when one language appears to have reached a plateau before any real progress occurs in the other language.
4. Antagonistic recovery: as one language improves, the other regresses. In some cases, the pattern alternates, with first one language improving, then the other (Nilipour & Ashary, 1989; Paradis, Goldblum, & Abidi, 1982; Paradis & Goldblum, 1989). This variant is also called "alternating antagonism," or see-saw recovery.
5. Selective recovery: only one language shows improvement (Aglioti & Fabbro, 1993).

In theory, these types seem clear. In practice, because of the problems inherent in testing bilingual aphasia and in

determining the premorbid mastery of each language, it can be difficult to distinguish among the first three types of impairment. Some authors use the label "differential impairment" when one language is better than the other, even when this reflects premorbid proficiency (Nilipour, 1988). According to Paradis' definition, these should be labeled as parallel. Some published cases of differential aphasia have been reclassified since the authors failed to take into account different symptom presentation in different languages, or did not use appropriate tests and bilingual norms (see Gomez-Tortosa, Martin, Gaviria, Charbel, & Ausman, 1995; Kohnert et al., 1998; Paradis, 1993b, 1997; Silverberg & Gordon, 1979). In at least one published case, impairment that is similar to Paradis' antagonistic pattern was due to the occurrence of additional lesion(s) (Moretti et al., 2003).

Before labeling a recovery or impairment pattern, one must carefully consider the symptom pattern of the specific languages, the patient's dialect, sociocultural factors (what is a normal pattern for the patient's peer group), and the nature of the test used (Paradis, 1995b). Given the complementarity principle, and given that bilinguals usually have different premorbid levels of proficiency in their languages, and different levels in different language modalities, and given that aphasia can differentially affect each language modality, ratings of impairment should be done separately for auditory comprehension, reading, verbal expression, and written expression. The case of an English-Nepalese bilingual illustrates how the "strong" language can vary across tasks (Byng, Coltheart, Masterson, Prior, & Riddoch, 1984).

The few studies done thus far also highlight the need to proceed cautiously in classifying bilingual aphasia by syndrome type. Dronkers and colleagues (1995) have shown that the aphasia classification of a patient can change when credit is given for regional dialect. The issue of classifying aphasia is complex. Non-CLD patients are assigned to different syndromes using the WAB and the BDAE in English (Crary, Wertz, & Deal, 1992). It is not surprising, therefore, that attempts to classify CLD patients by syndrome will often lead to unreliable results. Of course, it is not necessary to label an aphasia syndrome or patterns of bilingual impairment or recovery. Treatment and counseling generally target symptoms and language processing, and/or maximize the use of residual abilities, not labels. Still, to the extent that labels are used, they must be used cautiously, and seen as representing tendencies or general patterns, not absolute truths.

The syndrome types described in English-, Italian-, French- and German-speaking patients appear to exist in a wide range of languages. There is no data about whether the incidence of these syndromes in bilingual patients is similar to that in unilingual patients.

Many authors have attempted to explain nonparallel recovery. The literature contains proposals usually based on speculation, or on observation of a few, nonrandomly

selected patients. After reviewing the various theories and their supporting case reports, Paradis (1989) concludes: “no single principle or hierarchy of principles has emerged to explain the whole array of recovery patterns. Neither primacy, nor automaticity, habit strength, stimulation pre- or post-onset, appropriateness, need, affectivity, severity of the aphasia, type of bilingualism or type of aphasia could account for the non-parallel recovery patterns observed” (p. 127).

The literature offers little information on the incidence of each type of impairment. Clinical experience suggests that parallel impairment and parallel recovery are by far the most common patterns, especially after the first few weeks. There is some support for this view in the literature (Chary, 1986 quoting Nair & Virmani; Junqué, Vendrell, & Vendrell, 1995; Lhermitte, Hécaen, Dubois, Culioli, & Tabouret-Kelly, 1966; Paradis, 1977; Vaid & Genesee, 1980). There are also a number of published cases of parallel impairment and recovery (Dronkers et al., 1995; Mimouni, Béland, Danault, & Idrissi, 1995; Nilipour, 1988; Roberts et al., 1997; Sasanuma & Park, 1995). There are more published reports of nonparallel patterns, because of a tendency to write-up the unusual or interesting patterns. We need studies of unselected, consecutive cases with detailed language histories and thorough testing to determine the incidence of parallel and nonparallel recovery.

ISSUES IN INTERVENTION

Treatment for bilingual aphasia has been neglected in the literature. Little published information exists on the effects of treatment and even less on appropriate methods. Two types of studies provide some guidance: studies of the effects of treatment in various languages; and a small number of studies of the symptoms of bilingual aphasia. The principles that guide unilingual treatment are also relevant to bilingual treatment. The following section presents these, along with a liberal dose of suggestions based on clinical experience and a review of published treatment studies (Table 9–1). Most findings and suggestions presented below have not yet been tested formally, though they have proved effective in clinical practice.

Effects of Treatment in Bilinguals

On the one hand, bilingual treatment studies are few in number, and vary widely in the level of detail and hence in their value in supporting clinical practice. On the other hand, the studies that have been done, and the unilingual treatment studies in a range of languages, suggest that treatment principles that work in unilinguals often work in bilinguals as well. A study by Wiener, Obler, and Taylor-Sarno (1995) documented the treatment outcomes, length-of-stay, and reasons for discharge for 54 unilingual and 55 bilingual patients in a New York City rehabilitation center. The

authors expected to find that the bilingual patients were underserved (shorter treatment, fewer types of treatment) and made less improvement than the unilingual patients. Instead they found that “bilingual patients showed recovery that was virtually equivalent to that of unilinguals” (p. 55).

There are reports that when only one language is used in treatment or practice, one or more of the patient’s untreated languages improve (Edmonds & Kiran, 2006; Holland & Penn, 1995; Penn & Beecham, 1992). The treated language may improve more than the untreated one (de Luca, Fabbro, Vorano, & Lovati, 1994; Fredman, 1975; Laganaro & Overton Venet, 2001; Wender, 1989), especially for expressive language tasks (Sasanuma & Park, 1995). This finding has been replicated in single case studies (Edmonds & Kiran, 2006; Roberts et al., 1997; Watamori & Sasanuma, 1976, 1978) and in group studies (Junqué, Vendrell, & Vendrell-Brucet, 1989; Junqué et al., 1995).

Other studies, however, have found equal improvement in two or more languages following treatment in one language on expressive tasks (Edmonds & Kiran, 2006; Penn, 2003), or equal improvement in receptive language (Sasanuma & Park, 1995), or greater gains in the untreated language (L2) (Roberts, 1992). The participants in two of these studies ($n = 2$ in Sasanuma and Park, and $n = 1$ in Roberts) were 3 months or less post-CVA when treatment began. Therefore, the effects of spontaneous recovery cannot be separated from treatment effects. There are at least two other reports of greater gains in the untreated language (L1) (Durieu, 1969 and Linke, 1979 cited in Paradis, 2004 p. 91). Hinckley (2003) provided roughly equal amounts of therapy in Spanish and English, but found greater gains in Spanish, the patient’s first-learned and stronger language. Kohnert (2004) provided very brief treatment in Spanish, then in English, to a patient and found that while both languages improved, the between-language generalization and the maintenance of gains were both greater for cognate words than for non-cognate words in a patient approximately 15 months post-CVA. Given that only four treatment sessions were given, these results should be interpreted very cautiously.

Some authors have interpreted a lack of generalization from one language to another as support for the view that the two languages are stored in separate systems. However, we know that some unilingual patients do not generalize from treated to untreated stimuli. This does not mean that the two sets of stimuli are stored in “different systems.” Nor does it mean that the two languages are processed in different areas of the brain. As we learn more about within-language generalization, we will be better able to interpret between-language generalization, and vice versa.

Roberts and Kiran (2007) point out a recurring flaw in the body of studies of treatment effects. Patients are often identified as having different patterns of bilingualism (e.g., late vs. early acquisition; or fairly equal proficiency vs. one-language dominant). If their response to treatment is different,

TABLE 9-1

Studies of Bilingual Aphasia Treatment Greater Gains in Treated Language or Gains Associated in Time with Language of Treatment

Authors, Date	<i>n</i> and Age, Education; Time Post-onset	Languages Known and Ages Learned or First Exposure	Information on Language of Birth	Focus/Method of Treatment	Design	Dependent Variable(s)	Length and Frequency of Treatment/ Previous Treatment	Results
Roberts, de la Riva, & Rhéaume, 1997	<i>n</i> = 1, 46 years old; MA linguistics; 4 years post- CVA	French L1, English L2 by age 8; constant use of both from age 5 or 6 onward	Slightly stronger French in all 4 modalities, by self-report	Anomia; Howard 1985 phonol cues	Treatment in French only; multiple baselines	% correct on 3 sets of 10 words; also BAT, BDAE French and English	3 times per week; total of 12 sessions; no treatment for past 2 years	For treatment stimuli: strong gains in TL; equal and limited generalization to UL and to other stimuli in TL; little change in standard tests
Watanori & Sasanuma, 1976	<i>n</i> = 1; 65 years old; 1 university degree, plus additional studies; approx. 3 months post-CVA	Japanese L1, English L2 from early childhood	"used with equal proficiency" but no rating reported	Treatment in English only (after 2-week trial in Japanese); stimulation method	Pretest-posttest	Scores on MTDDA and modified PICA	Approx. 1 year	Approx. equal gains in TL and UL for auditory comp. and reading; greater gains in TL (English) on verbal and written expression
Laganaro & Overton Venet, 2001	<i>n</i> = 1, 50 years old; university, including unspecified post-grad studies; engineer; 8 months post-gunshot wound	Spanish L1, English L2, French L3— not listed but deduced	None	Alexia; computer ex on spelling, lexical decision, categorization, rhymes, word- building	Alternating treatment design; alternating blocks in Spanish and English	% correct and speed on lexical decision and reading tasks devised for this patient. No formal tests.	Once per week with daily home practice of approx. 1 hr; 8 weeks of treatment	Gains in both Ls, with slight advantage for TL in most blocks of 2 weeks

(continued)

TABLE 9-1

Studies of Bilingual Aphasia Treatment Greater Gains in Treated Language or Gains Associated in Time with Language of Treatment (Continued)

Authors, Date	n and Age, Education; Time Post-onset	Languages Known and Ages Learned or First Exposure	Information on Language of Birth	Focus/Method of Treatment	Design	Dependent Variable(s)	Length and Frequency of Treatment/ Previous Treatment	Results
Galvez & Hinckley, 2003	n = 1; 71 years old; 6 months post-R CVA	Spanish L1, English L2, age at first exposure unknown	Very incomplete LOB info; born in unnamed country outside U.S.; overall self- rating "equally proficient"	Semantic treatment for anomia	Treatment in Spanish only until reached 80% on treatment stimuli; then English treatment	BAT Spanish and English	Unknown frequency and unknown no. of sessions — No info on previous or simultaneous treatment	Spanish naming and English naming improved after Spanish treatment; no other scores reported; at end of study, BAT in both Ls improved scores
Gains Do Not Match Pattern of Treatment								
Hinckley, 2003	n = 1; Age not given; "highly educated"; 4 months post-CVA	Spanish L1, English L2, learned "as a teenager"	none	anomia	Alternating treatment design; L changed every session; equal time on each language	BAT; PALPA	7 weeks; frequency not stated; semantic and phonemic cues and repetition; recent or simultaneous treatment unknown	No scores given for pre/post naming task; gains on BAT and PALPA much greater in Spanish than English
Penn & Beecham, 1992 (same patient)	n = 1; 38 years old; 19 years school; lawyer; 9 months after his 2nd CVA (prior CVA 3 years previously)	Ndebele L1; Pedi L1 or L2; Afri- kaans, English, Zulu; and 5 others; age of first exposure not given; Ndebele earliest; English at school	Best Ls Ndebele and Pedi; 3rd best Zulu; most-used Afrikaans; English 6th best; no modality-s pecific ratings	Discourse structure	Treatment in English only; pretest- posttest	Score on Profile of Communi- cative Appro- priateness; qualitative analysis of discourse; rate of speech	9 sessions in 14 weeks; no info provided on previous treatment	Scores not given; description of improvement in all Ls spoken and better organized and more appropriate discourse

Mixed Results

Galvez & Hinckley, 2003	$n = 1$; 71 yrs old; 6 mo post-onset	Spanish L1; English L2 w/ "little exposure" to English up to age 18	"Equally proficient" by self-report; no breakdown by modality	Anomia skill-based tx, semantic and phonemic cues	"Multiple-baseline across behaviors"; tx in Spanish up to 80% criterion, then in English	Scores on target stimuli not provided; score on short BAT, naming and other modalities	Unknown Recent or simult. tx: unknown	Unclear; text contradicts figures in Table 1; both languages treated; both improved approx. equally
Edmonds & Kiran, 2006	$n = 3$; 53, 53, and 56 years old; 8 to 9 months post-CVA; 10 or 12 years education	P1: L1 Spanish, L2 English starting at age 21; P2 and P3: both Ls from birth	P1: slightly better in Spanish; P2 and P3: stronger in English	Semantic feature analysis treatment for anomia	Train each list of 10 to criterion level; "multiple baseline across participants and behaviors"	Scores on target stimuli, related and unrelated words; WAB, BNT, PALPA, BAT	13 to +40 sessions; no info provided on previous treatment	Varying levels of progress and generalization within and between languages

Key: TL = treated language; UL = untreated language.

most authors conclude that their different bilingualism levels are the cause of the observed differences. Given the variable (and still unpredictable) patterns of response to treatment, and given that some unilingual patients fail to generalize gains to untreated stimuli and/or modalities, this leap of logic is surprisingly naïve. Roberts and Kiran (2007) identify other methodologic flaws or challenges all authors (and clinicians) face in trying to devise bilingual aphasia treatment and understand its results. They propose a number of concrete solutions to meet these challenges. We need better-designed studies and more complete descriptions of patients (see also Roberts, Code, & McNeil, 2003), especially their language background. Authors and readers need to be much more cautious in how they interpret results. Some unilingual adults with aphasia generalize treatment gains to untreated stimuli and/or modalities, while others do not. So, when a bilingual patient either generalizes or fails to generalize gains, we should not be too quick to assume that the explanation for the results must be the patient's bilingualism.

Treatment

Treatment Methods

The studies just cited show that a general stimulation approach can be used in bilingual patients who speak English and Japanese (Watanabe & Sasanuma, 1976, 1978) and Japanese and Korean (Sasanuma & Park, 1995). Howard's phonemic cueing technique was used with a French-English bilingual patient with chronic aphasia (Roberts et al., 1997). Other studies give little information about the treatment method (de Luca et al., 1994; Junqué et al., 1989; Junqué et al., 1995) or describe activities or examples of types of tasks (Fredman, 1975; Wender, 1989).

Other sources, however, show that a number of aphasia treatment methods have been used in a range of different languages. These include PACE therapy (Carlomagno, 1994; Sasanuma, 1993), Melodic Intonation Therapy (Belin, Van Eeckhout, Zilbovicius, & Remy, 1996; Van Eeckhout, Pillon, Signoret, Deloche, & Seron, 1992; Visch-Brink, van Harskamp, Van Amerongen, Wielaert, & van de Sandt-Koenderman, 1993). Examples of cognitive neuropsychological approaches, cueing techniques, and Blissymbols in a range of languages can be found in sources specifically highlighting international work (e.g., Holland & Forbes, 1993), but also scattered throughout the published aphasia-treatment literature.

In adapting a technique developed in one language for use in another, the specific characteristics of each language must be borne in mind. Some cues that have great value in one language, such as word order in English, may have little value in another. Also, cues that are not possible in English may be important to use in other languages. The gender of

nouns in Spanish, for example, to assist word retrieval, or the auxiliary used to conjugate verbs in French or Italian. In some languages, rehabilitation strategies unique to that language must be developed, as for kana/kanji reading and writing in Japanese (see Sasanuma, 1993).

Another possible pitfall in adapting therapy techniques is establishing appropriate hierarchies of difficulty for tasks and stimuli. The syntactic difficulty of different sentence types must be determined in a language-specific context. In choosing stimuli, based on word frequency, cultural variations can be important. Also, controlling for cognate words in a naming or other lexical task is important for some language pairs (see earlier section). A task may be easier if it involves cognate words than if there are no cognates, at least for some patients (Ferrand & Humphreys, 1996; Kohnert, 2004; Roberts & Deslauriers, 1999; Stadie et al., 1995). Word-frequency lists are of unknown validity for bilingual speakers, as are age-of-acquisition norms, for reasons outlined above. This means that the selection of stimuli and assessment of task difficulty for each patient will depend to a great extent on the clinician's ability to observe patterns, and experiment with various dimensions of a task to adjust its difficulty on a patient-by-patient basis.

The fact that a treatment approach has been used with speakers of different languages does not guarantee that it is appropriate for bilingual speakers of two of those languages. Studies are needed. Until these studies are done, unilingual-treatment studies offer some guidelines about changes needed to adapt a method from one language to another. They also demonstrate that the principles the method is based on can apply to both languages. A high level of linguistic competence is needed to adapt most treatment strategies into different languages.

Setting Goals in Treatment

The principles for unilingual treatment apply also to bilinguals: goals should be realistic, meaningful to the patient, and tailored to the individual patient's deficits. The factors relevant in unilingual work apply to bilinguals. Some additional factors must be considered, however.

Realistic goals are based on the patient's pre- and post-morbid proficiency and patterns of use. Improving a patient's L2 or reversing the attrition that has occurred in a little-used L1 are not part of our clinical mandate. Given how little is known about prognosis in bilinguals, our goals must be even more modest, and our comments to the family about prognosis more guarded than for unilinguals. As the recovery progresses, as the treatment brings changes or fails to bring changes in targeted aspects of communication, our goals will change, and our prognosis along with them.

The patient's need for each language in various situations is a key factor in setting goals. Even when therapy is carried out in both languages, this does not mean that all tasks

should be. For example, if the patient used only one language for reading, the treatment goals should reflect this.

In tailoring treatment goals to the patient's deficits, processing and self-cueing strategies are important factors. These often reflect the interaction of the two languages. Some bilinguals use processing strategies from one language to interpret the other (Heredia & Altarriba, 2002). An L1 English speaker may rely on word order as a cue for thematic roles when processing sentences in L2, even when L2 does not use word order to mark them (Liu, Bates, & Li, 1992, for example). It is important for the clinician to consider factors from both languages, and the possible interaction of languages, in interpreting error patterns.

In overcoming word-retrieval problems, there are strategies that are unique to bilinguals. First, when unable to say what he wants to in one language, the patient may simply switch to his other language. This is an obvious and appropriate strategy, if the listener is bilingual. Some patients use it spontaneously. For others, explicit teaching may be needed. If the listener has even some grasp of this other language, the message may be understood, or enough of it to move the exchange along. In language pairs with cognates, saying or writing a cognate word in one language will often allow even a unilingual speaker of the other language to understand the word. This switching behavior when talking to a bilingual listener has been documented in patients with aphasia (Marty & Grosjean, 1998; Springer, Miller, & Bürk, 1998), and is seen daily in clinical settings.

A second strategy that bilinguals use spontaneously is producing a word from one language to self-cue its retrieval from another (Roberts & Deslauriers, 1999; Roberts et al., 2002). This can be encouraged or explicitly taught if it is an effective strategy for the patient and not pathological or uncontrolled switching (see Grosjean, 1984).

Choice of Language(s) of Treatment

Regardless of the treatment goals and methods, the languages used in treatment should reflect premorbid use and proficiency. Although anecdotal reports suggest that treatment in more than one language is harmful (e.g., Chlenov, 1948; Wald, 1958, 1961 cited in Paradis, 1993b; Paradis, 2004), there is no recent, controlled study on this issue. Case studies in which treatment has been offered in two or more languages, with positive outcomes (e.g., Edmonds & Kiran, 2006; Hinckley, 2003), provide support for clinical impressions that most patients can keep their languages separate and that, if they regularly use more than one language in their daily lives, they benefit from treatment that targets these languages. The only exceptions to this are the rare cases that display a blended pattern of impairment. For these patients, treatment may need to be restricted to one language. For most patients, in light of the research showing that the two languages interact, and that bilinguals regularly

use their languages as a whole system, with both languages always active to some degree, there is little support for limiting treatment to one language. Clinical experience shows that most patients can work in one of three ways:

1. Working on one language with the clinician, and the other language at home or with a volunteer. This may be the only way to work with a language the clinician does not speak.
2. Alternating languages. This involves a block of sessions in one language, followed by a block in the other. Each block can be a certain number of consecutive sessions or can be measured in weeks, with regular probes to see whether treatment gains in one language are generalizing to the other language(s).
3. Separate the languages by modality, reflecting the patient's premorbid patterns of use. For example, work on writing in one language and auditory comprehension in both languages.

In the rare cases where a patient "loses" a language they used extensively, they may want to work on this language but be unable to. Clinical experience suggests that it is pointless to attempt to work in a language until the patient can access it fairly consistently. Work in the other language(s), provide passive exposure to the "lost" language, and probe it regularly to see if it reappears. When and if it does, the balance of languages in treatment can be adjusted to include this language. The case described by Roberts (1998) illustrates this approach.

The questions of what pattern of languages to use in treatment and of generalization between languages are closely linked. Both are complex and both require study. To the extent that treatment generalizes from one language to another, treatment in only one language may be ethically appropriate. However, when generalization does not occur, treatment may be necessary in both languages needed by the patient.

FUTURE TRENDS

It seems safe to predict that interest in bilingual aphasia will continue to grow as more clinicians and researchers recognize its importance. There has been a surge of interest in bilingual/multilingual language processing in nonimpaired speakers. The findings from these studies of language-localization and word and sentence processing are shedding light on the psycholinguistics of bilingualism. Models of bilingual language processing, an arcane and very tiny field 10 years ago, are the focus of considerable interest and are being revised in light of these new experimental results. Logically, studies of speakers with aphasia can contribute to our understanding of multilingual language processing, although this line of research remains relatively undeveloped.

Aphasia-treatment studies will continue to grow in both number and sophistication, using designs that are now common in the unilingual aphasia-treatment literature. For these

studies of treatment to coalesce into a body of knowledge that can be interpreted and applied to clinical practice, it is vital that authors and reviewers insist on greater consistency across studies in how patients are described. Authors and readers must also learn to be more cautious in drawing conclusions from studies with small numbers of patients.

The most uncertain area may be assessment. Existing tests need to undergo thoughtful, objective review according to established psychometric standards; their suitability for use with bilingual speakers must be explored. It means very little to say that a patient scored 12 in Spanish and 14 in English if we do not know whether the Spanish and English tests are all of equal difficulty and if we do not know what the normal range of variability might be for retesting a single patient using the same tests or task.

Other future trends will depend, in part, on how we meet the challenges inherent in studying CLD patients. The first challenge is objectivity. We must be open to results that contradict our own, or society's, expectations about a particular group. Test performance and treatment outcomes for some CLD patients may be better than for other patients, or worse, or there may be no difference beyond minor sampling differences. As the calls for more focus on CLD issues are answered by studies with hard data, we must interpret this data objectively. We must give equal weight to the similarities across groups as well as to the differences. We must be very cautious in saying why a result was obtained.

The second challenge is experimental rigor. Factors related to bilingualism and culture are difficult to control in studies already complex because of the many neurologic and linguistic variables related to the aphasia. Given the difficulty in finding patients with similar linguistic, cultural, and neurologic status, collaborative studies (across centers and in different countries) will help ensure adequate sample sizes and representative results. As discussed by Roberts and Kiran (2007), appropriate experimental control and the publication of replications will be essential to allow correct interpretation of the results.

The third challenge is cultural and linguistic competence. With study, and interaction with people of various cultures, clinicians can become culturally aware, and learn to adapt their methods to reduce cultural stumbling blocks on the clinical path. Linguistic competence represents a greater challenge. A significant challenge for the profession is to recruit and train people who meet the required standards.

The final challenge is time. A bilingual patient takes more time than a unilingual one. Finding, adapting, or developing tests and treatment material, finding and training interpreters, and testing in two languages instead of one are among the factors that take more time. Working in two languages in treatment also adds to the time required, especially for cases in which the gains in one language do not generalize to the other and the patient needs to regain use of both languages. Given the increased interest in CLD issues, we may hope to

see experimental support for specific treatment methods, and more tests to support our clinical work. However, without adequate time, these positive developments will not benefit the patients. Clinicians in many settings are subject to limits in the number of sessions they may provide, or the length of stay the patient is allowed. These constraints and pressures to see more patients in shorter times will make it increasingly difficult to give bilingual patients the care they need. Research documenting the best methods and their impact will support our efforts to obtain essential services for CLD patients.

KEY POINTS

Clinicians who work with CLD patients should read as widely as possible in the literature on culture and on bilingualism. Among the points that are clinically important are the following:

1. Language and culture are closely tied.
2. It is important to consider the possible influence of cultural factors on clinical work, using the patient's background to suggest factors that may be relevant, and interpreting behavior within the appropriate cultural context. It is equally important to avoid cultural stereotypes and assumptions. Each client is a unique individual from a specific microculture, within a macroculture.
3. Bilingualism is a continuum, with different levels of ability for different linguistic tasks and different domains of use. Bilingual abilities change over time with patterns of use or disuse.
4. A bilingual person is a unique speaker-hearer, with abilities in each language that often reflect the influence of the other.
5. The languages of a bilingual are (usually) stored in the left hemisphere, as they are for unilinguals, in largely but perhaps not completely overlapping cortical and subcortical regions.
6. Lexical items are connected across languages, with between-language facilitation and interference both occurring in neurologically intact adults. Cognates appear more closely linked than non-cognates. These between-language factors should be considered in interpreting aphasic error patterns and in planning treatment.
7. It can be difficult to assess bilingual patients for many reasons, including availability of tests, local norms, the need for interpreters, and a lack of data on individual test-retest reliability on aphasia tests.
8. Interpretation of test results should be done in light of the patient's premorbid level of bilingualism, dialect(s), patterns of use, and the features and unique symptom hierarchy of each language tested.

9. Five patterns of impairment and five patterns of recovery have been identified, with parallel patterns believed to be the most common.
10. A number of treatment principles and methods have been successfully used with a range of languages. However, we need much more research into treatment methods for bilingual patients with aphasia and into cross-language generalization.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Review the definitions for: bilingualism; domains of use; microculture; level of bilingualism; parallel recovery; differential recovery; types of impairment vs. types of recovery.
2. Can you think of two domains of use for language that are not listed in this chapter?
3. a) Estimate your own level of bilingualism in each of the four language modalities on a scale of 1 to 7.
b) Then ask someone else to rate your proficiency in each of the modalities. Are the ratings the same?
c) Explore the reasons for each rating with the person rating you.
4. Why is bilingualism so difficult to define?
5. Assessment: obtain a copy of the Multilingual Aphasia Examination, the Bilingual Aphasia Test, or the Aachen Aphasia Test.
a) Compare the sections and number of items per test with the Boston Diagnostic Aphasia Examination or the Western Aphasia Battery. Compare the ease of scoring and the instructions given for administering and scoring the test. How important are the ease of scoring and clarity of the recording forms?
b) Prepare a short paper or a presentation for your class/rehabilitation team/continuing-education discussion group about what makes a good aphasia test, and how close each test you have examined comes to meeting the standards. It may be helpful to obtain a chapter on how to assess the quality of a test; psychology textbooks and research-methods textbooks (e.g., Kazdin's *Research Design in Clinical Psychology*) often contain succinct overviews of the criteria an ideal test would meet (validity, reliability, sensitivity, etc.)
6. Do you think it will be possible to develop a valid and reliable test for naming abilities in bilingual speakers? Pick a specific type of speaker that you often see or that is common in your country or city to help you imagine the kinds of challenges that might arise. How would you go about developing such a test?
7. Imagine you want to present treatment results for your next bilingual patient at clinical rounds or a small conference. What testing or tasks would you need to add to your usual clinical procedures to be able to do this? These might include obtaining a baseline for one of the behaviors you will work on in therapy by testing two or three times instead of just once before starting treatment; recording treatment sessions (video and/or audio) so you can rescore the patient's answers; retesting the patient on the same stimuli used during the pretherapy baseline tasks. How will you measure generalization between languages?
8. What do you think is the biggest challenge in improving service to bilingual adults with aphasia in your city/region/country? Suggest specific strategies to meet this challenge.
9. Identify three small, practical steps that you, your university, or your treatment center could take to improve service for bilingual patients with aphasia. Discuss the feasibility of implementing each of these steps.

Life-Participation Approach to Aphasia: A Statement of Values for the Future

LPAA Project Group (in alphabetical order): Roberta Chapey, Judith F. Duchan, Roberta J. Elman, Linda J. Garcia, Aura Kagan, Jon G. Lyon, and Nina Simmons-Mackie

Unprecedented changes are occurring in the way treatment for aphasia is viewed—and reimbursed. These changes, resulting from both internal and external pressures, are influencing how speech-language pathologists carry out their jobs.

Internal influences include a growing interest in treatments that produce meaningful real life outcomes leading to enhanced quality of life. Externally, we are influenced by disability rights activists encouraging adjustments in philosophy and treatment and by consumers frustrated by unmet needs and unfulfilled goals. Most recently, a strong external influence is emanating from the curtailment of funding for our work, which has caused a significant reduction in available services to people affected by aphasia.

To accommodate these varied influences on service delivery, it is important to take a proactive stance. We therefore propose a philosophy of service delivery that meets the needs of people affected by aphasia and confronts the pressures from our profession, providers, and funding sources. Our statement of values has been guided by the ideas and work of speech-language pathologists as well as by individuals in psychology, sociology, and medicine (see the ASHA Web site, www.asha.org/public/speech/disorders/LPAA.htm, for a detailed reference list). We intend neither to prescribe exact methods for achieving specific outcomes, nor to provide a quick fix to the challenges facing our profession. Rather, we offer a statement of values and ideas relevant to assessment, intervention, policy making, advocacy, and research that we hope will stimulate discussion related to restructuring of services and lead to innovative clinical methods for supporting those affected by aphasia.

DEFINING THE APPROACH

The “Life Participation Approach to Aphasia” (LPAA) is a consumer-driven service delivery approach that supports individuals with aphasia and others affected by it in achieving their immediate and long term life goals (note that “approach” refers here to a general philosophy and model of service delivery, rather than to a specific clinical approach). LPAA calls for a broadening and refocusing of clinical practice and research on the consequences of aphasia. It focuses on reengagement in life, beginning with initial assessment and intervention, and continuing, after hospital discharge, until the consumer no longer elects to have communication support.

LPAA places the life concerns of those affected by aphasia at the center of all decision making. It empowers the consumer to select and participate in the recovery process and to collaborate on the design of interventions that aim for a more rapid return to active life. These interventions thus have the potential to reduce the consequences of disease and injury that contribute to long-term health-care costs.

THE ESSENCE OF LPAA

We encourage clinicians and researchers to focus on the real-life goals of people affected by aphasia. For example, in the initial stages following a CVA, a goal may be to establish effective communication with the surrounding nursing staff and physicians. At a later stage, a life goal may be to return to employment or participation in the local community. Regardless of the stage of management, LPAA emphasizes the attainment of reengagement in life by strengthening daily participation in activities of choice.

Residual skill is thus seen as only one of many requisites. For example, full participation depends on motivation and a consistent and dependable support system. A highly supportive environment can lessen the consequences of aphasia on one’s life, whatever the language impairment. A nonsupportive environment, on the other hand, can substantially increase the chance of aphasia affecting daily routines. Someone with mild aphasia in a nonsupportive environment

TABLE 10-1

Examples of the Shift in Focus of Life-Participation Approach to Aphasia

LPAA	Examples of Shift in Focus
Assessment includes determining relevant life participation needs and discovering clients' competencies	In addition to assessing language and communication deficits, clinicians are equally interested in assessing how the person with aphasia does <i>with support</i>
Treatment includes facilitating the achievement of life goals	In addition to work on improving and/or compensating for the language impairment, clinicians are prepared to work on anything in which aphasia is a barrier to life participation (even if the activity is not directly related to communication)
Intervention routinely targets environmental factors outside of the individual	In addition to working with the individual on language or compensatory functional-communication techniques, clinicians might train communication partners or work on other ways of reducing barriers to make the environment more "aphasia-friendly"
All those affected by aphasia are regarded as legitimate targets for intervention	In addition to working with the individual who has aphasia, clinicians would also work on life-participation goals for family and others who are affected by the aphasia, including friends, service providers, work colleagues, etc.
Clinician roles are expanded beyond those of teacher or therapist	In addition to doing therapy, clinicians might take on the role of: • "communication partner," and give the person with aphasia the opportunity to engage in conversation about life goals, concerns about the future, barriers to life participation, etc. • "coach," "problem solver," or "support person" in relation to overcoming challenges in reengaging in a particular life activity
Outcome evaluation involves routinely documenting quality of life and life participation changes	In addition to documenting changes in language and communication, clinicians would routinely evaluate the following in partnership with clients: • life activities and how satisfying they are • social connections and how satisfying they are • emotional well-being

might experience greater daily encumbrances than another with severe aphasia who is highly supported.

In this broadening and refocusing of services, LPAA recommends that clinicians and researchers consider the dual function of communication: transmitting and receiving messages and establishing and maintaining social links. Furthermore, life activities do not need to be in the realm of communication to deserve or receive intervention. What is important is to judge whether aphasia affects the execution of activities of choice and one's involvement in them (see Table 10-1 (www.asha.org/public/speech/disorders/LPAA.htm) for a few examples of how LPAA may lead to a broadening and refocusing of services).

THE ORIGINS OF LPAA

Functional and Pragmatic Approaches

LPAA draws on ideas underlying functional and pragmatic approaches to aphasia and shares some common values with

those who take a broad approach to functional communication treatment by focusing on life-participation goals and social relationships. In our view, however, the term "functional" does not do justice to the breadth of this work. In addition, the term is often used narrowly to mean "functional independence in getting a message across." Although LPAA recognizes the value of this type of impairment-level work, it should form part of a bigger picture where the ultimate goal for intervention is reengagement into everyday society.

Human Rights Issues and Consumers' Goals

LPAA is a means of addressing the unmet needs and rights of individuals with aphasia and those in their environment. Indeed, the Americans with Disabilities Act (ADA), signed into law on July 26, 1990, requires that physical and communication access be provided for individuals with aphasia and other disabilities and allows them legal recourse if they are blocked from accessing employment, programs, or services in the public and private sectors.

In 1992, ASHA provided guidelines for a “communication bill of rights” (National Joint Committee for the Communicative Needs of Persons with Severe Disabilities). Its preface states that “all persons, regardless of the extent or severity of their disabilities, have a basic right to affect, through communication, the conditions of their own existence.” Communication is defined as “a basic need and basic right of all human beings” (p. 2). ASHA thus views communication as an integral part of life participation.

Emphasis on Competence and Inclusion

LPAA philosophy embraces a view of treatment that emphasizes competence and inclusion in daily life, focusing as much on the consequences of chronic disorders as on the language difficulty caused by the aphasia. Along with other movements in education and health care, LPAA shifts from a focus on deficits and remediation to one of inclusion and life participation (see Fougereyrollas et al., 1997; WHO, 1997). Such international changes in focus point to the need to address the personal experience of disability and promote optimal life-inclusion and reintegration into society.

Changes in Reimbursement and Service Delivery

Health care and its reimbursement system have undergone an unprecedented overhaul in America. Financial exigencies have led to an emphasis on medically essential treatments and others seen as likely to save on future health care costs. Many of the incentives in this model result in the provision of efficient short-term minimal care, rather than the longer term, fuller care supported in the past.

LPAA represents a fundamental shift in how we view service delivery for people confronting aphasia. Since LPAA focuses on broader life-related processes and outcomes starting from the onset of treatment, service delivery and its reimbursement will require novel means that stand outside most current practices. We are confident that cost-sensitive and therapeutically effective models are possible. Our purpose in this introductory article is to prompt a discussion with providers and consumers as to whether life participation principles and values should play a more central role in the delivery and reimbursement of future service delivery for all those affected by aphasia.

THE CORE VALUES OF LPAA

LPAA is structured around five core values that serve as guides to assessment, intervention, and research.

The Explicit Goal Is Enhancement of Life Participation

In the LPAA approach, the first focus of the client, clinician, and policy-maker is to assess the extent to which persons

affected by aphasia are able to achieve life participation goals, and the extent to which the aphasia hinders the attainment of these desired outcomes. The second focus is to improve short- and long-term participation in life.

All Those Affected by Aphasia Are Entitled to Service

LPAA supports all those affected directly by aphasia, including immediate family and close associates of the adult with aphasia. The LPAA approach holds that it is essential to build protected communities within society where persons with aphasia are able not only to participate but are valued as participants. Therefore, intervention may involve changing broader social systems to make them more accessible to those affected by aphasia.

The Measures of Success Include Documented Life-Enhancement Changes

The LPAA approach calls for the use of outcome measures that assess quality of life and the degree to which those affected by aphasia meet their life participation goals. Without a cause to communicate, we believe, there is no practical need for communication. Therefore, treatment focuses on a reason to communicate as much as on communication repair. In so doing, treatment attends to each consumer’s feelings, relationships, and activities in life.

Both Personal and Environmental Factors Are Targets of Intervention

Disruption of daily life for individuals affected by aphasia (including those who do not have aphasia themselves) is evident on two levels: personal (internal) and environmental (external). Intervention consists of constantly assessing, weighing, and prioritizing which personal and environmental factors should be targets of intervention and how best to provide freer, easier, and more autonomous access to activities and social connections of choice. This does not mean that treatment comprises only life resumption processes, but rather that enhanced participation in life “governs” management from its inception. In this fundamental way, the LPAA approach differs from one in which life enhancement is targeted only after language repair has been addressed.

Emphasis Is on the Availability of Services as Needed at All Stages of Aphasia

LPAA begins with the onset of aphasia and continues until consumers and providers agree that targeted life enhancement changes have occurred. However, LPAA acknowledges that life consequences of aphasia change over time and should be addressed regardless of the length of time post-onset.

Consumers are therefore permitted to discontinue intervention, and reenter treatment when they believe they need to continue work on a goal or to attain a new life goal.

CONCLUSIONS

Our health-care systems are undergoing change and, as a result, so are our professions. How we allow this change to affect our clinical practice, our research directions, and our response to consumer advocacy is up to us. We need to educate policy-makers that being fiscally responsible means having a consumer-driven model of intervention focusing on interventions that make real-life differences and minimize the consequences of disease and injury.

While it is clear that the implicit motivation underlying all clinical and research efforts in aphasia is related to increased participation in life, the path to achieving that goal is often indirect. Because LPAA makes life goals primary and explicit, it holds promise as an approach in which such goals are attainable. We invite other speech-language pathologists to join us in discussing and developing life participation approaches to aphasia.

Chapter 11

Social Approaches to Aphasia Intervention

Nina Simmons-Mackie

OBJECTIVES

Major strides have been made in the past decade in the development of social approaches to aphasia (Byng & Duchan, 2005; Byng, Pound, & Parr, 2000; Elman, 2005; Elman & Bernstein-Ellis, 1999a, 1999b; Holland, 1999; Kagan, 1998; Kagan, Black, Duchan, Simmons-Mackie, & Square, 2001; LPAA Project Group, 2000; Lyon, 1992, 1996; Parr, 1996; Pound, Parr, Lindsay, & Woolf, 2000; Sarno, 1993a, 2004; Simmons-Mackie, 1993, 1994, 1998a, 1998b, 2000, 2004b; Worrall, 2000b). It is the objective of this chapter to explain the rationale, philosophy, and principles of socially motivated approaches to aphasia and to provide examples of assessment and intervention methods that fit into the social model philosophy.

This chapter will (1) introduce and define a social model of aphasia intervention; (2) describe social approaches and contrast social approaches with traditional restorative and functional approaches; (3) outline the principles of a social approach to intervention; (4) introduce assessment strategies appropriate to a social model of management; and (5) describe intervention objectives and examples that fit within a social approach.

RATIONALE FOR SOCIAL APPROACHES

The goal of a social approach is to promote membership in a communicating society and participation in personally relevant activities for those affected by aphasia. The ultimate aim of a social approach, enhancing the living of life with aphasia, is consistent with the philosophy of “Life-Participation Approaches to Aphasia” (see Chapter 10). The need for a social approach to aphasia management draws from several sources.

First, aphasia is a chronic disorder with long-term consequences beyond the acute disruption of communication. In spite of linguistic gains, many people with aphasia experience

residual communication problems that significantly impact their daily lives. Those affected by aphasia report social isolation, loneliness, loss of autonomy, restricted activities, role changes, and stigmatization (Herrmann, Johannsen-Horback, & Wallesch, 1993; LeDorze & Brassard, 1995; National Aphasia Association, 1988; Parr, 1994; Parr, Byng, Gilpin, & Ireland, 1997; Sarno, 1993a, 1997). In fact, “a frequent tale from people who live with aphasia is of being disengaged from life, excluded from involvement, or allowed in, but only on the periphery” (Pound, 2004, p. 50). Many of these long-term consequences are not addressed by traditional aphasia intervention. Such untreated psychological and social problems can increase disability, diminish community reintegration, and reduce response to rehabilitation (Sandin, Cifu, & Noll, 1994). The cycle of diminished participation in various aspects of life can take a drastic toll on self-confidence and personal identity (Shadden, 2005).

In addition, funding sources have pressed for more “functionally relevant” outcomes and evidence that our services make a difference in the lives of our clients (Frattali, 1996, 1998a; Johnson, 1999). Restructuring in health care has forced us to balance quality outcome with cost of care. Pressure from consumers, desire to improve outcomes, and changes in the health-care industry suggest an urgent need for creative approaches that increase the quality of communicative life for those affected by aphasia. A social model provides a philosophical framework for implementing interventions that fulfill these requirements.

EXPANDING THE MANAGEMENT FOCUS

In traditional aphasia therapy the emphasis has been on improving linguistic or cognitive processing. These restorative therapies have been effective in changing language performance. Such approaches tend to focus on the “impairment” of the individual with aphasia, and rely on formal tests and treatment probes to determine the level of deficit and degree of change after therapy. Certainly, restoration of communicative processes is an important goal for people with aphasia. However, gaps between changes on linguistic measures and “real-life” functional performance of people with aphasia have been noted (Holland, 1998a). Therefore,

functional therapies have been developed to address performance of daily activities and communication “in use” (Frattali, 1998a; Holland, 1982, 1991; Worrall & Frattali, 2000). Functional-skills approaches often focus on the ability to utilize compensatory strategies and perform typical tasks such as using the telephone or making a grocery list. However, the personal experience of aphasia and individual life-style adjustments have rarely been addressed in restorative and skills approaches. For example, in spite of improved linguistic processing and success on “functional” tasks, clients and families continue to report social isolation, loss of confidence, decreased roles, and limited communication opportunities (Parr et al., 1997). Therefore, expansion of functional approaches to encompass quality of life and social participation has been recommended (Frattali, 1998a; Kagan & Gailey, 1993; Worrall, 2000a). A social approach expands intervention to address the living of life with aphasia, including life-style changes and psychosocial issues.

CONTRASTING MEDICAL AND SOCIAL MODELS

The traditional health-care paradigm has been described as a “medical” or “biomedical” model with an explicit focus on management of “illness.” Social models have arisen in an effort to shift the emphasis away from treating the illness to promoting health. The medical model has been the prevailing paradigm in aphasiology (Sarno, 1993b), and the influence of the medical model remains evident in our practices. For example, when the responsibility for “cure” and authority for decision-making is placed with the clinician (i.e., the “expert”), then clinicians tend to dictate goals and control treatment. While professional expertise is needed, the marked power differential can create a passive, dependent “patient” who learns to “take the cure” with little participation in life choices (Pyypponen, 1993). In a social model, clients take an active, participatory role in their own health-care decisions. The focus of rehabilitation shifts towards a “client-centered” perspective that involves maximizing opportunities for informed choices and taking full account of each person’s preferences, needs, and social contexts (Cardol, De Jong, & Ward, 2002).

The medical model is also evident in our terminology. Thus, “patients receive treatment,” as though treatment is a tonic that will cure aphasia (Pyypponen, 1993; Sarno, 1993a, 1993b). When complete recovery is not the result, individuals with residual aphasia face discharge from treatment with little attention to chronic affects (Hersh, 1998). By contrast, the social model requires a long-term view of aphasia. The focus shifts to optimally “living with” aphasia, with the emphasis on health rather than illness (LPAA, 2000; Lyon, 1992; Pound, 1998b).

In a medical model, “problems” tend to be located within the individual. A social model orients away from defining

the problem as situated wholly within the individual. That is, problems result from an interaction between the individual’s organic condition and his or her social and physical environment (World Health Organization, 2001). In a social model disability is a consequence of disabling attitudes and barriers imposed by society, not simply an impairment that resides within the individual. Thus, aphasia is not only a disorder, but also a situation in which opportunities and rights are not readily available. Both internal problems and external barriers must be addressed for optimal return of function and well-being.

ELEMENTS OF A SOCIAL MODEL

The “social” of social model refers to the broad concept that people are members of society and reside within a sociocultural context. As Goodwin (1995) describes, aphasia is more than a lesion within the skull; aphasia is also located outside of the person in dynamic relationships with others and in the social community. Thus, aphasia is addressed as an element of a social system and communication is viewed as a social act. Through communication we express and create our ideas, and also our personalities, our culture, and our life values. Communication fulfills a critical social goal when it allows us to reveal a healthy identity or “create a positive face” (Goffman, 1967). Because of the social significance of communication, disrupted communication entails social meanings and consequences; hence, the importance of a social model.

INTEGRATING PSYCHOSOCIAL AND COMMUNICATION INTERVENTION

When social systems do not support communicative access and participation, psychosocial well-being and quality of life are diminished (Cruice, Worrall, Hickson, & Murison, 2003; Doyle et al., 2004). Participation in various realms of life (e.g., leisure activities, social relationships) is closely tied to positive affective states and subjective well-being (Sveen, Thommessen, Bautz-Holter, Wyller, & Laake, 2004), yet participation in such activities is closely tied to the ability to communicate. Studies report relationships between communication disorders and quality of life or psychological well-being (Cruice et al., 2003; Doyle et al., 2004). For example, negative mood states, restricted social participation, and less life satisfaction are associated with communication disability (Doyle et al., 2004), while communication ability is associated with greater well-being and social functioning (Cruice et al., 2003).

While psychosocial issues associated with aphasia have long been recognized, they have remained on the outskirts of therapy. Traditionally, remediation of psychosocial problems has been divorced from the communication impairment and aphasia therapy. Typically, counseling and education are considered the approaches of choice for psychosocial issues. Yet these services are often unavailable or tangential to the “real”

therapy. In addition, psychosocial problems such as depression and loneliness are sometimes accepted as a natural and expected consequence of aphasia. Finally, an aggressive research emphasis on the linguistic dimensions of aphasia has tended to overshadow psychosocial issues, resulting in neglect of “the person” (Byng et al., 2000; Sarno, 1993a, 1993b).

Attention to the psychosocial dimensions of aphasia is considered an integral part of communication in a social model (Bouchard-Lamothe et al., 1999; Brumfitt, 1993; Lafond, DeGiovani, Joannette, Ponzio, & Sarno, 1993; Müller, 1999; Müller & Code, 1989; Pound et al., 2000; Sarno, 1991; Simmons-Mackie, 1998b, 2000). Psychosocial issues are not separable from communication. Social affiliation and maintaining a healthy identity are major goals of human communication (Tannen, 1984). We craft our utterances and construct our interactions as a social and emotional endeavor. When communicative interactions are successful, we obtain emotional and social rewards. Through communication we obtain membership in a communicating society. This critical aspect of communication cannot be overlooked. Although often artificially separated in the literature, communication and psychosocial issues are woven together into the fabric of human existence. A social model recognizes that those affected by aphasia must fulfill psychosocial needs through communication. In fact, LaPointe (2002) has argued that psychosocial issues and neurolinguistic aspects should be integrated to create a “sociology” of aphasia.

DEFINING APHASIA IN A SOCIAL MODEL

The definition of aphasia is expanded within a social model to reflect more than linguistic or cognitive-processing deficits. Thus, aphasia is an impairment due to brain damage in the formulation and reception of language, often associated with diminished participation in life events and reduced fulfillment of desired social roles. Kagan (1995) defines aphasia as an impairment in communication that masks inherent competence. Byng and colleagues (2000, p. 53) define functional-communication goals in aphasia as “being able to communicate competently, through your own communication skills and those of others and feeling comfortable that you are representing who you are.” By expanding the definition of aphasia we acknowledge that the meaning of aphasia to the person with aphasia and to those around him or her is greater than the linguistic deficit alone. Aphasia is a diagnosis, but also aphasia is a socially constructed way of being that is created through the experiences of the person with aphasia, those around the person, and society (Penn, 2004).

SOCIAL MODEL VERSUS SOCIAL APPROACHES

The phrase “social model” is used in this chapter to refer to a philosophy that guides and frames assessment and

intervention. A social model is not a specific therapy approach or technique; rather, it is a value system adopted by clinicians, organizations or programs that deliver services within this philosophy. Social-model values call for aphasia intervention that promotes meaningful life changes and outcomes that are viewed relative to the individual’s preferred roles and responsibilities within society. Furthermore, intervention is considered part of the individual’s social context. Thus, the intervention experience and therapy interactions promote healthy identity and social integration. Social-model values invite people with aphasia and their families to share control and decision-making with clinicians, and treatment reflects client-centered values and practices (Byng & Duchan, 2005).

The “social model” has often been viewed as an alternative to impairment-focused treatment (Duchan, 2001). In fact, a social-model philosophy provides a framework within which any treatment approach might be employed. Intervention within a social model is determined more by the values and beliefs of therapists and organizations than by the actual “activities” carried out in therapy (Byng & Duchan, 2005). For example, conversational group therapy is touted as an approach that fits within social approaches to aphasia. However, an authoritarian clinician who sets all goals, controls therapy decisions, rationes turns, and evaluates productions is not functioning within a social model philosophy.

While this chapter helps to define a social model, the specific methods and techniques described will constitute “social approaches” practiced within a social model philosophy. Social approaches focus specifically on social participation, psychosocial well-being, and life contexts. Social approaches to aphasia intervention have appeared under general labels such as social model approaches, consequences therapy (e.g., addressing the consequences of aphasia) (Holland, 2005, personal communication), life participation approaches (LPAA, 2000), or functional communication approaches (Worrall, 2000b). Within the general umbrella of social approaches are a wide range of therapies that address living life with aphasia.

PRINCIPLES OF A SOCIAL APPROACH

A social approach to aphasia management can best be conceptualized through a set of basic principles. Management is designed to (1) address both information exchange and social needs as dual goals of communication; (2) address communication within authentic, relevant, and natural contexts; (3) view communication as dynamic, flexible, and multidimensional; (4) focus on the collaborative nature of communication; (5) focus on natural interaction, particularly conversation; (6) focus on personal and social consequences of aphasia; (7) focus on adaptations to impairment; (8) embrace the perspective of those affected by aphasia; and (9) encourage qualitative as well as quantitative measures.

Dual Goals of Transaction and Interaction

Communication is designed to meet two primary goals: the exchange of information (transaction) and the fulfillment of social needs (interaction) (Simmons, 1993; Simmons-Mackie & Damico, 1995). In traditional aphasia therapy clinicians have focused on the transactional aspects of communication. For example, functional therapies have been designed to promote message exchange and to get ideas across in whatever way possible (Davis & Wilcox, 1985). Social goals of communication have been largely ignored. While certainly the exchange of messages is important, the social goals are equally, if not more, important. Through communication we not only exchange information, but also develop and maintain an identity and sense of self, fulfill emotional needs, provide connections with other people, and promote our membership in groups. Appreciation of the social goals of communication is critical to fully addressing the consequences of aphasia.

Address Communication within an Authentic Context

Communicative change must make a difference in personally relevant contexts of those affected by aphasia. Much traditional aphasia therapy and most formal aphasia tests are conducted in relatively controlled contexts and focus on decontextualized tasks and discrete elements of language (e.g., naming, sentence completion). By contrast, natural communication occurs in a complex, dynamic social context with shifting expectancies, social roles, and goals. When communication is stripped of its natural context, we get a skewed appreciation of a person's communicative life. A full appreciation of communication within natural, personally relevant contexts is imperative to ensuring effective therapy outcomes. "Authentic contexts" are at the forefront of decision-making, assessment, and intervention in a social approach.

Communication as Dynamic, Flexible, and Multidimensional

Aphasiologists have evaluated communication in terms of "idealized" normal language. We assess "deficits" based on expectations of how a standard speaker would perform. While this helps determine an objective skill level, it potentially deludes us into viewing communication as invariant and static. In reality, informal communication includes dysfluencies, word errors, revisions, and sentence fragments (Button & Lee, 1987; Shiffrin, 1987). The following is a transcription of a question asked to a presenter at an aphasia conference: "So is this like one of the uh uh one of those that we've seen before . . . at least I have . . . and how can we be sure to make the uh uh ree uh make the shift?" No one seemed disturbed by this question proffered by a well-respected aphasiologist; yet, according to traditional standards the production would not be considered normal. In fact, such deviations are typical

of the informal discourse of standard speakers. It is important that clinicians fully appreciate the flexibility and creativity of language in use. Many devices that deviate from "idealized language norms" are used in natural conversation to meet communicative goals. Tannen (1984) examines the use of interruptions and joint talk in standard conversation as a means of achieving affiliation in certain cultural groups. Utterances such as "oh," "well," and "you know" are used to bracket information and manage the flow of discourse (Shiffrin, 1987; Simmons-Mackie & Damico, 1996b). Goodwin (1987) describes purposeful "forgetfulness" as a strategy used by couples to bring a spouse into a conversation. Thus, strategies are often used to serve a goal beyond the accurate and grammatical production of language. Perhaps in the practice of aphasia assessment and intervention, a more open-minded view of behavior and an appreciation of situated pragmatics are needed (Duchan, 1997; Simmons, 1993). Social approaches assume the flexibility and creativity of communication, and social goals are taken into account when assessing communication.

Communication Is Collaborative

In a social approach the focus is shifted away from the individual with aphasia and onto the collaborative nature of communication (Simmons, 1993). Conversation is a co-constructed activity in which participants negotiate important social actions and work to help each other understand with as little effort as possible (Clark & Wilkes-Gibbs, 1986; Milroy & Perkins, 1992). Research repeatedly affirms that communication is a collaborative achievement (Goodwin, 1995, 2003; Hengst, 2003; Hengst, Frame, Neuman-Stritzel, & Gannaway, 2005; Klippi, 1996; Oelschlaeger & Damico, 1998a, 1998b; Simmons-Mackie, Kingston & Schultz, 2005). Social roles are established and maintained through interactive cooperation (Brumfitt, 1993; Simmons-Mackie & Damico, 1999). Speaking style, content, discourse structure, and even opinions are modified to accommodate to speaking partners and context (Bell, 1984; Giles, Taylor, & Bourhis, 1973). A view of communication as a collaborative achievement requires expanding research and management efforts beyond the individual with aphasia to include the communicative skills of those "around" the person with aphasia and the dynamics of interaction.

Focus on Natural Interaction: Conversation

Conversation in its myriad forms has been labeled the primary site of human communication in our society (Clark & Wilkes-Gibbs, 1986). However, "functional communication" is often defined in terms of very goal-directed, transactional tasks such as cashing a check, asking for directions, or ordering in a restaurant. It is likely that the social chat that surrounds these activities is as important as the task itself.

Therefore, success in and enjoyment of conversational interactions is a potentially important objective in aphasia intervention. Until recently, research rarely focused on natural conversation in aphasia, assessment rarely included a sample of natural conversation, and few intervention approaches directly targeted conversation. Fortunately, research on conversation and other communicative genres in aphasia has grown considerably in the past decade, providing valuable data to aid in focusing on natural interaction and conversation (Goodwin, 2003; Hengst et al., 2005; Oelschlaeger & Damico, 1998a, 1998b).

Focus on Adaptations and Enablement Rather than Impairment and Disability

A social approach involves a positive stance towards life with aphasia. While impairment tends to be the focus of traditional aphasia therapy, successful adaptations to aphasia and ability (rather than disability) are primary in social approaches (LaPointe, 2005). Attention to the prevalence of adaptive strategies used by a person with aphasia can make a difference in our predictions of functional outcomes.

In fact, an overemphasis on deficits might obscure appreciation of adaptive behavior. For example, when asked to describe a client's naming response—"uh uh pen"—clinicians routinely described word-finding problems or processing delays (Simmons-Mackie, 1993). However, the "uh uh" behavior could also be described as a successful floor-holding strategy. When communication is disrupted, nonstandard compensations might be required to meet communicative goals. Successful adaptations are often contrary to what are considered normal or preferred behaviors (Booth & Perkins, 1999). For example, one client with chronic aphasia often bombastically announced "I can't talk" when addressed by strangers. Analysis suggested that he preferred to "powerfully" terminate the interaction rather than expose his communicative "weakness." Thus, to meet his own identity needs, this man chose what some might consider a pragmatically undesirable behavior. What is deemed "appropriate" is judged in terms of the goal of the behavior and available alternatives.

In addition, the adaptive skills and attitudes of speaking partners of people with aphasia will influence the success of interactions. Therefore, emphasis expands beyond the adaptation of the individual with aphasia, to adapting society to enable the person's participation. A considerable literature has arisen that describes characteristics of enabling or disabling physical and social environments (Howe, Worrall, & Hickson, 2004). Social approaches necessitate a focus on aspects of the environment that enable the person with aphasia. In a social approach the clinician focuses on the adaptive purpose of behaviors, builds on existing adaptations, and takes into account social as well as linguistic goals.

Focus on Personal and Social Consequences

As noted, a social model assumes that communication has a critical sociocultural role. Impaired communication can be associated with social consequences, potential social barriers, and resulting psychological issues. Thus, understanding the impact of aphasia on a person's life is as important as consideration of the disorder itself (Cardol et al., 2002). Consequences are judged based on the personal experience of the communication problem, which will undoubtedly vary among those affected by aphasia. Thus, one individual with mild aphasia might experience no life changes while another individual with the same impairment might experience significant life changes and personal loss. Aphasia also creates personal and social consequences for family and friends, who might experience loneliness, stigma, embarrassment, energy depletion, and changed roles.

Consequences not only vary among individuals, but also might vary from one context to another. Thus, using a picture board to convey food choices at home might be quite different from using the aid in a restaurant with an unprepared waitress. In part, the personal experience of aphasia depends on cultural attitudes and knowledge regarding the disability and expected life roles of those affected by aphasia. Addressing the consequences for all those affected by aphasia will help to promote a healthy social system.

The Perspective of Those Affected by Aphasia

It is difficult to address consequences of aphasia without a full appreciation of how those affected "perceive" these consequences. Consumer perspectives and consumer satisfaction are a priority. Rather than simply deciding what a client "needs," intervention is based on consumer perceptions of life changes, barriers to participation, and important life goals. Research confirms that people with aphasia are able to participate in interviews and ratings in order to share their perspectives (Doyle, 2005; Hilari, Wiggins, Roy, Byng, & Smith, 2003; Hoen, Thelander, & Worsley, 1997; Kagan, 1999; LeDorze & Brassard, 1995; Lyon, 1998b; Parr et al., 1997; Simmons-Mackie & Damico, 2001). Personal choice and autonomy are driving factors in management. The focus is broadened from reducing impairment, to building meaning and purpose in life *as perceived by* those affected by aphasia. That is, in a social approach those confronting aphasia chart the direction of intervention in concert with clinicians.

Qualitative as well as Quantitative Measures

In a social approach clinicians access the subjective experience of aphasia and describe outcomes relative to the rich authentic context of daily communicative life. Subjective experience and richly contextualized events call for qualitative as well as quantitative approaches to description. Qualitative approaches such as ethnographic interviews,

personal narratives, and observational assessment provide important insights to drive management plans (Simmons-Mackie & Damico, 2001). Qualitative and descriptive methods are gaining attention as viable additions to research and assessment (Booth & Perkins, 1999; Damico, Simmons-Mackie, Oelschlaeger, Elman, & Armstrong, 1999; Fox, Poulsen, Bawden, & Packard, 2004; Perkins, Crisp, & Walshaw, 1999; Simmons-Mackie & Damico, 1996a, 1999; Sorin-Peters, 2004a).

EFFECTIVENESS OF SOCIAL APPROACHES

Although the social model is a relative newcomer to aphasiology and additional research is needed, a growing data base is accumulating to support the notion that social communication, communication opportunities, and well-being are amenable to intervention. For example, improvements in communication, relationships, and social participation have been documented after including communication partners in treatment (Boles, 1997; Hickey, Bourgeois, & Olswang, 2004; Hopper, Holland, & Rewega, 2002; Kagan et al., 2001; Lyon, 1998b; Lyon et al., 1997; Rayner & Marshall, 2003; Rogers, Alarcon, & Olswang, 1999; Simmons-Mackie, Kearns, & Potechin, 2005). Changes in adjustment, knowledge of aphasia, and functioning were reported among people with aphasia and their families after participating in brief intensive programs offering psychosocial support and education (Fox et al., 2004; Hinckley & Packard, 2001). Improvement in communicative success as well as qualitative changes in knowledge, confidence, and relationships were found by adapting principles of adult learning to working with couples on communicative skills and issues related to living with aphasia (Purdy & Hindenlang, 2005; Sorin-Peters, 2004b). Elman and Bernstein-Ellis (1999a, 1999b) report positive effects of social group therapy for patients with chronic aphasia on both linguistic and psychosocial measures. Integrating psychosocial support and access to social interaction into a community-based program has also been successful (Hoen et al., 1997; Ireland & Wotton, 1996; Kagan, 1999). Reports have begun to surface regarding intervention focusing specifically on enhancing participation in relevant life situations. For example, Lasker, LaPointe, and Kodras (2005) report successful ratings of job performance for a college professor with aphasia after intervention designed to facilitate teaching. The cost-effectiveness of social approaches has been reported since “meaningful” life and/or relationship changes have been effected with relatively few sessions (Lyon, 2004; Sorin-Peters, 2004b). There are also reports of positive effects of approaches that modify external barriers or facilitate participation in activities of choice (Garrett & Beukelman, 1995; Howe et al., 2004; Lyon et al., 1997; Rose, Worrall, & McKenna, 2003; Simmons-Mackie & Damico, 1996a, 2001; Simmons-Mackie et al., 2007). Indirect evidence of the potential

importance of socially oriented goals has come from research demonstrating associations between social relationships or participation and well-being, quality of life, and recovery (Cruice et al., 2003; Doyle, 2005; Hilari & Northcutt, 2006).

GOALS OF INTERVENTION IN A SOCIAL APPROACH

Socially motivated approaches conform to the ultimate goal of Life Participation Approaches to Aphasia—that is, to enhance the living of life with aphasia. To achieve the overall goal of living a satisfying life with aphasia, objectives might include (1) enhancing natural communication; (2) increasing successful participation in authentic events; (3) providing support systems within the speaker’s community; (4) increasing communicative confidence and positive sense-of-self; and (5) promoting advocacy and social action. These objectives serve to guide intervention. Actual goals evolve out of a dialogue through which individuals with aphasia and clinicians negotiate specific outcome targets.

ASSESSMENT WITHIN A SOCIAL MODEL

Assessment in a social model encompasses a variety of tools that document accomplishment within the goal domains outlined above. Traditional measures such as standardized tests remain appropriate to determine the level and pattern of deficits. However, measures of outcome beyond linguistic or cognitive skills are needed to determine whether intervention is making a difference in the lives of those affected by aphasia (Frattali, 1998a, 1998b; Holland & Thompson, 1998). For people with aphasia, making a difference probably means returning to work, enjoying dinner with friends, sharing a good joke, or gossiping over coffee. Thus, assessment is designed to provide insight into well-being, personal consequences, and lifestyle affects of aphasia.

Situating Intervention within a Framework

Various frameworks and models are available to help organize assessment. For example, the World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF) (2001) emphasizes the multiple domains that comprise health, including body structure and function, activities and participation, and contextual factors. Kagan and colleagues (2005; in progress) have adapted and expanded the ICF framework and designed a simple schematic (Living with Aphasia: Framework for Outcome Measurement [A-FROM]) that serves as a guide to situate assessment and intervention. Figure 11–1 depicts the four key domains of life that dynamically interact and intersect to form one’s “quality of life” at the center.

Figure 11-1. Living with Aphasia: Framework for Outcome Measurement (A-FROM) (adapted from Kagan et al., in press).

Assessment in the domain of *aphasia severity* entails documenting relevant linguistic or cognitive processes, either those targeted on traditional aphasia batteries or the impairment as viewed by the person with aphasia. The domain of *participation* includes a person's relevant life habits, roles, and situations, such as employment, relationships, social conversation, or leisure activities. This domain also includes activities that are components of life habits or situations such as activities of daily living or functional tasks. *Personal, emotional, and identity* factors refer to inherent characteristics of the person (e.g., age, gender) as well as to factors related to psychosocial well-being and identity (e.g., confidence, self-esteem). *Environment* refers to the physical or social environment in which a person functions. Aspects of these domains interact to create life with aphasia or *quality of life* at the center of the schematic. Assessment might target one or more of these domains. For example, changes might be documented in a person's self-esteem and confidence (personal domain) after intervention aimed at eliminating environmental barriers to communicative participation (environment domain).

In addition to different domains of assessment, measurements might accrue from different sources. These include the perspectives of the person with aphasia, clinician judgments (e.g., clinician ratings or observations), or proxy ratings or reports. The source of information should be clear since "insider" judgments (e.g., perspectives of the person with aphasia) often differ from "outsider" judgments (e.g., reports of others, clinician evaluation) (Cardol, de Haan, Van den Bos, & de Groot, 1999; Cruice, Worrall, Hickson, & Murison, 2005; Doyle, 2005; Parr et al. 1997). Assessment

also can be divided into evaluation of capacity versus evaluation of actual performance (WHO, 2001). "Capacity" refers to a person's *ability* to perform a task in a clinical setting or test situation. "Performance" refers to what a person actually *does* in his or her daily life. For example, someone with aphasia might be able to make a phone call (capacity), but does not make phone calls during daily life (performance). Assessment approaches applicable to social intervention for aphasia are described below, and examples of tools are listed in Table 11-1. Measures of the linguistic or cognitive deficits are not included since this topic is covered in detail elsewhere.

Perspectives of Those Affected by Aphasia

A variety of tools assist the clinician in obtaining information from the perspective of those affected by aphasia relative to aphasia severity (the impairment), life participation, the communicative environment, and emotional factors.

Ethnographic Interviews

Ethnographic interviews have been recommended to determine the personal viewpoints of those affected by aphasia (Simmons-Mackie & Damico, 1996a, 2001). By analyzing interviews before, during, or after the intervention, general themes are identified that help focus intervention or document outcomes. Aspects of life participation, emotional adjustment, and environmental factors relevant to intervention and outcome can be accessed through interviews. Candidates for interviews include both the person with aphasia and others impacted by the aphasia. Ethnographic interviewing and analysis requires training and practice in order to access the authentic perspectives of informants. Readers are directed to Spradley (1979) and Westby (1990) for explanations of the methodology.

Communicative Profiling System (CPS)

An approach to assessment based on qualitative research methods is the Communicative Profiling System described by Simmons-Mackie and Damico (1996a, 2001). Interviews, personal journals, and observation are used to identify personally relevant behaviors, social relationships, emotions, and situational contexts of participation. Thus, the client and significant others catalog the behaviors that they consider significant to life with aphasia. A social-network diagram is devised to represent the people with whom the person with aphasia interacts on a regular basis, as shown in Figure 11-2. Description of relationships helps identify the quality of social networks. Psychosocial and affective issues are also catalogued. Finally, the contexts or activities that the person participates in on a regular basis are described. These layers of description help the clinician gain insight into communication patterns and motivations.

TABLE 11-1

Examples of Assessment Tools for a Social Approach to Aphasia**Obtaining Perspectives of Those Affected by Aphasia**

Ethnographic interviews (Simmons-Mackie and Damico 1996a; 2001; Spradley, 1979; Westby, 1990)

Professional Judgments

Assessment from the perspective of the professional is another source of measured outcomes. The speech-language pathologist evaluates performance as compared to defined target goals or expectations of “normal.” In fact, most traditional assessment tools involve scoring or ratings completed by the professional to document aspects of communication.

Professional judgments or ratings are typical for measuring communicative effectiveness, performance of functional daily activities, and describing characteristics of conversation.

Activities and Participation**Functional Assessment and Activities of Daily Living**

Using tests of functional communication clinicians assess or rate performance across a variety of categories or tasks typical of the daily activities of most people (Frattali, Thompson, Holland, Wohl, & Ferketic, 1995; Worrall, 1992). For example, the clinician rates observed or reported performance on “talking on the phone” or “reading the newspaper.” In a social model, interpretation of such data must be balanced with information on the personal relevance of each task, since the importance of functional tasks varies from person to person (Davidson, Worrall, & Hickson, 1999; Payne, 1994; Smith, 1985). Talking on the phone might be deemed highly important to one person, yet minimally important to another, even when their lifestyles appear similar. In addition, it is important that clinicians are aware of *actual* function in daily life, not simply the ability to perform various functional tasks.

Communicative-Effectiveness Ratings and Conversation Analysis

Analyzing communicative interactions using communicative-effectiveness ratings is a prevalent approach to assessment. Aspects of an exchange, such as success of message transmission, efficiency, naturalness, or pragmatic appropriateness are rated for baseline or follow-up data. Barrier activities, “simulated” functional scenarios, or samples of

Figure 11-2. Example of a Social Network Analysis for “M,” an Individual with Aphasia (Simmons-Mackie & Damico, 1996a, 2001).

natural conversation provide contexts for rating behaviors of interest (Lyon et al., 1997). The interaction, not simply the behavior of the client alone, is an important target of assessment (Leiwo, 1994). Kagan and colleagues (2004) report on two scales that provide insight into both the interactional and message-transmission skills of the person with aphasia and a communication partner. Ramsberger and Rende (2002) describe a method of analyzing “transactional” success in conversation. Communicative-effectiveness ratings need not come solely from the perspective of the professional. Clients or others (e.g., family, friend, employer) can rate their own perceptions of communicative effectiveness, as in the Communicative Effectiveness Index (Lomas et al., 1989). In addition, perceived conversational engagement or enjoyment during natural conversation might be a rating target.

Since performance on linguistic tasks does not necessarily predict how one performs in natural conversation (Beeke, Wilkinson, & Maxim, 2003; Horton, 2004; Wilkinson, 2004), analysis of conversation is an important component of assessment, particularly if intervention is to effect changes in natural social interactions. Conversation Analysis (CA) is a potential tool for documenting communicative interactions (Perkins et al., 1999). The Conversation Analysis Profile for People with Aphasia is based on principles of CA (Whitworth, Perkins, & Lesser, 1997).

Measures of Participation

While the preceding functional and communication measures provide useful information, documenting actual social

participation is important for capturing meaningful life changes. There are a number of approaches to measuring participation. Simmons-Mackie & Damico (1996a, 2001) apply social-network analysis and contextual inventories to identify social contacts and activities performed on a regular basis as reported by people with aphasia and their significant others. Personally relevant changes in these inventories represent life-participation accomplishments. An activity inventory for a person with aphasia who entered therapy 2 years post-onset is presented in Table 11-2; it is clear from visual inspection that both the number and quality of activities increased after “activity-focused” intervention. Similarly, social-network maps (as in Fig. 11-2) can serve as visual evidence of increased social relationships (Simmons-Mackie & Damico, 1996a, 2001). Lyon (2000) lists “obligated” and “free-time” activities pre- and post-aphasia to provide data on lifestyle changes. Others (Haley et al., 2005) describe an adaptation of the Activity Card Sort (ACS) (Baum & Edwards, 2001) to obtain information from adults with aphasia regarding their current and prior life activities. Simple frequency counts also provide data. For example, if a goal involves increasing the number of social contacts per week or the variety of activities, then simple counts document increases over time. Similarly, hours of participation might serve as a “quick and dirty” measure of increased activity.

Participation can be judged from either an outsider perspective (e.g., ratings or counts by experts) or an insider perspective (e.g., reports or ratings by the person with aphasia). For example, clinicians, family members, or hospital staff might keep journals or observational diaries to document aspects of communication and participation of the person

with aphasia. Observational data collected by the clinician in natural communication situations is valuable in documenting the presence and success of adaptations or compensations and changes over the course of treatment. Increasingly, however, assessment of social participation and functioning in society *as judged by those affected by aphasia* has been viewed as an essential element in rehabilitation (Cardol et al., 1999; Kagan et al., in press). In other words, people place different values on particular life situations, frequency of activities, or social contacts. It is difficult to judge the “success” of social participation without capturing whether or not the changes are meaningful to the person with aphasia and/or family.

Goal-Attainment Scales

Improvement over time in actual participation can be measured with scales designed to judge movement towards particular individually defined life-participation goals (Pound et al., 2000; Simmons-Mackie, 2000). For example, the individual who wishes to participate in an adult-education class works with the therapist to identify requirements to be achieved in order to meet this goal. Relevant scales can be developed to document achievement towards selected life goals. For example, return to work might be documented along an ordinal scale ranging from unemployed (rated as 1) to working full-time at full pay with adaptations (rated as 5). Within the goal scale, each rating is defined (e.g., a 3 = half-time, reduced salary/benefits). While results of such measures are not always comparable across patients and do not inherently indicate the significance of changes (Hesketh & Hopcutt, 1997), personal-goal-attainment scales are valuable in combination with other measures. Methods of developing goal-attainment scales and statistically analyzing results are available (Schlosser, 2004).

Communicative Environment

Interview and observation are the most widely used methods of documenting environmental barriers to and enablers of communicative or life participation for people with aphasia (e.g., Simmons-Mackie et al., in press). Clinicians might interview people with aphasia and their family members to identify barriers to participation, particularly in personally relevant environments (e.g., home, hospital, work). Observation of authentic events and situations also provides information on social, physical, attitudinal, temporal, and organizational factors that enable or disable participation. Such assessments are typically directed at improving participation of a particular individual with aphasia; however, a more broad-based assessment might be conducted to determine the “aphasia friendliness” of various settings, facilities, or organizations.

Quality of Life

Another approach to assessment includes gathering self-reports or ratings of life satisfaction or quality of life (QOL).

Numerous measures are grouped as quality-of-life tools (Engell, Hutter, Willmes, & Huber, 2003; Hilari et al., 2003; Paul et al., 2004; Records, Tomblin, & Freese, 1992; Ross, 2005; Ross & Wertz, 2003; Ryff, 1989; Worrall & Holland, 2003). Typically, the person with aphasia conducts a rating across one or more dimensions believed to represent aspects of well-being, satisfaction, or QOL. Since QOL is highly personal and subjective, those actually affected by aphasia should complete the ratings, and the dimensions rated must be meaningful and important to the person. Many quality-of-life tools include items reflecting various domains, including aspects related to the health condition itself (e.g., aphasia severity), psychological or emotional state (e.g., confidence, depression), and/or social activities and participation (e.g., leisure activities).

INTERVENTION WITHIN A SOCIAL MODEL

A social approach to intervention involves the ever-present and overt goal of enhancing overall QOL and participation in activities of choice. Individual goals explicitly address practical and personally relevant outcomes. Specific objectives to be discussed below include (1) enhancing communication; (2) increasing participation in events; (3) providing support systems; (4) increasing confidence and positive identity; and (5) promoting advocacy.

Enhancing Communication

To participate fully in life, one important goal of intervention is enhanced communicative interactions. Thus, increasing the communicative skill and confidence of the person with aphasia and/or potential communication partners might constitute a focus of therapy.

Expanding Skill and Confidence in Conversation

Skill and confidence in conversation is an appropriate objective of socially motivated intervention. Significant attention to natural conversation is only recently being addressed in the aphasia literature. As Leiwo (1994, p. 480) explains, “a genuine social interaction with meaningful discourse topics sets different goals for communication than the more or less artificial metalinguistic tasks, role-playing tasks or discussions that employ stimulus pictures and cards. Different goals evoke different discourse strategies.” Research supports Leiwo’s statement. For example, traditional therapy discourse includes a pervasive “teaching” discourse structure—the Request-Response-Evaluation (RRE) triad—in which the therapist “requests” the client to perform some task (e.g., What is this?), the client “responds” (e.g., pencil), and the therapist “evaluates” the response (e.g., “good job”) (Simmons-Mackie & Damico, 1999; Simmons-Mackie, Damico, & Damico, 1999). This RRE structure is not typical of adult social conversation. Natural conversation—the

everyday, ordinary talk that serves both social and transactional goals—involves varied discourse structures, creative discourse devices, varying social stances, and shifting social roles. This contrasts markedly with the relatively rigid structure of traditional therapy, in which therapist-patient roles tend to be maintained and discourse structures are relatively restricted (Ferguson & Armstrong, 2004; Silvest, 1991; Simmons-Mackie et al., 1999; Wilcox & Davis, 1977). Even conversation between therapist and client often conforms to interview patterns, with therapists asking questions and clients responding (Holland, 1998b; Simmons-Mackie & Damico, 1999). Restricted discourse structures and passive roles provide little occasion for practicing the myriad skills typical of natural conversation. In order for people with aphasia to practice strategies for engaging in conversation, then mediated and supported opportunities should be provided.

Conversation Therapy

One means of enhancing conversational interaction is direct conversation therapy (Simmons-Mackie, 2000). Conversation therapy refers to planned intervention that is explicitly designed to enhance conversational abilities. It does not necessarily involve “conversing” during therapy, although usually a conversational context is appropriate. Conversation therapy is goal-directed and individualized. It is not simply having a conversation. The goal of having a conversation is to exchange information and fulfill social needs. The goal of conversation therapy is to improve one’s skill and confidence as a conversational participant. Conversation therapy focuses not only on message exchange, but also on social communication skills appropriate to specific communicative events. Thus, aspects of interaction such as power and control, variety of social roles, range of discourse structures, and issues of self-esteem gain equal importance to linguistic form and content. Improving skill in activities such as arguing, joke-telling, storytelling, and gossiping might be addressed, along with the usual speech act repertoire. Conversation therapy might also focus on exploiting the use of paralinguistic, nonlinguistic, and contextual cues to enhance conversation (Goodwin, 2003; Hengst et al., 2005; Simmons-Mackie et al., 2005). Finally, emphasis is placed on gaining confidence as well as building skill in participating in communicative interactions.

Enhanced Compensatory-Strategy Training

Improving natural interactions often requires the use of compensatory strategies. Traditionally, the individual with aphasia has been taught compensatory strategies designed to enhance message transmission across a variety of situations. For example, strategies such as gesture, writing, asking for repeats, and using augmentative aids are widely used to improve communication in the face of residual aphasia

(Simmons, 1993). Training in such message transmission strategies has not always generalized as well as we might expect (Kraat, 1990; Simmons, 1993; Thompson, 1989). One reason is probably related to the social appropriateness of strategies and the necessity for both parties to understand and use strategies. For example, Sachett, Byng, Marshall, and Pound (1999) demonstrated that communication partners must modify their own communication to accommodate strategy use by the person with aphasia. Simmons-Mackie (1998a) suggests that accommodation theory might explain this to some degree—that is, people in conversation tend to alter their manner of communication to be “like” the other person’s style of communication (Bell, 1984; Giles et al., 1973). If a nonaphasic partner does not use writing, then it is less likely that the aphasic speaker will feel comfortable doing so. Furthermore, most compensatory strategies are trained independent of their natural use; thus, natural social contingencies are not present. Also, strategy training has not emphasized creativity and flexibility in generating novel applications during the rapid, dynamic flow of conversation. Therefore, an expanded approach to compensatory strategy training is suggested.

In enhanced compensatory strategy training, creativity, generativity, and interactivity are priorities. For example, rather than simply training a corpus of gestures or drawings, the client learns to generate ideas via vocalization, drawing, or gesture within a dynamic interchange. Examples include Lyon’s (1995) interactive-drawing approach to training drawing as a collaborative effort between communication partners, and Demchuk’s (1996) creative communication approach in which people with aphasia generate pantomime scenarios using principles drawn from dramatic enactment. In such approaches, creativity and spontaneity are reinforced. Clients are encouraged and supported in generating their own novel strategies, and existing strategies are reinforced and expanded. Therapy is conducted in a richly contextualized interaction. For example, drawing is practiced within a conversational exchange in which both the client and clinician augment verbal productions with drawings. The person with aphasia is considered a partner in identifying and elaborating a strategy repertoire.

Interactive as well as transactional strategies are included in enhanced compensatory strategy management. For example, strategies for shifting the communicative burden or encouraging the nonaphasic partner to continue talking might be important methods for a person with severe aphasia to stay in a conversation. A range of variables is considered in selecting strategies, such as the amount of “burden” placed on the partner (e.g., having to guess what a gesture means), stigma associated with the strategy (e.g., does it call attention), naturalness (e.g., performed relatively automatically versus requiring much conscious effort), time constraints (e.g., does it take too long), affect on the “flow” of interaction, and appropriateness in a specific context (e.g.,

attitudes, cultural norms) (Simmons-Mackie & Damico, 1997).

We as clinicians must maintain an open mind about potential strategies. That is, many strategies are not “normal” yet they constitute the best available alternative for a given person. For example, avoiding interaction is often considered a “problem” by speech-language pathologists who are anxious for their clients to use their residual communication skills to participate in society. However, if the client feels that participating is more “punishing” than sitting home alone, then the avoidance behavior serves a necessary social objective. In such a case it might be important to identify “supported” activities that are rewarding and work towards building contexts that satisfy the client’s social needs, rather than eliminating a strategy without a viable alternative.

Conversational Coaching

Conversational coaching, introduced by Holland (1988; Hopper et al., 2002), provides for practice of communicative scenarios with the guidance of the speech-language pathologist, who serves as a “coach.” The approach involves (1) identifying a goal or scenario to target in therapy; (2) planning what is needed; (3) developing a script and resources; (4) practicing with coaching as needed; (5) performing the scenario; and (6) evaluating the outcome. For example, one client wanted to “argue” with her dietitian about her unpalatable diet. Planning involved identifying the main ideas, how to begin, possible strategies, useful resources such as pictures and written words, and important details to convey. Together, the client and clinician developed a scripted scenario. Practice sessions revealed a number of potential weak spots and alternative strategies. In addition, manner of delivery was targeted to avoid angering the dietitian. In the process, the client identified strategies applicable to other situations and her confidence soared. Thus, a scripted scenario not only met a specific communicative need, but also served to build confidence and skill in general. In addition, the format of conversational coaching tends to “equalize” the roles of therapist (coach) and client (communication player), creating a more client-centered approach. Thus, an important element of coaching is the emphasis on symmetric discourse, the client’s active role and attention to “face saving” as a priority (Leiwo, 1994). Another important element of conversational coaching is script-training. Scripts, prescribed or routinized courses of action or talk, pervade our daily lives. For example, favorite stories that are told and retold within families often have a relatively set structure and content. Routine activities often entail relatively habitual elements of communication (e.g., ordering from a catalog, calling a taxi). Various approaches to script- and text-training have been advocated for improving a range of discourse genres such as telling jokes or making introductions (Armstrong, 1993; Hinckley

& Carr, 2005; Youmans, Holland, Munoz, & Bourgeois, 2005).

Group Therapy

Group therapy is an effective context for improving communication and well-being in aphasia (Elman & Bernstein-Ellis, 1999a, 1999b). Moreover, groups provide an ideal context for conversation therapy. The key to addressing conversational skills within a group format is to focus on interaction rather than practicing didactic, discrete skills. Such groups foster a sense of joint purpose and emphasize meaningful communicative interactions (Graham & Avent, 2004). Overlaying a teaching style and traditional therapy tasks (e.g., naming, sentence formulation) onto a group is unlikely to fulfill the requirements of conversation therapy. Rather, promoting conversation within a group context requires considerable skill in facilitating participation, equalizing control, and promoting confidence. In addition to peer conversation, groups can build skill and confidence in a variety of natural communication genres such as telling stories, arguing, or complaining. Role-playing has been suggested as a mechanism for easing into difficult communication activities since groups can jointly problem-solve, enact roles, and evaluate performances. Texts and videos are now available with information and ideas for managing aphasia groups (Avent, 1997; Elman, 2007; Marshall, 1999; Pound et al., 2000).

Scaffolded and Supported Conversations

One method of promoting conversation that works well in a group or role-play context is to employ scaffolding techniques. In order to scaffold communication the clinician or other group members provide cues or facilitators within the natural flow of interaction. In other words, others mediate the participation of a person with aphasia. Damico (1992) proposes suggestions for scaffolding.

1. The clinician follows the communicative contributions of the client rather than controlling or directing the discourse. In other words, the clinician is available to expand and facilitate, but avoids “taking over” (e.g., asking all the questions, dictating topics, requesting performances).
2. Interaction emerges from a meaningful activity. For example, sharing vacation photos might elicit more interactive communication than asking someone to tell about a trip.
3. Responses are mediated or facilitated within the natural give-and-take of the interaction. For example, the clinician might use subtle gestural prompts or write key words to support a client during the interaction.
4. Feedback should be appropriate to the communication event. If the communication is understood, then the talk

proceeds; if not, then a request for clarification is in order. Thus, clients experience natural consequences for communicative success and failure, rather than evaluative feedback such as “good talking.”

Contrast the following examples of communication. A group of people with aphasia have watched a short excerpt from an “I Love Lucy” show.

Example 1

Clinician: John, can you tell me about Lucy’s job?
 John: (Laughs) Eating.
 Clinician: Well, (laughs) that is what she did, but what was her real job?
 John: (Shrugs)
 Clinician: George, what was her job supposed to be?
 George: Candy.
 Clinician: Good, she worked with candy. Claire, what was her job?
 Claire: (gestures)
 Clinician: Right, she was supposed to put the candy in the box.

Example 2

Clinician: (Laughing) Oh boy! Isn’t that Lucy something?
 Claire: (Laughing) (gestures shoving food into her mouth)
 Clinician: (Laughs) (writes “eating” in large letters while Claire gestures)
 John: Eating, eating (gestures).
 Claire: Too much (laughing and gesturing).
 Clinician: Eating candy! Not too much for me—I could eat it all.
 George: Me too. Eat it all. Candy.
 John: Mmm. I like candy.

The first example is a didactic, clinician-focused interaction in which the therapist attempts to elicit specific responses from the group members. The second example is a scaffolded conversation in which the content and direction flows with the group interaction. The clinician provides a written prompt (“eating”) and models a verbal production (“I could eat it all”) within the natural give-and-take of conversation. Although scaffolded conversation is the intent, it is appropriate for both the clinician and group members to occasionally “step outside” of the interaction to serve as “coaches” and make “meta” comments or suggest potentially useful strategies.

Duchan (1997) expands on the idea of scaffolding discourse to suggest that the therapist support multiple

aspects of the interaction. She provides guidelines for interactive therapy with children that can be generalized to adults with aphasia. She suggests that the role of the clinician shifts from that of “interventionist imparting knowledge” to that of “facilitator supporting role change” (Duchan, 1997, p. 10). The supports provided include social (e.g., relating well, creating positive role identity), emotional (e.g., helping one another save face, feel empowered), functional (e.g., achieving communication goals), physical (e.g., providing accessible materials), discourse (e.g., scaffolding), and event support (e.g., providing contexts, letting participants know what to expect).

Partner Training

Another method of enhancing communication is through trained and knowledgeable communication partners. Partner-training is appropriate for family members, caregivers, friends, colleagues at work, and the community at large. Thus, interactions ranging from social conversation with poker buddies to discussion with one’s attorney can be facilitated when speaking partners are knowledgeable and skilled. Training speaking partners actually improves the communication of the person with aphasia (Boles, 1997; Hickey et al., 2004; Hopper et al., 2002; Kagan et al., 2001; Lock et al., 2001; Lyon, 1997, 1998b; Lyon et al., 1997; Rogers et al., 1999; Simmons-Mackie et al., 2005). In fact, Kagan (1995, 1998; Kagan et al., 2001) reports that onlookers judge the aphasic speaker as more competent when they interact with a trained partner who provides “communication support.” Thus, success of the interaction and judgments of competence depend not only on the person with aphasia, but also on the skills of the nonaphasic communication partner.

Partner training accomplishes several objectives. First, speaking partners learn concrete strategies to support communication when aphasia interferes. Second, trained speaking partners who use augmentative tools provide a context that encourages the partner with aphasia to use such modes. Third, partner training results in altered expectations and perceptions of speakers with aphasia. Once partners recognize that people with aphasia can be competent and interesting human beings, they are less likely to avoid interactions or feel bewildered by communicative failures. Finally, partner-training can expand opportunities for communication. By alleviating embarrassment, feelings of helplessness, and fear, it is more likely that partners will provide supportive opportunities to communicate.

Direct partner training and feedback are necessary for interactive patterns and techniques to be learned and incorporated into daily use (Simmons et al., 2005). Counseling or providing lists of do’s and don’ts is insufficient. Moreover, communication partner training does not involve teaching partners to be “therapists” for the person with aphasia. In

fact, such an approach often creates a teacher-student interactive relationship that differs in structure and social dynamics from natural adult social interaction. Rather, a successful speaking partner requires an understanding of how to facilitate a satisfying conversation. This includes knowledge of potential strategies and insight into characteristics of interactive communication. Appendix 11-1 lists examples of compensatory strategies for speaking partners of people with aphasia. In addition to successful communication strategies, partners need to learn how to create an interaction that feels natural and reinforces the confidence and autonomy of the person with aphasia. Research suggests that an empowering attitude might be as important as use of a concrete strategy for speaking partners of people with aphasia (Simmons-Mackie & Kagan, 1999; Simmons-Mackie et al., 2005).

Improving the skills of the partner is only one part of the intervention: the person with aphasia is also responsible for promoting successful exchanges. Thus, intervention might be directed at people with aphasia along with their regular partners. Intervention aimed at the dyad often extends beyond didactic instruction in communicative skills. For example, programs have focused on various combinations of communicative-skills training, counseling, and education (Boles & Lewis, 2000; Fox et al., 2004; Hinckley & Packard, 2001; Purdy & Hindenlang, 2005; Sorin-Peters, 2004b).

Increasing Successful Participation in Authentic Communication Events

Without opportunities to communicate, improved language is a trivial accomplishment. For most of us, communication takes place in the context of life activities. For example, people converse while eating lunch with friends, attending art openings, or playing cards. In fact, research suggests that subjective well-being and involvement in social activity are positively associated (Cardol et al., 2002; Diener, 1984; Fuhrer, 1994; Fuhrer, Rintala, Hart, Clearman, & Young, 1992). Among individuals with physical disability “greater life satisfaction was reported by persons who were doing more to maintain customary social relationships . . . and spending more time in ways customary for their gender, age and culture” (Fuhrer, 1994, p. 362). In a social approach the speech-language pathologist is responsible for increasing opportunities for communication outside of the clinical environment and for addressing barriers beyond the individual’s impairment.

One means of increasing participation in relevant communication events is to ensure that relevant life activities are accessible and successful (Lyon, 1996, 1997; Lyon et al., 1997; Simmons-Mackie, 1993, 1994, 2000). This might involve programs designed to provide supported-participation opportunities. Dedicated aphasia centers are now offering a variety of supported opportunities, such as leisure, exer-

cise, and conversation groups for people with aphasia (e.g., www.aphasiacenter.org; www.aphasia.ca; www.ukconnect.org; www.ydac.on.ca). For example, the Aphasia Center of California provides a participation-based approach to improving reading skill and enjoyment. Book clubs are offered that involve guided reading assignments, adapted materials appropriate for various levels of aphasia, and facilitated group discussion (Bernstein-Ellis & Elman, 2006). Such participation provides a typical experience of everyday life with support. Moreover, anecdotal evidence suggests that guided participation may facilitate reading skill.

Other approaches focus specifically on enhancing participation in relevant life situations. (Lyon, 1996, 2000; Sarno & Chambers, 1997). Lyon (2004) describes individual intervention at the level of “life processes.” His approach involves identifying what is important in someone’s life, identifying barriers, and working with all concerned to facilitate participation in authentic life situations. Lyon warns that a good outcome of such intervention is a renewed sense of purpose and engagement in life, not necessarily “complete happiness” (since this is rarely achievable with or without aphasia). Similarly, activity-focused intervention involves identifying potential activities or life situations with the client and intervening to ensure successful participation (Simmons-Mackie, 2000). The activity need not be “communication-centered”; rather, the goal is to enhance life participation. Once an activity of choice is identified, then the clinician in collaboration with the person affected by aphasia determine characteristics of the activity that will be addressed to ensure success. This might involve working with the client to build specific skills or strategies and/or modifying the activity to accommodate the person with aphasia. It is particularly helpful for the clinician to participate in the identified activity in order to fully appreciate the requirements and identify an entry point that helps smooth the way for participation. Prior or existing pastimes as well as new activities are appropriate targets of intervention. It is not the intent to strive for a “pre-aphasia” lifestyle. Rather, a satisfying life with aphasia is the goal. The clinician, client, and others identify activity goals such as hobbies, interests, functional tasks, volunteer jobs, or employment in which the client would like to participate. Through interviews, prior interests and future aspirations can be gleaned. An interest survey can identify potential new activities. For example, clients might sort a large variety of activity pictures (e.g., grooming pets, cooking, gardening, painting, walking, etc.) into preference categories. In this way a rough inventory of preferences can serve as a starting point for identifying potential activities. It is important that choices are client-motivated and that participation is directly facilitated. Simply identifying an activity and encouraging participation is generally unsuccessful.

Case Example

Moderate Aphasia

TG, a woman with moderate aphasia, expressed interest in returning to her Bible class at church. In spite of improvements in communication and her expressed desire to return to class, she avoided doing so. A visit to the event with the clinician was initiated. During this visit TG and the clinician met privately with the bible-class teacher. At the suggestion of the teacher, TG agreed to pass out coffee and snacks, but insisted that she did not want to participate in the class discussion. The teacher suggested that TG and the clinician explain aphasia to the class. Since TG was visibly alarmed at this prospect, the clinician offered to present to the class. As TG greeted her old friends and served coffee her demeanor changed; the demands of serving did not require sophisticated conversation and allowed her a “soft” initiation back into the group. Interestingly, once the clinician began to talk to the class about aphasia TG “forgot” about her pledge to remain quiet and became absorbed in the discussion. During this discussion the therapist modeled various methods for facilitating interaction and made suggestions to the class members. Over the next few weeks, a variety of additional adaptations were identified. For example, the teacher provided TG with a written lesson-script that TG could use to follow the discussion and access difficult words. The class began using a flip chart to write key words during the discussions; all agreed that this facilitated their discussion as much as it helped TG. In effect, the teacher and other class members learned how to support TG’s communication and facilitate her reentry into the class, and TG gained confidence in her ability to participate.

Activity-focused intervention shares similarities with traditional functional therapies that address performance of specific activities. However, many functional therapies focus on discrete tasks or generic skills such as writing a grocery list or ordering in a restaurant. Unfortunately, learning specific tasks does not ensure actual participation in the event. Functional approaches can be expanded to be more socially valid by ensuring that intervention is contextually situated and by modifying the environment as well as training the client. Thus, the functional task should be defined to address all parameters that will increase participation. Finally, a satisfying life is rarely limited to performing “chores”; therefore, it is important that an array of chosen life activities provide opportunities for socialization and fulfilling engagement.

In addition to intervention focusing directly on life habits, a related method of increasing participation is to identify and eliminate barriers to participation. Disability

has been defined as a limitation of access to normal life due to physical or social barriers (French, 1993; Byng et al., 2000). Frameworks of health and disability have helped focus intervention on factors that affect participation (Kagan et al., in press; WHO, 2001). In such models both internal and external factors affect one’s participation in life. Internal factors pertain to physical and psychological functions such as cognitive, linguistic, motor, or sensory integrity. These internal consequences, such as language-processing deficits, are often addressed in traditional rehabilitation. Environmental factors include the physical and social structures of the outside world. Physical barriers include architectural, visual, auditory, or temporal elements that disrupt communication or participation. For example, attempting to communicate in a noisy bank lobby or trying to conduct business when impatient people are waiting in line could be very difficult for a person with aphasia. Societal barriers to communication include attitudinal, political, governmental, economic, and educational factors. Barriers can be observable, such as complex written signs in buildings, or hidden, such as prejudice, negative attitudes, and ignorance. Garcia, Barrette, and Laroche (2000) suggest that sometimes a simple shift in viewpoint will reconfigure an impairment into a barrier that can be removed. For example, a person with aphasia who has difficulty talking on the telephone would be unable to perform a job that depends on phone use. Thus the “verbal impairment” of the individual prevents job performance. However, if the individual with aphasia could perform the same functions using electronic mail, then “phone use” can be considered a barrier that could be removed to help accommodate the disability. This shift in focus away from the problems of the individual and onto the external barriers is an important paradigm shift required in adopting a social approach (Garcia et al., 2000).

Providing Communicative Support Systems within the Speaker’s Community

Related to measures designed to increase participation in relevant activities is the concept of providing an environment conducive to successful communication and participation. Participation in society is most likely to occur when environments are “aphasia-friendly” or communicatively accessible (Ghidella, Murray, Smart, McKenna, & Worrall, 2005; Kagan & LeBlanc, 2002; Simmons-Mackie et al., in press). A communicatively accessible environment provides ease of communication and access to information, systems, and choices (Howe et al., 2004). Thus, a goal of intervention is to create an environment that facilitates participation (Cardol et al., 2002). As noted above, this can be accomplished in part by identifying and modifying barriers within the environment. Similarly, it is important to identify methods of enabling participation, such as providing physical and

social accommodations. People with aphasia have a right to accessible communication and services even if this requires accommodations (ADA, 1990; ASHA, 1992). As Kagan and Gailey (1993) suggest, supported communication can be considered the “ramp” that enables people with aphasia to participate. A variety of environmental and social factors have been identified as potential barriers or facilitators for people with aphasia (Howe et al., 2004; Parr et al., 1997).

Skilled Partners and Prosthetic Communities

Partner-training (as discussed above) not only enhances communication, but also potentially expands opportunities for satisfying interactions. Thus, trained partners within an individual's community serve as communicative support systems and enable improved participation of the person with aphasia. In order to build expanded support systems, intervention might focus on training individuals within existing social networks. For example, a number of successful interventions with family members of the person with aphasia are reported in the literature (Boles, 1997; Hopper et al., 2002; Lyon, 1998b; Rogers et al., 1999; Simmons-Mackie et al., 2005). However, social life usually extends beyond our immediate family. Therefore, potential communication partners outside of the immediate family might be identified and trained. For example, a friend within the community (e.g., fellow club member, neighbor) might be willing to support community reentry.

In addition, the support system might be expanded to include new communication partners such as new acquaintances, aphasia-group members, volunteers, or peer mentors. Lyon (1992, 1997) has paired individuals with aphasia with a volunteer and worked on effective communication as a dyad. He also works with the dyad to identify an activity they can share as a means of facilitating life participation. Kagan (1998) and Hoen and colleagues (1997) describe community-based programs designed to provide opportunities for successful conversation between trained volunteers and people with aphasia. Peer mentors are another source of expanded social networks and supported communication. Peer mentors are individuals with aphasia who agree to visit, serve as social contacts, assist as advocates, help with counseling, or perform other needed services (Cohen-Schnieder, 1996; Ireland & Wotton, 1996). For example, two people with aphasia might be matched to fulfill some need such as providing a ride to an aphasia group or helping with a project. The helping relationship serves both individuals since helping others is often an important missing element after the onset of aphasia.

In addition to training specific individuals to interact with people with aphasia, community training is an important element of a social approach. Community education at religious institutions, community organizations, businesses, medical facilities, or educational institutions increases public

knowledge and promotes positive attitudes. For example, Simmons-Mackie and colleagues (2007) describe a project designed to improve access to information and decision-making for people with aphasia within three health-care facilities. The project included staff training and on-site problem-solving to establish and support sustainable improvements in communicative access. Staff of the facilities reported changes, not only in their own ability to facilitate communicative access, but also in the culture of their programs and in the participation and well-being of clients with aphasia. Training people within the community in methods of supporting communication could have far-reaching consequences. Gradually the “community” of people trained to support communication with people with aphasia can be expanded, resulting in aphasia-friendly “prosthetic communities.”

Resources as Supports

In addition to trained partners, a variety of resources such as pictures, paper and markers, remnant books, written aids, vocabulary notebooks, maps, or communication boards can support communication. The Pictographic Communication Resource Manual is a collection of thematically organized pictures developed specifically to support conversation with people with aphasia (Kagan, Winckel, & Shumway, 1996a, 1996b). In addition, pictographic resources aimed at particular groups (e.g., clergy, nurses, physical therapists) can enhance communicative interactions (Kagan & Shumway, 2003). Studies have demonstrated that graphic support or written key-word choices during conversation promote increased participation of the person with aphasia (Garrett & Beukelman, 1995; Garrett & Huth, 2002). Lasker and colleagues (2005) describe resources used to support a college professor with aphasia that included a computer-based communication system with synthesized voice output and “key word” PowerPoint slides. Others also report various computer aides designed to support communication in aphasia (Bruce, Edmundson, & Coleman, 2003). A variety of resources have been suggested to prevent institutionalized individuals with aphasia from remaining “anonymous” to caregivers. Communication plans that specify likes and dislikes and life-story notebooks that give a brief history with family photos, and key life events can provide a context for sharing information with caregivers (Genereux et al., 2004; LeDorze, 1997). Remnant books or memory albums also serve as resources to initiate topics and sustain conversation. Changes in physical environments can also support communication (e.g., a surface for writing, changing seating arrangements) (Lubinski, 2001). Finally, several reports describe the potential power of “aphasia-friendly” Web sites for linking people with aphasia to goods and information. Characteristics of accessible Web sites include a variety of modifications such as simplified text, reduced visual distractions, pictures to augment text, and

large print (Egan, Worrall, & Oxenham, 2004; Elman, 2001; Elman, Parr, & Moss, 2003; Ghidella et al., 2005; Petheram, Parr, Moss, Byng, & Newbery, 2004; Rose et al., 2003; Singh, 2000).

Increasing Communicative Confidence and Positive Sense of Self

Human beings place great value on feeling important and successful. In fact, much of our communication is crafted to present a public identity or “face” (Goffman, 1967). Our view of ourselves is “reevaluated” constantly as we interact with others and obtain verification or contradiction of our perceived self-image and roles (Brumfitt, 1993). Communication and identity are entwined with the social roles we enact. Unfortunately, role change is a major consequence of aphasia. For example, unemployment after aphasia often results in the loss of a significant role and important part of one’s “identity.” Similarly, each communicative interaction has the potential to disrupt one’s self-image as a competent person. The cycle of communication breakdown, changed social roles, and loss of identity can undermine the goals of aphasia therapy. Therefore, a positive outcome depends on the development of a healthy sense of self with aphasia (Brumfitt, 1993; Byng et al., 2000; Sarno, 1993a, 1993b, 1997). A robust identity not only contributes to improved quality of life but also directly relates to one’s willingness to use residual communication skills. The person who lacks confidence is far less likely to risk participating in social situations. Development of productive new roles, robust identities, and healthy relationships often depends on support and external assistance or direction (Rolland, 1994). For example, research suggests that positive supportive relationships (i.e., those that foster autonomy while facilitating communication) strengthen self-esteem and confidence among people with aphasia, while patronizing, controlling, or negative interactions reduce confidence and motivation to participate (Andersson & Fridlund, 2002).

Modifying the Structure and Content of Services

In part, a healthy identity can be encouraged by attending to how our services promote or inhibit an empowered identity. Impairment-oriented therapy might actually undermine the development of a healthy identity with aphasia by emphasizing what is wrong and exposing failures (Byng et al., 2000; Ferguson & Armstrong, 2004; Simmons-Mackie & Damico, 1999). The social structure of traditional therapy could also devalue the person with aphasia by reinforcing the roles of “expert” therapist and “impaired” patient (Simmons-Mackie & Damico, 1999). Byng and colleagues (2000) caution that we must work on impairments with sensitivity, keeping in mind the potential effects on the developing sense of self of the person with aphasia. Perhaps by modifying the didactic

structure of therapy and moving towards a collaborative partnership approach, we might enhance the client’s autonomy and sense of self. Furthermore, moving the emphasis away from the impairment and onto the interaction and external barriers reduces the emphasis on individual problems. Attention to the emotional impact of our services is as important as attention to the linguistic effects.

Case Example

Anomic Aphasia

RT, a 55-year-old man with anomic aphasia, contacted a university clinic seeking therapy. RT was 10 years post-onset and had functioned for the past 8 years independently. Although unemployed, he managed his own investments and enjoyed travel to visit friends. RT described his disability as “not too bad.” His reasons for self-referral were to improve his ability to write letters and to converse in groups. RT attended the university clinic for an initial assessment that entailed administration of several standardized aphasia tests by a young female student-clinician. Later, the student-clinician and supervisor conducted a detailed counseling session to appraise RT of the test results. The assessment and subsequent conference were typical of a traditional evaluation. RT was visibly upset during the testing and conference. He remarked that he had no idea he was “so bad off” and appeared embarrassed to have “appeared the fool” in front of the “pretty girl.” His usually outgoing personality gave way to depression as he faced his self-delusion regarding the extent of his disability.

This example raises an important ethical question: Was the exposure of residual deficits via standard testing in the best interest of this client? Standardized assessment did not allow RT to use many of his compensatory strategies to succeed. The assessment did provide a “window” into the pattern and severity of his language disorder; however, it also markedly impacted RT’s self-confidence and sense of self. Traditionally, the importance of linguistic data might outweigh the negative psychosocial impact. However, a social model forces us to reconsider and weigh the overall impact of our practices on the person as a whole. This example is not an argument for eliminating standard tests; rather, it is an argument for carefully considering the client’s stated goals and the potential impact of each procedure on communicative, social, and psychological well-being.

Modifying Our Own Language and Attitudes

Our language and attitudes can also empower or enable others. As specialists in language, aphasiologists undoubtedly know the power of words. Duchan (1997) describes “negative rhetoric” associated with medical approaches and more

positive rhetoric often used in participation approaches. Shifting our usage to wording that avoids the biases of the medical model might help the client focus on living with aphasia over the long term. Thus, words such as “patient,” “treatment,” and “discharge” imply a “treatment and recovery” course similar to illness. Such terms reinforce the illness model and possibly allow us to shed some of our responsibility for long-term outcome. Substituting goals such as “reintegration” as opposed to “discharge” shifts the emphasis to the chronic nature of aphasia, and promotes a client-centered rather than service-delivery emphasis.

In addition, language can help those affected by aphasia learn that the person is not the disorder (Rolland, 1994). Too often the disability and the “self” become one (Goffman, 1963). Language can help externalize the disorder to reinforce the fact that the person is far more than the aphasia. For example, saying “you seem to be having trouble with your bridge club” places the burden on the person, while saying “the aphasia seems to be getting in the way of participating in your bridge club” places the onus on the aphasia. Thus, problems are the disorder, not the person. Attention to service-delivery styles and language use can help ensure that our practices promote a healthy identity as well as improved communication.

Counseling and Psychosocial Support

In addition to examining the structure of therapy and our own language, speech-language pathologists have a responsibility for aspects of counseling (Brumfitt, 1993; Cunningham, 1998; Holland, 1999; Luteran, 2001; Müller, 1999; Wahrborg, 1989). Those affected by aphasia need information and guidance in exploring the effects of aphasia on their lives. The speech-language pathologist is uniquely qualified to help other professionals understand the consequences of aphasia, to teach supported communication, and to ensure that counseling needs are met. In addition, counseling and communication intervention overlap. For example, disability powerfully affects relationships and role boundaries within families and couples (Rolland, 1994). Typically communication processes are critical for reestablishing a functional, balanced relationship. With aphasia the pre-onset modes of communication within relationships are altered. Focusing intervention at the level of the “couple” can assist both parties in identifying new ways of communicating (Boles, 1997; Boles & Lewis, 2000; Lyon, 1998b; Purdy & Hindenlang, 2005; Sorin-Peters, 2004b).

In fact, many aspects of aphasia therapy fall squarely within the realm of counseling. Counseling should be an integral part of therapy for aphasia since language is required for negotiating new identities and developing strategies for coping with life (Moss, Parr, Byng, & Pertheram, 2004). Clinicians can promote well-being by adopting an active “listening” role instead of an “instructing” role; that is, by sharing control with

the person with aphasia and acknowledging his or her lived expertise in aphasia. Holland (in progress) advocates for applying principles of positive psychology to aphasia intervention. The values of a positive health approach can promote well-being, optimism, and hopefulness—elements important to living successfully with aphasia (Andersson & Fridlund, 2002; Sveen et al., 2004). In addition, LaPointe (2005) reminds us that an important aspect of coping involves finding the small things in life that make it worth living—“dressing up . . . soaking in a Jacuzzi . . . saving a manatee . . . helping others . . . renting a goofy movie . . . [or] listening to an audiotape” (p. 16).

Psychosocial support groups, caregiver support groups, and self-advocacy groups might serve to expand this counseling focus (Byng et al., 2000; Elman, 2007; Holland & Ross, 1999; Pound et al., 2000). The chance to “tell their stories” not only provides communication opportunities for people with aphasia and caregivers but, when appropriately validated, sharing stories is an important means of building a new sense of self with aphasia (Moss, Parr, Byng, & Pertheram, 2004; Pound, 2004). Groups provide a context for exploring topics related to living with aphasia such as identity, stress management, relationships, and emotions. Caregiver groups help those who experience aphasia as a family member or caregiver to address concrete issues, provide psychological support, and help build new identities. Self-help groups provide a mechanism for people confronting aphasia to define their own needs and assist each other in addressing these needs (Coles & Eales, 1999).

Adult-learning approaches that combine elements of education, counseling, and communication skills-training have been introduced for people with aphasia and their family members (Purdy & Hindenlang, 2005; Sorin-Peters, 2004b). Such methods approach the “learners” (people with aphasia and family members) as competent adults and collaborators in the learning process. Change evolves out of the learner’s own experiences, reflective observations, and active experimentation. An important “counseling” element of such programs is the chance for participants to explore and validate the experience of living with aphasia. Reported outcomes include not only improved communicative skills but also changes in emotional well-being and relationships.

Self-Advocacy and Empowerment

Byng and colleagues (2000) propose self-advocacy as a means of (1) enhancing self-esteem, (2) developing skills and knowledge, and (3) promoting empowerment. Strategies for promoting self-advocacy include focusing on strengths, building social and political consciousness, promoting a group or community identity, gaining a role in community service, and ensuring that people with aphasia are partners in, rather than recipients of, services. Pound (1998a) described a self-advocacy project in which people with aphasia developed personal portfolios. Like pictorial vitae many

of the portfolios depicted life before and after the onset of aphasia. Clients reported that this process of examining their lives resulted in significant insights into their own identity and appreciation for their accomplishments since the onset of aphasia.

Self-advocacy groups have addressed topics such as identity and life roles, attitudes towards disability, assertiveness, and development of support networks (Pound, 1998a; Byng et al., 2000). Individuals explore personal values and identify values that are inconsistent with a healthy self with aphasia (Fuhrer, 1994). For example, placing high value on being an expert storyteller might be contrary to achieving a satisfactory view of oneself. Instead of the “storyteller,” the person with aphasia might need to identify other aspects of his or her self upon which to build self-worth (e.g., pet lover, father, spiritual person). Clients might explore new ways of expressing personalities. For example, Simmons-Mackie (2004a) offers suggestions for alternate methods of conveying humor. Clients can learn that methods of expressing oneself need not be traditional; painting, drawing, poetry, dramatics, and music also serve self-expression and release. Exploring such issues in a group with other people with aphasia can help with the reassessment of life values and objectives.

Caveats of a Social Approach

Communication provides a foundation for maintaining autonomy—the right to make our own decisions, freedom from control by others, and the ability to enforce our own values. Thus, a goal of aphasia intervention is to promote choice, freedom from control, and expression of personal values. However, any therapy approach carries with it the potential for invading rights and privacy. Therapists must avoid imposing their own values and choices in the name of treatment. Expanding and supporting participation is not to be construed as a license to “remake” peoples’ lives according to our own prescriptions and values. Work must be conducted in complete collaboration with those affected by aphasia and with an understanding of their values and desires. Confidentiality and sensitivity to intrusion into personal situations and relationships are extremely important. If partners are to be recruited and trained, the clinician must ensure that the help is not invasive or embarrassing to those involved. Explanations of intervention procedures or contracts in simple written and pictograph form might ensure that clients fully understand the methods and objectives of intervention, and participate in the plan and implementation. Part of a successful outcome in aphasia intervention involves enforcing a sense of one’s own autonomy and personal rights.

Promoting Advocacy and Social Action

The role of the speech-language pathologist includes not only intervention with those affected by aphasia but also development of social and political systems that support par-

ticipation for people with aphasia. Advocacy means that we “practice what we preach” relative to inclusion. For example, people with aphasia can serve as aphasia-group leaders or co-facilitate groups. People with aphasia can be “teacher-clients,” rather than patients, in university clinics in recognition of their unique and valuable perspectives. People affected by aphasia are qualified to serve on our boards of advisors or as co-investigators in research. Aphasia-group members can offer services as a panel of experts to educate others such as allied-health students or community leaders. Byng and Duchan (2005) provide examples of how people with aphasia might be integrated into organizations at all levels. For example, board meetings with aphasic members are conducted in accessible language with aphasia-friendly supports. Through these expanded roles, accessibility strategies are modeled. Such partnerships offer many advantages, not the least of which is the bold affirmation of the expertise and value of people with aphasia.

Speech-language pathologists and those affected by aphasia have an important role in building public recognition of aphasia and promoting availability of accessible services. Aphasia is a relative “unknown.” In fact, in a recent public survey only 5% of those surveyed knew the meaning of the term “aphasia” (Simmons-Mackie, Code, Armstrong, Stiegler, & Elman, 2002). Aphasia is mentioned in the public press with much lower frequency than other disorders with similar incidence rates (Elman, Ogar, & Elman, 2000). The impacts of poor public awareness include reduced funding for research and services, lack of understanding and acceptance by the public, and barriers inadvertently reinforced by political and public actions (Elman et al., 2000). Advocacy activities promote the development of a “group identity” for those affected by aphasia and increase public awareness. Advocacy efforts can also be integrated into aphasia management to provide a context for building a positive sense of self with aphasia while simultaneously educating the public.

Case Example

Identity Work

MC, a 62-year old woman with Broca’s aphasia and apraxia of speech, had attended individual and group therapy for several years. According to her family, MC remained depressed and socially isolated and failed to participate in former activities. Within her aphasia group MC often complained about the “bad treatment” that she received in the community, particularly in medical encounters. For example, she described how nurses and doctors talked to her husband and ignored her “like she was a lump of nothing.” She related stories of overhearing nurses talking

about her as if she were not present, and described patronizing and incomprehensible interactions with health-care providers. After hearing these stories on several occasions, the clinician suggested that she and other group members “do something” to educate health-care providers. The result was an “expert panel” designed for people with aphasia to present their stories to classes in a local nursing program. Panel members worked with their therapists to create scripts and practice presentations with various communication supports. MC approached this experience with gusto—she felt that she must be an advocate for people with aphasia. Each semester the group described their prior feelings of helplessness and inadequacy in health-care encounters and offered insight into methods that the nursing students might use to facilitate communication and interactions. MC announced to her therapist that she felt like a “new me” and described recent encounters in health care—“now they listen to me.” Friends and family noted a change in MC’s demeanor and confidence. The panel experience not only provided MC with a communication opportunity; it also gave her life renewed meaning and enhanced her self-esteem and assertiveness.

Along with public recognition, inclusion of people with aphasia in existing community services is necessary. People with aphasia have a right to access information and services such as adult-education and leisure programs. Texts that provide information about coping with aphasia can be made available to those confronting aphasia (e.g., Lyon, 1998a). Manuals written in a style that is accessible to people with aphasia can outline available resources and benefits (e.g., Parr, Pound, Byng, & Long, 1999; Sarno & Peters, 2004). Aphasia-friendly Web sites can provide information as well as social connections to other people with aphasia (e.g., www.aphasiahelp.org; www.shrs.uq.edu.au/cdaru). Pictographic “consent forms” and documents promote access to health-care choices for people with severe aphasia (Kagan & Kimelman, 1995; Simmons-Mackie et al., 2007). Organizations such as the National Aphasia Association (United States) (www.aphasia.org), the Aphasia Hope Foundation (www.aphasiahope.org), and Speakability (United Kingdom) (www.speakability.org.uk) provide information and support. Public education can help inform others of methods that can be used to increase accessibility and participation (Appendix 11-2).

THE FUTURE OF SOCIAL APPROACHES: EXPANDING SERVICE-DELIVERY OPTIONS

With the advent of social models and changing health-care systems, alternative means of delivering services are being explored and advocated. For example, the prevailing practice of offering treatment for aphasia only during the acute stage

has been criticized (Elman, 1998; LPAA, 2000; Lyon, 1992; Simmons-Mackie, 1998b). Rather than shift from treatment to no treatment, a continuum of services should be available throughout the person’s life with aphasia (Elman, 1998; Pound, 1998b; Simmons-Mackie, 1998b). Expanding our concept of services in aphasia requires that we recognize that aphasia is both an acute problem and a lifelong condition for those affected. As people learn to live with aphasia and as life situations change, the need for and type of services will change. Changed living arrangements, marriage, death of a loved one, or an opportunity for employment can create new goals and challenges. Ideally, those affected by aphasia should have access to support and professional expertise during such life changes. Services might constitute an array from which clients can select those appropriate to their current life goals (Elman, 1998). Thus, in addition to individual and group therapy, a range of services such as community-based programs, support groups, self-help programs, advocacy services, vocational programs, leisure programs, educational services, and counseling might be appropriate (Müller, 1999). An expanded service-delivery model will likely involve changes in our own services, as well as addition of services outside the domain of speech-language pathology. Expanding services beyond the health-care umbrella to include social or community agencies is a possibility. Adult day-centers and programs for the elderly might be re-engineered to accommodate those affected by aphasia. Adult-education programs such as basic computer and Internet training or art classes can be tailored to people with communication disabilities. Although not all of these services should or can be offered by speech-language pathologists, the speech-language pathologist is uniquely situated to ensure that the availability of varied services is adequately addressed. Thus, our roles, responsibilities, and payment sources are likely to shift as service delivery adjusts to changing demands.

As recently as 2004, Sarno listed the most compelling issues affecting intervention for aphasia, including: (1) limited access to services due to funding; (2) continued adherence to a medical model of recovery and rehabilitation; (3) views that aphasia intervention is exclusively a process of language repair; (4) ongoing stigmatization of aphasia associated with an uninformed and intolerant society; and (5) a lack of specialized services that include intervention aimed at the communicative, social, and psychological consequences of aphasia. Clearly, the future must address these barriers to holistic services for those affected by aphasia. A first step for clinicians and programs is to build a culture consonant with social model values.

CONCLUSION

Social approaches to intervention hold promise for promoting inclusion of people affected by aphasia in a communicating

society. Creative and socially motivated approaches to management of aphasia are emerging around the world. Such approaches have arisen from the belief that communication is more than putting words together to get an idea across. Rather, communication is part of the foundation of social structure and human dignity. This philosophy drives efforts to establish effective and efficient methods for enhancing the living of life with aphasia. As Sarno has suggested, aphasia rehabilitation is a moral imperative in which “those who work with the communication-disabled are members of a moral community seeking to empower and restore individuals to a meaningful life experience” (Sarno, 2004, p. 28). The opportunity to retool aphasia management in keeping with this view is both an exciting and daunting prospect.

KEY POINTS

1. Adopting a social model requires a philosophical shift from traditional, medical-model approaches.
2. A social model is based on the belief that communication is a social act; through communication we create and express our ideas, our identities, and our life values, and ensure our membership in society.
3. In a social approach, communication and psychosocial functioning are considered inseparable.
4. A social approach focuses not only on communication and life participation of those affected by aphasia, but also on the communicative, physical, social, and emotional environment.
5. Long-term personal consequences of aphasia are the focus of intervention in a social approach.
6. Traditional clinician roles and service-delivery models are likely to expand and change with the adoption of social approaches.
7. The ultimate aim of a social approach is to enhance the living of life with aphasia.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. List all of the activities or events that you participated in over the past week. Consider the effects that aphasia might have on each of these activities or events. Choose one of the activities and consider methods for modifying the activity to support someone with moderate aphasia.
2. Discuss the differences between a medical model of aphasia intervention and a social model of aphasia intervention.
3. Explain the relationship between psychosocial adjustment and communication.

4. What are the principles of a social approach as defined in this chapter?
5. Listen to a “real” conversation (e.g., friends, co-workers). Identify examples of the following within the conversation:
 - a. Behavior designed to “save face” or project an “identity”
 - b. Evidence of “collaboration” in conversation
 - c. Behavior that “deviates” from accurate, syntactically complete sentences
 - d. Strategies that seem to help manage the interaction rather than add specific “information”
6. Garcia and colleagues (2000) provide an example of reconfiguring a functional disability (inability to use the phone) into an external barrier (lack of availability of electronic mail) as a means of identifying accommodations for people with aphasia. Think of two examples of “problems” in aphasia that might be “recast” as external barriers.
7. How does assessment in a social approach differ from traditional assessment (e.g., standardized aphasia tests, probes of language behaviors)?
8. How does traditional therapy discourse usually differ from natural, adult conversation?
9. What is “enhanced compensatory-strategy training”?
10. What are four possible benefits of training the communication partner of a person with aphasia?
11. What is an aphasia-friendly “prosthetic community”?
12. Describe one method of enhancing a positive sense of self with aphasia.

APPENDIX 11.1

Examples of Strategies for Communication-Partners of People with Aphasia

Slow the rate of speech
 Chunk ideas with pauses between
 Insert pauses between topics
 Simplify sentence structure
 Convey one idea at a time
 Place key information at the end of the sentence
 Repeat key words
 Write key words as referents
 Rephrase when not understood
 Use direct instead of indirect referents (“Mary” vs. “she”)
 Use gestures, body lean, and gaze to shift topics
 Use verbal terminators to end a topic (“so much for that”)
 Use verbal introductions to open topics (“Let’s talk about . . .”)
 Use redundancy (“Where’s Spot, the dog?” vs “Where’s Spot?”)
 Use alerting phrases or gestures (touch, “uhh, John”)
 Emphasize key content with stress and intonation
 Tolerate the other person’s silence
 Use gestures and pantomime to add information while talking
 Backchannel to encourage the aphasic speaker (“mhm,” “I see,”
 “oh yes”)
 Paraphrase, summarize, or reinterpret to verify, elaborate, and sustain topic

Verify your understanding by paraphrasing, repeating, or questioning as needed
 Use “thematic written support” (Garrett & Beukelman, 1995)
 Use props (magazines, photo albums, pictures)
 Subtly incorporate words that the person with aphasia “didn’t get” into your own utterances
 Get information from his or her body language—focus on more than the talk
 Progress from the general to the specific in questioning
 Provide and use paper and markers to support talk
 Draw or write key ideas while talking
 Use the augmentative strategies of the person with aphasia to model and establish equality
 Use the environment (talk about a picture on the wall)
 Establish shared experiences as topics (sports, gardening)
 Focus on doing things together versus carrying out discussions
 Avoid teaching comments such as “you said that right”
 Reflect feelings communicated nonverbally (“Oh boy, that makes you angry”)
 Establish equality in relationship by following the aphasic individual’s lead, acknowledge opinions, etc.

APPENDIX 11.2

Advocacy Strategies for Supporting Participation of the Person with Aphasia

Build public awareness and understanding of aphasia
 Establish attitudes and behaviors that promote inclusion
 Promote public knowledge of facilitating behaviors and accommodations
 Provide communication aids and materials to support communication
 Provide communication in an accessible format (e.g., alternatives such as pictures and written instructions, multiple-modality communication, large print)
 Encourage environmental adaptations to promote communication (reduce noise, provide alerting systems, make speakers visible to the person with aphasia, alter signage)

Alter information complexity
 Prepare for management of emergency or unexpected situations (e.g., written message for transport driver, police, or hospital staff)
 Provide accessible information regarding services

Chapter 12

Environmental Approach to Adult Aphasia

Rosemary Lubinski

OBJECTIVES

The primary objective of this chapter is to introduce new and practicing clinicians to the concept that their clinical endeavors involving adults with aphasia will be enhanced if they consider the physical and social environment as part of their intervention. After reading and discussing this chapter, clinicians should be able to define the components of the physical and social environment, state their environmental philosophy regarding adult aphasia, identify physical and social factors in the environment that impede communication opportunities, and plan strategies to create a positive communication environment for the adult with aphasia, family members, and staff working in rehabilitation, long-term care, and home care.

The concept of **functional** dominated rehabilitation in the 1990s, and now **evidenced-based practice** emerges as the emphasis in the new century. Rehabilitation specialists are required by private and governmental health care insurers, and by consumers themselves, to demonstrate that therapy simultaneously emanates from scientifically proven methodology and makes a discernible difference in the everyday life of the patient. Numerous trends in health care have generated this focus, and the most potent of these is rapidly increasing financial cost, particularly to the escalating population of older adults. In 2004, Medicare and Medicaid, two of the primary health care insurers for the elderly, cost the U.S. population \$308.9 billion and \$276.9 billion, respectively (Hoffman, Klees, & Curtis, 2005). These expenses will swell as the first wave of baby boomers reaches age 65 in the next few years and as they enjoy a longer life span. Thus, payers want to reimburse for proven methodologies that result in real-life benefits for those receiving speech-language pathology services.

Speech-language pathologists have a particular challenge—providing intervention to adults with aphasia that

meets the two criteria of scientific merit and functional relevance. Well-accepted models, such as those offered by the Quality Standards Subcommittee of the American Academy of Neurology (Miller et al., 1999) and a rating scale used in the Scottish Intercollegiate Guideline Network (n.d.), exist for determining the best scientific evidence. Graduate programs in speech-language pathology are introducing evidence-based practice in both academic coursework and clinical practicum. The American Speech-Language-Hearing Association (ASHA) has a focused initiative on evidence based practice and has published several documents, including a position statement (2005) on this topic.

Only a limited body of research currently meets the highest levels of scientific rigor for evidence-based practice yet addresses the unique needs that each adult with aphasia brings to the therapeutic context. Most importantly, we have few well-established models of what variables should be considered to be important functional outcomes; consequently, few standardized assessment tools exist for documenting changes in functional communication (e.g., Frattali, Thompson, Holland, Wohl, & Ferketic, 1995). Clinicians are well aware that their therapeutic efforts often extend beyond the individual with aphasia to the broader social and physical environment, and that these outcomes should be documented and provided as evidence for the value of speech-language intervention. For example, a growing literature on quality-of-life issues, both for adults with aphasia and for their caregivers, reveals a recognition that outcomes need not be limited to changes in receptive or expressive communication skills alone. (For in-depth discussions regarding quality of life for survivors of stroke, see, e.g., Brumfitt & Sheeran, 1999; Duncan et al., 1999; Paul-Brown, Frattali, Holland, Thompson, & Caperton, 2001; Ross & Wertz, 2003; Sarno, 1997; Sturm et al., 2002; Vickery, Gontkovsky, & Caroselli, 2005; Williams, Weinberger, Harris, & Biller, 1999. For in-depth discussions regarding quality of life for the family members of survivors of stroke, see, e.g., Evans, Connis, Bishop, Hendricks, & Haselkorn, 1994; Kalra et al., 2004; McCullagh, Brigstocke, Donaldson, & Kalra, 2005; Palmer & Glass, 2003; Visser-Meily, Post, Schepers, & Lindeman, 2005). A new generation of clinical research must be performed to

Specific communication skills	Effectiveness of communication	Caregiver effectiveness	Satisfaction with clinical services	Quality of life	Environment
Improves receptive access to expressive, community cognitive skills to maximum	Demonstrated personal communicative competence despite disorder(s)	Uses facilitating strategies to repair communication breakdowns	Extends treatment strategies outside the clinic	Participates in a variety and quantity of activities of choice	Provides physical and social home and thinking and communicating
Improves social and vision and hearing to maximum aphasia	Adapts proactively to communication changes	Copes with stress and burden associated with caregiving and communication breakdowns	Assumes independent problem solving for communication breakdowns	Has a sense of control and choice regarding communication partners and activities	Provides financial support for short and long term intervention
	Uses alternate means when needed				Increases public awareness of and its personal and societal effects
Client focused _____					
Caregiver focused _____					
Society focused _____					

Figure 12-1. Array of intervention outcomes.

blend the science of the brain with the authentic needs of patients with aphasia and their caregivers.

One of the present needs we have as clinical aphasiologists is a model for conceptualizing the range of therapeutic outcomes we might achieve with our clients. Such a model should include specific receptive and expressive communication skills and extend to broader environmental outcomes for both the individual, significant others, and society. Figure 12-1 illustrates a continuum of intervention outcomes that begins with specific receptive and expressive communication skills that are identified and measured through formal traditional tests or trained observation of such skills in communicative interaction. Clinicians typically initiate intervention by improving these skills and concentrating on topics that are of everyday usefulness to the client. Clinicians assume that improvement in discrete skills within the context of isolated therapy will be reflected in everyday communicative interaction with a variety of communication partners.

The focus on using these skills in a variety of contexts moves us to another level of possible intervention outcomes, which are called “effectiveness skills.” Effectiveness skills

allow the individual to demonstrate, to the degree possible, personal communicative competence regardless of the presence of communication difficulties. For some individuals with aphasia, skill development will be modest, yet their ability to communicate through a variety of communication channels and with skilled communication partners will result in effective communication. These are the individuals who “max out” on traditional aphasia tests but are able, to some extent, to understand and express themselves in real-life communicative contexts. They are often those persons with chronic aphasia who have been dismissed from therapy, want to participate in an intervention program, but may not demonstrate continued progress on traditional outcome measures. Effectiveness skills involve the individual’s ability to adapt proactively to communicative changes. Some individuals might combine communication channels such as speaking and gesturing, use augmentative and assistive devices, or seek communicative support from communication partners when needed. Thus, regardless of his or her performance in terms of communicative skills, the individual is able to maintain an active communication role.

Because communication is a dyadic process, effective functional intervention must include primary and potential communication partners, particularly family members and other formal and informal caregivers. Two subtypes are possible for this third domain of outcomes. The first outcome is the ability of communication partners to use facilitating strategies to maintain communicative interaction with the individual who has aphasia. Thus, communication partners understand that they have a responsibility to become active and creative problem solvers when communication breakdowns occur with the individual having aphasia. A second outcome is to maximize caregiver ability to cope with the challenges of communicating on a daily basis with someone who has communication difficulties. Caregivers will not support therapeutic outcomes or use strategies if they feel burdened when communicating with an individual with aphasia. Outcomes that involve increasing the ability of caregivers to facilitate interaction and cope with the communicative challenges should be legitimate outcomes of speech-language pathology intervention.

A fourth type of outcome is assumed under the rubric of satisfaction with clinical services. This category is more than patients “liking” therapy or the clinician. Patients and caregivers are more likely to implement therapy strategies in their daily interaction if they perceive that the clinical services they are receiving reflect their communicative needs and genuinely benefit them on a daily basis. Clinicians have an obligation to seek frequent verbal and written feedback to document perceived satisfaction with the intervention program. An added benefit of seeking such input is that the client and caregiver assume more accountability for defining their needs and evaluating progress. Satisfaction can be measured in several ways, including use of the ASHA NOMS Measurement System that has a section devoted to patient satisfaction (ASHA, 1998). Most clinics design their own in-house tools to document patient satisfaction with clinical services, and some centers also might use large-scale health-care patient satisfaction instruments, such as those developed by the Rand Corporation (1994).

The very essence of what we do in therapy is ultimately intended to create a better quality of life for adults with aphasia and caregivers. Quality of life is a complex, multidimensional, and subjective category of outcomes that is based on respondent self-perceptions of numerous and often overlapping areas, including health, independence, socialization, and so forth (Ross, 2005). Outcomes can be documented with broad quality-of-life assessment tools, either those created for patients with aphasia or those designed for caregivers. Data from such instruments indicate that speech-language outcomes can embrace an extensive array of physical, health, social, psychological, and emotional needs of both the individual with aphasia and family members.

Finally, many clinicians realize inherently that therapeutic effectiveness is influenced by the dynamic physical and social

environments in which our clients live and communicate. Two individuals with similar communication profiles might demonstrate their communicative competence differently because of how their physical and social environments create, support, or impede opportunities to communicate. Adults with aphasia and their environment create a single, inextricably interwoven unit that in turn affects the people, events, and relationships occurring around them. It may be efficient to isolate the communication sequelae of stroke from individuals and their environment, but the process results in a synthetic assessment of the individuals and their communication assets and difficulties. The stroke and its physical, cognitive, emotional, and communicative sequelae serve as active agents of change for individuals, their social networks, and the physical surroundings. Therefore, if communication therapy is to be functional and truly tailored to the individual's needs and resources, a broader perspective on the goals of therapy, the agents of change, and the evaluation of outcomes must be offered.

Further, environmental outcomes should also include changes in public awareness of aphasia and increased commitment to providing social and financial support for short- as well as long-term intervention. As therapeutic effectiveness across the continuum is documented, collated, and analyzed, this information must be shared with the general public and policy makers at local and national levels as well as with the professional community. A circular relationship exists between what the public perceives as important intervention endeavors, what the public supports both politically and financially, and what services are available (and for how long) to the individual and family.

ENVIRONMENT

Here, “environment” is defined as the spectrum of influences that impinge on and are influenced by an individual during his or her life cycle. These forces emanate from the external physical and social environment together with those that arise from the unique internal contributions of each individual. Note that these influences do not have a simple summative effect; rather, a change in any one can reverberate within the whole system. Each component has the potential to cross-fertilize the others. The combination of these external and internal stimuli forms a “total environment” for each person. Figure 12-2 presents a schematic diagram for the relationship of the individual to his or her total environment. Keep in mind that all environments contain a variety of individuals who in turn influence each other.

External Environment

The external environment is comprised of the physical world, the immediate social milieu in which an individual resides, and the social, political, and economic values,

Figure 12-2. Relationship of a person to his or her total environment.

norms, and institutions of the larger society. These concurrent and interactive stimuli operate in tandem to help define how individuals will function in any setting.

Physical Environment

The physical stimuli in a person's external environment include the natural phenomena perceived through the senses, man-made contributions of buildings and artifacts (built environment), and the use of time and space. These stimuli create the physical context in which individuals function and help to determine both where and how they will live and the rules they will develop to maintain order within that landscape. Individuals assume control over their physical environment when possible to enhance their way of life.

The physical environment can create either access or barriers to communication for individuals who reside or function in a particular environment. If communication is to occur, individuals must perceive that they or their communication partners can function and move both safely and easily within that setting (Brawley, 1997). The environment must be structured so that communicating individuals can come within a reasonable and effective physical distance of each other. Distance is determined by one's sensory abilities and by sociocultural conventions. Effective communication also depends on having physical access to individuals and activities of choice that generate topics and desire to communicate. Persons must perceive that they have the option

to gain access either independently or with easily accessible personal or technological assistance.

Thus, the physical environment can either impede or support access to communication opportunities for those with aphasia. Keep in mind that in addition to the physical and communicative disabilities associated with stroke, many of these persons will also experience physical, sensory, and cognitive changes related to aging that interact powerfully with the built environment (e.g., arthritis, presbycusis, low vision, and dementia). Among the most important physical environmental impediments to communication is the reality—or the individual's perception—that the environment is unsafe or difficult to navigate. Some individuals are anchored to a limited number of physical environments because they or their communication partners cannot safely and independently traverse within or between settings. Such physical isolation is true for many adults with aphasia who reside in the community or in some level of institutional care. Other examples of barriers include confusing spatial design; lengthy hallways, stairways, or floor coverings that preclude independent navigation; inadequate and poorly controlled lighting, acoustical, and heating/cooling treatment; limited areas designed for group or private communicative interaction and activities that generate socialization; and furnishings that create physical obstacles to interaction.

Such physical environmental barriers become critical for individuals with aphasia for two reasons. First, there may be little or no awareness on the part of caregivers or individuals with aphasia that the physical environment affects access to communication opportunities. Other health, financial, and caregiving issues frequently take precedence over creating physical access to communication opportunities. It is not unusual that a person with aphasia is relegated to one location that is chosen by caregivers for reasons of safety and efficiency of care. Both in the home or in an institution, adults with aphasia are often placed in front of a television or near where meals are served. Physical placement is generally decided by a caregiver to facilitate delivery of care. Second, persons with aphasia have limited communication skills to verbally control their physical environment. For example, it may be difficult to communicate how the environment could be structured or modified to facilitate desired interaction and activities that stimulate conversations.

Immediate Social Milieu

Through social interaction, individuals learn their roles and the expectations of others in their environment. From infancy to old age, individuals assume a variety of roles that are influenced by the expectations of the sociocultural environment as well as by their own characteristics. Societies prescribe guidelines for how an individual should progress to and from various roles during the life cycle.

Formal social behavior is learned through direct, explicit communication (e.g., by the rules and laws of social organizations). In contrast, mores, or traditional customs, are acquired more subtly. These are learned through informal interaction within specific subsystems, such as family, work groups, and social activities (Ittelson, Proshansky, Rivlin, & Winkel, 1974). These two types of norms determine how much individual involvement, support, independence, personal growth, and expressiveness will be tolerated (Moos, 1976).

Each environment creates its own personality and provides individuals with a network of social capital. Social capital is created by the combined resources and values of all the social networks in which individuals function (Putnam, 1995). Hopefully, these social networks can be mobilized to provide adults with aphasia with social and physical support, meaningful opportunities to communicate, and assistance when communication difficulties create breakdowns in interaction. Social networks, such as the family as well as religious, work, and fraternal organizations, help individuals to realize their physical and emotional needs through both real and perceived support. A strong body of evidence suggests that social support is important in successful aging (e.g., Krause, 2001) and in coping with disability (e.g., Young & Olson, 1991).

Fundamental to the immediate social environment is the family. "Family" is broadly defined here as the network of individuals with whom the an individual with aphasia is closely involved on a daily basis. This can be an immediate system of spouse and/or children, or it can extend to other, multiple networks of relatives, friends, and informal or professional caregivers (Turnbull & Turnbull, 1991). An individual's family provides information about its broader culture and affords economic, socialization, daily care, and emotional support. The characteristics of the family, or of any of its components, will affect and be influenced by their relationships with larger social groups such as work, school, church, political, leisure, and medical/rehabilitation organizations.

Both individuals and their immediate and extended families are challenged when the individual incurs some type of disability, such as a stroke and ensuing aphasia. The roles and relationships that have been established may be imbalanced, and the family system must adapt if it is to remain integral and meet the needs of the individual family members (Maitz, 1991). Scholte op Reimer, de Haan, Rijnders, Limburg, and van den Bos (1998), in a study of 115 partners 3 years after a stroke, found that they perceived a high level of responsibility, uncertainty about patient needs, and restraints on their own socialization. Some partners also felt that the patient relied exclusively on them for care. In a meta-analysis of stroke caregiving, Han and Haley (1999) found that stroke caregivers exhibit high levels of depression at both the acute and chronic phases of stroke.

Some families are equipped to cope with such difficulties. For example, LeDorze (1995) found that some spouses believed aphasia united them with the individual having aphasia. Many families will face some degree of confusion or chaos unless they are provided with support. From the initial crisis through living with chronic aphasia, most families will experience an evolution in their reaction to the difficulties of coping with stroke and aphasia.

Family caregivers often assume added responsibilities regarding their loved one and the management of their home and daily life. These are in addition to changes in married life, family relationships, work, and social life. Besides the physical toll related to caregiving, the emotional impact includes increased irritability and anxiety, depression, loneliness, and fatigue (Michallet, LeDorze, & Tetreault, 2001; Michallet, Tetreault & LeDorze, 2003; Zemva, 1999). Michallet and colleagues (2003) state that communication difficulties are a "central source of stress . . . that combines with others sources of stress in lifestyle habits" (p. 853). Such reactions may result in increased burden and stress. Numerous studies indicate that increased depression in caregivers results in exacerbated depression in the adult with aphasia and in reduced rehabilitation outcomes (Han & Haley, 1999). This establishes a cycle of depression fueling depression.

Hemsley and Code (1996) caution us to remember that adults with aphasia and their caregivers have heterogeneous perceptions of recovery and adjustment to communication problems. For example, some studies show that families are not adjusted at 5 years poststroke (Holbrook, 1982), whereas others (e.g., Silliman, Fletcher, Earp, & Wagner, 1986) show that families improve over time. The need for individualized and qualitative assessment of family needs and conversational skills is echoed by LeDorze, Croteau, Brassard, and Michallet (1999).

Table 12-1 portrays a model for the stages through which individuals with aphasia and their families will evolve after the stroke. This model begins with the severe illness or crisis stage, and it evolves to subsequent stages of recuperation, rehabilitation, postrehabilitation, and institutionalization. This model is presented as a specific sequence of stages, but in reality, stages may be of varying lengths of time for individuals with aphasia and their families.

The family's initial concern after the stroke is coping with the sudden, life-threatening illness. The family, particularly the spouse, likely fears that the stroke will result in death or some disability. Not only is this fear directed toward the patient, but the family also feels anxiety about how their own lives will be changed by this crisis event. Numerous feelings, including obsessive concern, anxiety, helplessness, grief, and guilt, cloud this time. Few changes in family roles are likely to occur, however, because the family's energy is directed toward the immediate health crisis.

TABLE 12-1

Patient Stages, Possible Family Effects, and Potential Family Needs

Patient Stage	Possible Effects on Family	Potential Family Needs
Severe illness or crisis (acute)	Fear and shock Disequilibrium Anxiety Depression Guilt Helplessness Grief Obsessive concern Fatigue	Emotional support for entire family, particularly spouse and adult child caregiver, significant others
Recuperation	Sense of relief from acute stage Family works toward homeostasis Members assume needed roles and jobs Search for help begins Individuals try to maintain self-image	Continued emotional support Information about family demands, resources, concerns Informal education about stroke and its effects Family mobilized to work together Facilitative communication strategies modeled while communicating with adult who has aphasia
Rehabilitation	“Hope” that things will improve Expectation that patient will improve Want information about stroke, aphasia, depression, changes in personality, and other co-morbidities Solidification of new family roles Beginning of isolation from community Physical changes in home Possible logistical problems in attending therapy by patient and/or family members Possible financial problems Difficulties with travel and independence	Continued emotional support with more emphasis on self-reliance Information giving and counseling Problem-solving approach to communication difficulties Direct involvement in rehabilitation Discussion of family, individual, and clinician goals and expectations of therapy Definition of and access to community resources regarding financial aid, insurance, Medicare and Medicaid, etc. Peer support groups Counseling from social worker, occupational therapists, physical therapists, others Planning for postrehabilitation stage
Postrehabilitation	Frustration with daily communication Possible role overload for primary caregiver Possible health problems for primary caregiver Long-term changes in family roles Isolation of family from extended groups Possible reduction in intimacy between person with aphasia and spouse or significant other Over- or underexpectations for continued improvements	Participation in support groups Realization and support for caregiver personal needs Peer and extended group support Increase in normative features of home and person with aphasia Continued emotional support—referral to community counselors

TABLE 12-1

Patient Stages, Possible Family Effects, and Potential Family Needs (continued)

Patient Stage	Possible Effects on Family	Potential Family Needs
Institutionalization	Physical/psychological overload Lack of awareness of community alternatives Conflicting feelings of relief and guilt Further role changes Discomfort with setting Reduction in contact with institutionalized family member Preparation for family member's deterioration or death	Help in decision making Counseling regarding alternatives Support during decision making and entry Encouragement to visit; strategies for productive visits Information regarding impact of institutionalization on family member Modeling of facilitative communication strategies in this setting Work with facility staff to stress importance of communication with the individual who has aphasia Encouragement to develop new roles in this setting Encouragement to participate in activities with the patient both within and outside this setting Counseling regarding deterioration and death

Once the health of the patient who has had a stroke is stabilized, the patient and the family move into the recuperation stage. Initially, there is relief that the patient will live. The family tries to return to its pre-crisis state (homeostasis). In actuality, numerous changes are influenced by the normative stage of the family, its historical ability to cope with problems, the immediate tasks that need to be done and the resources for accomplishing them, and other demands on the family. For example, a mature family that has clear lines of communication, an established resource network of family and friends, and a history of successfully coping with problems may face a crisis differently than a family that is disengaged, interacts poorly, and has numerous conflicting demands on its members.

Stroke may occur in younger adults who are in the early stages of family development, but it is more likely to occur when the family is in the late life cycle. The elder spouse is likely to assume primary caregiving responsibility, although adult children play an increasingly important role in providing assistance to their parents. Further, children, particularly adult daughters, are likely to be employed outside the home and to be caught in the "sandwich" of caring for their own children and parents or for those of a spouse. The older family, however, comes to the stroke situation with both advantages and disadvantages. This family has many years of life resources and social capital that may assist in coping with stroke and aphasia (Rolland, 1990). The caregiving spouse, however, also may have health, physical, cognitive, or sen-

sory problems that complicate his or her ability to provide optimum care.

During the recuperation stage, the family is likely to concentrate on activities of daily living, such as walking, feeding, dressing, and toileting. They also have a simultaneous awareness that communication is disrupted. The communication difficulties now evident between the individual with aphasia and family members confound both physical care and social relationships. Kinsella and Duffy (1979) found that difficulty in communication results in a loss of the intimacy and support found in most marriages.

Most families in which someone has had a stroke do not come as units untouched by other problems in life. Numerous concurrent demands have an impact on the family dealing with aphasia. For example, Jones and Lubinski (unpublished), in a family-systems study of nine poststroke families, found that all families contended with stresses faced by maturing families, such as those related to launching children, managing retirement, and coping with the needs of elderly parents. Kelly-Hayes et al. (1988) found that family and social factors were equal to medical factors in determining the final outcome of patients after a stroke.

When medical conditions have stabilized and physical recuperation appears to be possible, therapies are likely to begin. For many families, this will be their first encounter with therapy for aphasia. During this rehabilitation stage, the focus is on helping the individual with aphasia to improve his or her communication skills. The family system

is also continuing its restructuring during this time. Role changes become more solidified so that even when individuals with aphasia return to their families, modifications in roles and routine are in place. Difficulties in communicating contribute significantly to the need for, yet also impede, the participation of the patient with aphasia in the restructuring of family roles. Unwittingly, the patient may become a marginal member of the family.

At some point, active rehabilitation will end as the individual with aphasia moves into the chronic stage post-rehabilitation. This is the beginning of a “new normal” set of roles and relationships for the individual and family (Allan, 2006). Some family caregivers may be overloaded by the demands of care and possible conflict with personal needs, and health problems are common among this group. Over time, family caregivers may realize that they need psychological support (Van den Heuvel et al., 2002)

Some individuals with aphasia may require relocation to long-term care if caregiving resources in the community are strained. This decision is generally difficult for the individual and family, and family members need information regarding their caregiving and residential options. Psychological support is important before and after making the decision.

The extended family of a person with aphasia is also affected by the stroke and the resulting communication problems. Friends and acquaintances may feel uncomfortable during interactions with the patient and may withdraw from former social interactions with the entire family unit or individual members within it. The family may lose some of its opportunities for social connectedness because one member cannot communicate. This results in disengagement of the family from the mainstream of the community.

Finally, the extended social system of the individual with aphasia is likely to include some new members, such as professional caregivers. Nurses and nursing assistants assume a prominent role in the lives of many patients with aphasia in the hospital, home, or long-term care settings. These individuals assume “quasi-family” roles, in that they perform intimate caregiving tasks and serve as primary communication partners for the individual with aphasia. They may or may not understand the nature of aphasia and how to reinforce gains made in therapy.

Broader Cultural Milieu

The broader social milieu is comprised of the social, political, and economic values of the culture that are translated to individuals through the social interaction they have with a variety of groups throughout their life. Basically, society is guided by the values that it deems as being important to pass on through the generations. Particularly relevant here is how society views disability.

How our broader society and individual cultures within it view disability in general and aphasia in particular also

affects opportunities to communicate as well as financial and physical access to rehabilitation services. North American culture has a divided view on how it perceives disability. First, it views disability as a consequence of interaction between individual characteristics and the “natural, built, cultural and social environments” (National Institute on Disability and Rehabilitation Research, 1999, p. 68578). Sotnick and Jezewski (2005) state that acknowledgment of and outside intervention for disabilities are favored in mainstream American culture (p. 26). Second, Western societies also feel a need to “protect the less fortunate.” Protection may lead to elimination of situations where the individual with aphasia (and, hence, society) might face communication frustration or failure. The individual with aphasia is now out of mainstream society and part of an unfamiliar and isolated minority group. Reintegration into society thus becomes more challenging.

Finally, when communication problems are evident, the individual has more difficulty demonstrating intelligence, social competence, and productive social roles—all qualities that are valued by Western industrialized societies. Safilios-Rothchild (1970) says that such societies do not tolerate “behavioral deviations [such as communication difficulties] that tend to disrupt the smooth functioning and easy flow of interpersonal relations” (p. 127). In general, contact with adults who have difficulty communicating arouses anxiety. The cultural norm is to mask such aversion, usually through avoidance.

Other cultures, even within North America, may have contrasting views of etiology, intervention options, and family involvement in rehabilitation. Thus, although there may be prevailing views on disability and rehabilitation within North America, the home culture of individuals with aphasia greatly influences how the client and family will perceive the problem and avail themselves of rehabilitation services. This is particularly important as the United States becomes an increasingly multicultural society. Note, too, that clinicians’ cultural views of disability and rehabilitation may differ from those of the individuals with whom they work. This difference may affect the formation of goals and the inclusion of family or others in the therapeutic process.

Finally, the political and economic environment also influences the individual, the family, and the larger society. Society must constantly evaluate its economic resources against the multiple needs of various constituencies. The growing number of elderly, particularly the very old, stresses the balance between social needs and economic resources. The current emphasis on evidence-based practice demonstrates society’s need to provide wisely for those with disabilities.

How health care and rehabilitation are approached is also influenced by the financial resources of those with aphasia and their social networks (Ingstad, 1990). The availability of personal financial resources or finances and of third-party insurance to cover prolonged rehabilitation may affect the

person's willingness to participate in therapy. Speech-language pathologists are encouraged to be culturally sensitive, but they must also be "economically sensitive" to client and family concerns about the cost of therapy and the perceived cost/benefit ratio. Knowing that a family cannot afford extensive therapy or that the costs of therapy will deplete a family's savings may determine how and where therapy is done and how progress is evaluated. Individuals with aphasia and their families appreciate a speech-language pathologist who acknowledges the financial burden of therapy.

Internal Environment

The individual is at the core of the environmental approach presented in this chapter. By contributing personal characteristics to the environment, the individual becomes an active member of it. Basic characteristics include the total and evolving array of physical, sensory, psychological, cognitive, communicative, and emotional traits and needs. Human beings enrich their environment with these distinctive features yet must rely on other individuals and groups for information, support, and feedback. The individual generates social imperatives but must also respond to social conventions.

Ideally, pressure from the physical and sociocultural environment will never exceed the person's ability to respond competently. Individuals are expected to know their social roles and match them to their biologic, intellectual, and emotional abilities. The interplay between human beings and their environment is delicate and dynamic, creating challenges for our ability to adapt and survive. Person-environment congruence, or "fit," is defined as the similarity between what the individual can contribute and the demands of the environment (Kahana, Lovegreen, Kahana, & Kahana, 2003; Lawton, 1970).

Individuals with aphasia come to their environment with a constellation of characteristics, including their personal history, age-related changes, and stroke-related disabilities. Physical and health concerns may have priority over communication rehabilitation for the individual or caregivers. The loss of social roles for survivors of stroke is particularly devastating. Dowswell and colleagues (2000) concluded in their qualitative study of survivors of stroke that these patients "deeply felt their change in status from 'doers' to receivers, from active to passive. Particularly painful was the inability to help others" (p. 513). This study also documented the deterioration of social life for survivors of stroke, partly as a result of physical obstacles but also because of feelings of shame and perceived moral judgments.

From these findings, it is not surprising that many survivors of stroke incur depression, a potential co-morbidity (e.g., Starkstein & Robinson, 1988; Wahrborg, 1991). Depression may be related to biochemical changes resulting from site of lesion or as a reaction to the challenges of stroke

and aphasia. From 30% to 60% of patients with stroke exhibit depression following their insult, and this depression may be long term (e.g., Cullum & Bigler, 1991; Egelko et al., 1989; Robinson & Benson, 1981). Grief and anxiety are natural consequences of the physical and psychological losses associated with stroke. As family members cope with the demands of the stroke and with their own feelings of loss, they may provide few opportunities for communication with the adult who has aphasia. A vicious cycle ensues, as fewer opportunities result in diminished social roles that then generate depression for the individual and hence fewer opportunities to communicate.

The depressive symptoms that individuals with aphasia may show can be multiple, ranging from pervasive sadness, dependency, and indecisiveness to physical and cognitive problems. The most extreme symptom includes suicide (Jenike, 1988). Such depression symptomatology may be interpreted, however, by family or professionals as confusion or dementia. The individual with aphasia and depression is in double jeopardy because of his or her difficulty in verbally and therapeutically expressing feelings.

Depression is not the only affective disorder exhibited among individuals with aphasia. Affective changes can be any of a constellation of reactions, including frustration, anger, hostility, anxiety, aggression, withdrawal, denial, regression, boasting, and catastrophic reactions (Wahrborg, 1991). Further, individuals with aphasia may also incur other cognitive changes, such as dementia including Alzheimer's disease, multi-infarct dementia, and dementia related to Parkinson's disease. Again, these must be differentially diagnosed from the aphasia itself and from any other concomitant psychological problems, such as depression.

Of particular interest in this chapter are the communication abilities and disabilities that individuals with aphasia contribute to their environment. For successful communication to occur, the individual must have some degree of ability to send and receive messages. Language, speech, and hearing mechanisms must be minimally capable of sending and receiving signals. Visual acuity also contributes to effective communication, because one decodes many nonverbal cues through vision. Communication will be unsuccessful when the sender transmits an unintelligible message, when he or she misperceives the availability of the receiver, and/or when the content is ambiguous, inappropriate, or irrelevant. Communication also becomes ineffectual when the individual does not comprehend signals, receives a distorted signal, is distracted by extraneous stimuli, or loses interest.

The inability to communicate successfully may be the most significant problem for individuals with aphasia—and the greatest price they must pay for their illness. Some patients may be stigmatized by their communication problem (Goffman, 1964). Each time they attempt to communicate and fail, they strengthen their own or others' perception that they are incompetent communicators. At a time when

communication is essential for adjustment and reintegration into the family and the community, their skill is impaired, and opportunities to interact are often seriously reduced.

Individuals with aphasia face a crisis each time they cannot quickly and efficiently express or comprehend the symbols of their environment. For example, each time individuals are bombarded by communication that comes too abundantly or quickly, they may reply unintelligibly or inaccurately, or they even may not respond at all. They find it difficult to fulfill their roles as adult communicators within their family and other social groups. Similarly, a crisis occurs each time individuals are isolated from communication opportunities by their voluntary withdrawal or by the retreat of significant communication partners. It may be easier to avoid communication and, thereby, lessen the frustration of failure.

ENVIRONMENTAL PHILOSOPHY

This chapter presents a model of assessment and intervention for adults with aphasia that derives from environmental and family systems theory and their application to aphasia rehabilitation. The philosophy discussed here is one that can be easily incorporated with other approaches presented in this text. Ideally, the environmental systems approach should complement and enhance other cognitive, linguistic, and communicative approaches while increasing their functionality for individuals with aphasia in their physical and social environment.

The environmental systems approach is based on the philosophy that effective and functional therapy emanates from a comprehensive rehabilitative management model that takes into consideration the interrelatedness of individuals, their communication abilities, the effectiveness of communication partners to facilitate communication, and the physical and social environment. Therapeutic goals should rightly focus on primary communication disorders, but the goals must also facilitate and strengthen those strategies that allow individuals with aphasia and their significant others to become effective communication problem solvers. If we acknowledge the principle that communication is a dyadic process, we realize that aphasia, by its very nature, creates problems for both members of that communication team. Although one individual incurs the stroke, each individual with whom that person communicates will face a predicament. The natural response by some communication partners is to talk for the individual with aphasia; for others, to anticipate every need; and for still others, to avoid communication because of potential problems. Each of these responses results in a loss of opportunity for the individual with aphasia to demonstrate intact or improving communication ability. Communicative avoidance also results in fewer opportunities for individuals with aphasia and their partners to initiate and evaluate productive communication problem-solving strategies. The diminution of communication

opportunities negatively affects the social relationships between those with aphasia and their communication partners, and it reverberates to larger social systems, including family, friends, and other social groups.

The philosophy underscoring this chapter is congruent with at least four models of disability and rehabilitation. First, Banja (1990) stated that rehabilitation should focus on “empowering a disabled person to achieve a personally fulfilling, socially meaningful and functionally effective interaction with the world” (p. 615). Speech-language pathologists who suspect that their therapy for aphasia is incomplete, artificial, and unfulfilling to the client, to significant others, or to themselves might find this approach to be a starting point for answering these questions. As Lyon (1992) states, “[S]ole preoccupation with the act of communicating has failed, so far, to deliver a solution to the problem of restoring optimal function (i.e., communication use and participation in life) in natural settings” (p. 9). The approach described here helps the speech-language pathologist to leave the cloister of the therapy office and enter the physical and social environment of the patients with aphasia.

Second, the environmental philosophy is compatible with the social model of disability that focuses on the relationship between individuals with impairments and society. Disability is viewed as the loss of ability to interact as a legitimate equal because of the barriers created by the physical, social, and economic environment (Burchardt, 2004). The significance of the environment in understanding disability is evident in this philosophy. For example, individuals with aphasia will communicate best in an environment that values and supports them regardless of their skill level. The World Health Organization (2001) framework that encompasses impairment, activity, and participation as well as the Life Participation Approach to Aphasia could both be assumed under the rubric of a social model of disability. In particular, a philosophy of communication rehabilitation emanating from England (e.g. Parr, Byng, Gilpin, & Ireland 1997; Parr, Duchan, & Pound, 2003) and Canada (Kagan, 2003) recognizes the impact of aphasia on a person’s self-identity and the important role of the community in reintegrating this individual into society. MacKay (2003), himself an individual with aphasia, considers aphasia as “a social problem that is subject to social action” (p. 812).

A third, relatively new framework that supports an environmental approach to intervention is called the capabilities framework. Originally proposed by Sen (1980) and Nussbaum (2000), this model suggests that capabilities should be the object of value. Burchardt (2004) describes these as a combination of individual ability resources, practical means and knowledge to carry out a variety of functions of choice, and the social, physical, and economic environment to support the individual in these endeavors (p. 738). Applied to communication and the environmental model, the capabilities framework focuses on the ends (communication

effectiveness, opportunities, and competence) rather than the means (specific skills).

The work of Hinckley (2001) on self-efficacy for aphasia and the philosophy of Shadden and Agan (2004) of renegotiation of identity in aphasia support groups complement both the social model of disabilities and the capabilities framework. In each, the active influence of the social environment is critical to the ability of individuals with aphasia to maximize their communicative competence.

OVERVIEW OF ENVIRONMENTAL INTERVENTION

The ultimate goal of environmental intervention is to create a positive communication environment. A positive communication environment is one in which individuals have plentiful access to communication opportunities of choice and are valued as meaningful communication partners. At the core of this intervention is the belief that, even in the face of severe communication disability, individuals with aphasia need and want to communicate and that the physical and social environment can be a catalyst to promote successful communication. Such an environment respects and supports individuals with aphasia and their significant partners. In addition, it eliminates or moderates physical barriers that impede the transmission and reception of messages and that preclude independent or assisted access to meaningful communication opportunities of choice within a variety of physical and social settings. A positive communication environment provides opportunities for socialization so that individuals with aphasia can demonstrate, to the extent possible, that they are socially and communicatively competent persons. Finally, keeping in mind that communication is a dyadic process, the environmental approach considers family members and other caregivers to be essential partners in the diagnostic and rehabilitation process.

Thus, twin benefits arise from adopting an environmental approach. First, individuals with aphasia achieve some degree of independent and successful communicative participation in their environment. Second, the physical and social environment becomes a stimulating and accepting milieu in which communicative interaction is likely to occur. Simply stated, the person with aphasia needs a stimulating and supportive physical and social environment that perceives communication as an important outcome of care. Accordingly, the therapeutic “client” consists of both the individual with aphasia *and* his or her environment.

Specifically, the environmental goals within the total rehabilitation program are:

1. To develop communication skills and those sensory and cognitive skills that underpin communication to the highest degree possible so that meaningful communication can occur.
2. To create a physical environment that promotes successful communicative interaction.
3. To create a positive communication environment that contains stimulating activities and a variety of interesting communication partners of choice.
4. To provide communication partners with techniques for facilitating and reinforcing communication through a variety of communication channels.
5. To develop self-actualization skills for individuals with aphasia and their significant others so that rehabilitation becomes a realistic and effective process.
6. To develop greater societal awareness of the nature and impact of aphasia and a philosophical and financial commitment to supporting communication intervention within the community.

IDENTIFICATION OF A COMMUNICATION-IMPAIRED ENVIRONMENT

The first step in the environmental rehabilitation program is to identify how the physical and social environment creates opportunities for, or barriers to, communicative interaction for adults with aphasia and their significant communication partners. A “communication-impaired environment,” the antithesis of a positive communication environment, is one that limits communication opportunities through its physical and social characteristics. Such an environment exhibits the following characteristics:

1. Lack of sensitivity to the value of communication as a cornerstone of effective functioning.
2. The idea that communication is a by-product, not a goal, of care.
3. Restrictive stated or unstated rules that limit communicative interaction.
4. Few or no communication partners of choice.
5. Limited physical accessibility to activities and partners.
6. Few reasons to talk that emanate from meaningful activities and interaction.
7. Lack of private, easily accessible places to talk.
8. Sensory dimensions that confound communicative interaction.
9. Cognitively boring.
10. Limited or no support for communication partners.

Many clinicians will recognize a communication-impaired environment by its obvious inadequate quantity and quality of communicative interaction, but more formal tools are needed to document the nature of these deficiencies. A Communication Environment Inventory is presented in Table 12-2. This inventory provides clinicians with a broad and qualitative guideline for evaluating the communication opportunities and barriers that reduce interaction

¹ Frequency is subjectively defined for each individual.

Comments:

Plan of Action:

Environmental Goals:

of the person with aphasia. This tool can be used to assess the communication environment in the family home or some level of institutional care, from assisted-living settings to long-term care facilities. Although it is not standardized, the evaluation tool can form the basis for a structured observation and discussion with clients and caregivers. The individual items on the list are rated on a continuum from frequently, which signifies items conducive to a positive communication environment, to never, which portrays a communication-impaired environment. Frequency of occurrence may differ for individuals and should reflect client, caregiver, and clinician definitions. For example, some patients with aphasia and their family members may define “frequently” as every day, whereas others may define it as three times per week. Note, too, that perception of the adequacy of frequency may change as the person with aphasia tries to enter more communicative contexts and faces environmental barriers.

Those items rated on the negative end of the scale provide areas for possible environmental intervention. This type of assessment process should naturally complement other approaches to communication evaluation for clients and their caregivers. For example, more in-depth assessment of the individual’s communication, sensory, and intellectual func-

tioning and evaluation of family or caregiver interaction with the client are essential and discussed elsewhere in this text.

The Communication Environment Inventory is divided into two major sections. The first section, Physical Environment, focuses on the built or structural environment. The second section, Social Environment, concentrates on social factors that may stimulate or decrease communicative interaction. Intervention focuses on strengthening those items that are frequently identified as encouraging communication and on reducing or eliminating those factors that create a more restrictive communication environment.

ENVIRONMENTAL INTERVENTION

Once the clinician has completed an environmental assessment, environmental concerns need to be prioritized through discussion with the client and caregivers. This discussion alone alerts the participants that effective intervention goes beyond development of communication skills. For therapy to be truly functional and successful, the participants need to become both sensitive to the environmental effects and environmental problem solvers. Keep in mind that goals must be identified that are reasonable and functional within

TABLE 12-3

Sample Goal Plans for Environmental Intervention

Environmental Concern	Environmental Goal
1. Client has restricted access to activities/partners of choice that stimulate conversation because of limited independent mobility.	1a. Family or staff will provide assistance to activities on a daily basis (e.g., personal aid, walker, cane, ramp)
2. Hallway background noise masks communicative intelligibility of client.	1b. Client will communicate his or her preference for activities and partners of choice on a daily basis.
3. Staff members ignore verbal attempts by the client.	2a. Staff will close door to hallway when communicating with client.
	2b. Client will indicate through gesture that door should be closed during interaction.
4. Spouse does not know what to do when client has word-finding problems and avoids communication to avoid further stress.	3a. At least two staff members will have a one-on-one conversation with client on a daily basis.
	3b. Client will verbally or nonverbally advocate the need for communication partners.
	4. Spouse will learn several strategies that facilitate word recall and use them on a daily basis.

the guidelines of the setting and payment sources. Examples are shown in Table 12-3.

Goal 1: Improve Communication, Sensory, Cognitive, and Emotional Skills

Rehabilitation efforts focus primarily on empowering the person with aphasia to use communication to lead a meaningful social role in a variety of contexts. The most immediate need is to help the individual retain or achieve status as an active and viable communication partner. This is done by strengthening specific receptive and expressive skills whereby individuals can intelligibly and meaningfully contribute their personal ideas and have their needs appropriately met. Traditionally, this goal is achieved through individual and group speech-language therapy sessions using a variety of approaches.

In addition, it is critical that the individual with aphasia come to the intervention arena with adequate sensory, cognitive, and emotional skills. Patients may need to be referred for hearing and vision examinations and possible follow-up with assistive devices. Additional visual and acoustic environmental accommodations may be needed to supplement individual interventions.

Some individuals with aphasia may have co-existing dementia. Aphasic versus dementia-related language and cognitive changes must be differentiated. Identification of dementia as a co-morbidity may mitigate progress and influence prognosis. It may also change the content and nature of information provided to and counseling of both the patient and caregivers. For example, individuals with declining cognitive skills may benefit from engagement in a variety of

cognitive stimulation programs, such as Montessori based group activities (Camp, 1999).

Finally, the speech-language pathologist must constantly be alert for symptoms of depression in the client with aphasia and in family caregivers. In some situations, referral to the family physician or a mental health specialist is appropriate. Several approaches to relieving symptoms of depression can be incorporated into daily therapy for aphasia. Tanner, Gerstenberger and Keller (1989) suggest that the speech-language pathologist incorporate frequent positive reinforcement into every session as a means of reducing depression. Other suggestions include encouraging the client to participate in activities of choice as well as peer-group therapeutic activities. Peer-group activities in particular are an excellent venue for peer counseling and discussion of coping strategies.

Perhaps the most important way to help cope with depression is to allow adults with aphasia time to talk. Ireland and Wotton (1996) provided 20 persons who had aphasia with 20 hours of counseling. Their descriptive study revealed that the participants valued being given time to talk in an attentive, noncritical, and private context. Outcomes included decreased depression, increased confidence, and better understanding of the emotional impact of aphasia and consequent life changes. One implication of this study is that speech-language pathologists may need to set aside specific therapeutic goals to allow individuals time to vent feelings in a therapeutic context.

Speech-language pathologists also need to consider long-term goals for the client with aphasia, including strengthening coping skills to deal with residual communication difficulties, achieving independence and socially fulfilling roles in the

community, returning to employment, and for some, preparing for long-term care. Preserving the self after a stroke is essential. For example, Kvigne, Kirkevold, and Gjengedal (2004) found that female survivors of stroke were able to return to their social roles and reestablish their sense of self and a meaningful life when supported. Teamwork with other rehabilitation specialists provides the optimum vehicle for accomplishing these goals.

Goal 2: Create a Physical Environment that Promotes Communication

No matter the setting in which the person with aphasia lives, either a family home or an assisted-living or long-term care setting, the physical characteristics of that environment become an important backdrop for communicative interaction. The physical setting should be a source of information, stimulation, and access to communication activities and partners for the individual with aphasia. It may be impractical to redesign the hospital or family home, but some realistic modifications that facilitate communication are usually possible. The factors that can be manipulated in most environments include (a) lighting and visual cues, (b) acoustic treatment, (c) furniture arrangement, and (d) environmental props. For a more in-depth discussion of these topics, the reader is referred to Calkins (1988) and Lubinski (1995).

Lighting and Visual Cues

Adequate illumination contributes to the safety and independence of persons with aphasia and their communication partners while creating a visually stimulating environment. A high proportion of patients and their spouses will exhibit visual changes associated with stroke itself (e.g., hemianopsia), aging (e.g., presbyopia, dry eyes, and blepharitis), and age-related diseases (e.g., glaucoma, cataracts, diabetic retinopathy, and age-related macular degeneration). These visual changes result in loss of visual acuity, blindness, low or blurred vision, and changes in central or peripheral vision. Older persons with aphasia may also have difficulty with glare, perception of patterns, contrast differentiation, color perception, and adjusting to changes in levels of illumination (Brawley, 1997).

In general, older patients will require more light that is uniformly bright and does not create shadows. O'Keeffe (2006) suggests that seniors need 30% more light for general tasks and fivefold brighter light for reading and task completion. This is best presented through natural daylight and dimmable, high-quality fluorescent lamps (Aging Eye, 2006; Brawley, 1997). Areas of diagnostic and therapeutic activity should also have focused task lighting that can be moved as needed. Visual stimuli necessitate clear contrast, and font size should be larger than normal (18-point print in a clear font is recommended). Rooms that are filled with glare from shiny surfaces or poorly controlled lighting

reduce the individual's ability to comprehend nonverbal cues, take advantage of contextual information, and derive cognitive and social stimulation from the visual environment. Glare is reduced by the use of ambient indirect lighting, non-glare floor coverings or non-gloss waxed floors, semi-gloss paint on walls, and adjustable window treatments (Brawley, 1997).

When possible, the person with aphasia should have visual access to windows facing outdoors or to areas where everyday activities occur, such as the kitchen and living room at home or the nursing station and lounge areas in a nursing home. Visual access gives the person with aphasia a sense of connectedness and cognitive stimulation with the physical and social environment.

The use of color in the environment also plays an important role. O'Keeffe (2006) suggests that older individuals perceive colors at the warm end of the spectrum best but will have difficulty with blue tones, pastels, and low-contrast colors. Improving visual contrasts through color enhances information and aids in visual discrimination. For example, walls painted in primary colors with contrasting colors for floors and doors aid in the identification of one's own personal areas. Patterned wallpaper also provides stimulation and orientation cues. Nameplates or other identification should be printed in large-size white letters on a contrasting dark surface.

Other simple strategies that enhance visual access include adding texture to surfaces of walls, furniture, and bedding and using warm, medium-intensity colors to facilitate orientation. Because some individuals with aphasia will be seated in wheelchairs, placement of visual information such as clocks, televisions, book cases, and bulletin boards should be adjusted appropriately for a seated person. Visual access stimulates thinking and, in turn, orientation and conversations.

Clinicians may find that persons with aphasia and their family members do not attend evening support programs, particularly during the winter months. This may result from difficulties in night driving and concern about walking in dimly lit parking areas. Keep this in mind when scheduling programs. Alternate transportation may be needed as well as additional lighting in walkways.

Perhaps the simplest strategy to enhance visual access is to ensure that the individual with aphasia has the best vision possible through regular referral for ophthalmologic or optometric evaluations. Use of prescription lenses or other visual assistive devices should be easily accessible. Speech-language pathologists should check a patient's chart to note whether visual-field disturbances exist or if glasses are needed for evaluations and therapy. Use of large-print, high-contrast materials and access to handheld or stand magnifying glasses or magnifying sheets should be encouraged. Individuals who have aphasia and severe visual difficulties may benefit from "talking books," high-tech reading machines, pocket-sized telescopes, or specially adapted, closed-circuit televisions for the visually impaired (Orr, 1997). Finally, visual access is

enhanced by coming face to face with the patient and asking what positioning facilitates visual access. Individuals with macular degeneration in particular may have better peripheral vision and be able to see when people or items are placed in that area. It is prudent to check with the client and ask, "Can you see me here? Move the place so you can best see it."

Acoustic Treatment

The primary goal of enhancing the acoustic environment is to ensure that intact auditory information reaches the individual with aphasia. In addition to difficulties in auditory comprehension, the patient may have difficulties hearing related to the aging process (e.g., presbycusis) or previous life experiences (e.g., employment in noisy environments) and other physical disorders. Note that hearing loss is the third most prevalent chronic condition associated with aging and increases both with aging and with institutionalization. Listening to speech in background of noise is particularly difficult for older persons in general (Kricos, 2006).

The first step in enhancing the acoustic environment is to begin with a referral for a complete otologic and audiologic evaluation. Keep in mind that untreated hearing loss is linked to both depression and social isolation in seniors regardless of the presence of aphasia (American Academy of Audiology, 2006). Individuals with both aphasia and a hearing loss should be encouraged to use a personal hearing aid or other assistive listening device to receive auditory information more adequately. Face-to-face communication also will optimize the use of listening aids and the reception of nonverbal cues.

Ambient noise in the environment may reduce the patient's auditory attention and comprehension skills, particularly during conversation. Clinicians should be aware of the auditory characteristics where they provide therapy and where individuals with aphasia are likely to converse or participate in activities. Institutional environments, such as hospitals and rehabilitation centers, often contain hard surfaces, which increase reverberation, as well as a variety of peripheral noise sources. Even therapy provided in a client's home may be susceptible to unwanted background noise. When possible, therapy should be provided in areas that are acoustically treated with sound-absorbing materials (e.g., acoustic tiles or panels, carpeting, and draperies) to reduce ambient noise and reverberation. Areas to avoid include those near doors, windows, and high activity centers. Heating/cooling systems, vacuuming devices, and food service also contribute background noise. Other noise-control strategies include turning off the radio or television when talking or providing therapy as well as closing a door or window to reduce noise from other areas or corridors. Always seek permission from the client before adjusting lighting or noise-producing sources. Individuals with aphasia may take better advantage of visual cues during conversation if they

have appropriate seating and adequate lighting. Each of these techniques is inexpensive. In addition, note that individuals with aphasia and a hearing loss may not understand information presented on public address systems. They may also benefit from telephones designed for those with motor or hearing impairments (e.g., remote speaker phones, cordless phones, voice print phones, and amplifiers) (Mann, 1997).

Clinicians and communication partners should consistently employ communication-enhancing techniques, including natural and clearly articulated speech with a slightly slower rate and a louder volume, eye contact, and appropriate pauses (Kricos, 2006). Communication that occurs within about a 3- to 4-foot radius from the person with aphasia is more likely to be heard than communication that occurs at greater distances.

Ideally, long-term care settings should have FM or other sound-reinforcement systems available, particularly in congregate areas, such as dining rooms and lounges (Crandell, Smaldino, & Flexer, 1995; Pichora-Fuller, 1997). Speech-language pathologists and consulting audiologists should define the acoustic needs of older patients with aphasia in long term care settings and provide suggestions for use of environmental assistive listening devices both in the design of new facilities and in the renovation of existing ones.

Individuals with aphasia and their caregivers who reside in the community should also use assistive listening devices that may be available in congregate settings such as senior centers, churches, theaters, and auditoria. Speech-language pathologists and audiologists should provide information about the types of environmental listening technology that are available and how to access them in community venues.

Noise control is important for adults who have aphasia with and without hearing loss. It does not, however, mean creating a sterile auditory environment. Everyday sounds are a source of stimulation, safety, and conversation. Stimulation from the myriad sounds of daily life, music, radios, and television can stimulate interaction with others in the environment. Auditory stimulation gives the individual with aphasia knowledge about his or her surroundings and a sense of belonging.

Furniture Arrangement

The arrangement of furniture determines where, when, and with whom the person with aphasia will talk. For example, the patient in a wheelchair may lack easy or independent access to favorite activities and social groups. Individuals with aphasia will be more likely to join a group if they feel they can enter with a minimum of inconvenience and disruption. Furniture, particularly chairs, should be movable to promote easy access, fit the person's size, and provide stable support while sitting or standing (Brawley, 1997). Circular furniture arrangement also facilitates eye contact and auditory reception with a variety of people. Small dining tables (four to six seats) encourage

conversational interaction more than larger tables do. Wheelchair accessibility is a priority for many adults with aphasia, and again, it is critical that furniture be movable to accommodate wheelchair accessibility.

Furniture arrangement in long-term care facilities should encourage access and participation in both large group activities and in one-on-one private conversations. Key to the large groups is flexibility and mobility of furniture to meet programming needs. Opportunities for small group activities, in which intimate, informal conversations might occur in a relaxed and comfortable context, should also be available.

It is crucial that persons with aphasia retain control or autonomy over some personal space in their home or institutional environment (Barnes & the Design in Caring Environments Study Group, 2002). Morgan and Stewart (1998) found that privacy is a vitally important aspect of the environment for older people in general. Some residents of long-term care settings may prefer settings that enhance privacy rather than socialization. All individuals, however, require areas and objects that reflect their unique histories, personalities, and interests. Adults with aphasia must perceive a sense of choice and ownership in their environments.

Some individuals with aphasia may be satisfied to sit in one area for extended periods of time if that area provides good visual access to the outside (e.g., street, garden, and activities) or to areas where activities occur (e.g., kitchen, nurses' station, and lounge). Finally, furniture arrangement should provide opportunities for privacy and intimate talk with chosen partners. This is especially true in long-term care settings, where conversations can become the property of all interested listeners. Areas in which private conversations can occur should be both available and accessible. Clinicians should also keep in mind that therapy provided in public areas, such as the patient's room in an institutional setting, can be a source of interest and eavesdropping. The issue of privacy should be considered when therapy is provided in community homes as well.

Environmental Props

Physical props in the environment also stimulate the general orientation of the person with aphasia and are a source of topics for communication. Keep in mind that the environment provides much information that the individual can use to remain independent, safe, and active. For example, adults with aphasia in the community need easy access to spaces and objects that support activities of daily living and personal interests. Any assistive devices that promote physical independence (e.g., walkers, canes, and handrails) also provide access to activities of choice and, hence, communication.

For individuals with aphasia who have relocated to long-term care, personal items and furniture, mementos, and favorite pictures give them consistency with their family,

home, and lifelong identity. Other props can promote comprehension and way-finding. For example, wall color and coverings, signage and visual stimuli, and bulletin boards serve as orientation devices. As much as possible, the physical "stuff" of the environment should reflect the person's history and interests while providing multi-sensory cues about time and place. Individuals with aphasia may need a variety of information sources to promote their way-finding.

Safety Issues

Safety should be a critical focus of communication intervention with adults who have aphasia. These adults may have impaired mobility related to hemiplegia and other health or sensory concerns. Both patients and their caregivers may limit opportunities for interaction if they perceive a potential threat to safety. Falls in particular are an important cause of injury and disability for older people and affect one in three adults aged 65 years and older (American Academy of Family Physicians, 2000). If adults with aphasia are to remain in the community, they need to be able to understand information that will keep them safe and secure. They also need to be able to communicate their safety needs both efficiently and effectively.

Safety topics for receptive therapy might focus on reading environmental signage related to medications, entrances and exits, hazardous materials, and instructions. For persons with aphasia who travel independently, reading transportation schedules and ticketing may be important. Similarly, expressive therapy might focus on verbal and nonverbal ways to communicate personal safety concerns on the telephone or in person. A variety of safety technologies may be suggested, including the telephone (e.g., cordless and voice activated), intercom systems, warning and signaling devices, and wearable lifeline devices) (Newton, 1997). Note, too, safety-focused therapy is also ideal for caregivers, who will better understand the patient's ability to function independently. Such a focus provides the family with a sense of security and comfort.

In addition, the environment needs to be designed to meet the safety needs of adults with aphasia. Although this chapter cannot discuss the topic in detail, major efforts should be made to assess the environment where these persons reside and delineate potential threats to safety. Examples include assessment of major living areas for design features and objects that might increase a potential for falls. A partial sample of suggestions includes creating clutter-free paths to the bathroom and telephone, providing adequate and non-glare illumination, using non-skid flooring, keeping assistive devices (e.g., walkers and canes) close, removing extension cords from pathways, and installing handrails in bathrooms and on both sides of steps (Family Caregivers Online, 2006).

Goal 3: Create a Positive Communication Environment with Stimulating Activities and Partners

The value of socialization for all persons, particularly older individuals, is undisputed. The recent MacArthur Study of Successful Aging investigated factors that contribute to healthy aging. Those investigators found that elders who participate in social activities or groups appear to gain the protective benefits associated with exercise. In particular, contact during conversation and exchange of friendship are key to optimizing the senior years (Rowe & Kahn, 1998; Seeman, 2000; Stern & Boyle, 2002).

Socialization is also an important factor in recovery following stroke. For example, in a meta-analysis of 39 quality-of-life studies of patients with stroke, limited socialization was one of the important factors related to reduced quality of life (Bays, 2001). Belanger, Bolduc, and Noel (1988) found a decrease in leisure and management of personal affairs 6 months poststroke. They also found that social contacts with family increase poststroke, but that a concomitant decrease occurs in contact with friends and others. Ellis-Hill and Horn (2000) found that even post-acute stage stroke respondents who received inpatient and outpatient rehabilitation reported a depressed sense of self, limited social activity, and psychological morbidity.

LeDorze and Brassard (1995) documented the perception of the consequences of aphasia held by patients, family members, and others. Both patients and family members noted reduction in interpersonal family relationships and intimacy as well as a restriction on activities. Helmsley and Code (1996) showed that social dysfunction remained an area of concern for both patients and their significant others at 9 months poststroke. Numerous other studies and reviews have also commented on the social isolation experienced following aphasia (e.g., Hermann & Wallesse, 1989; Lyon, 1992).

It is logical, therefore, that socialization is important for those with aphasia. Persons with aphasia may have to rely on family members for socialization activities because of both physical and communicative difficulties. Such reliance places the responsibility on family members to serve both as sources of stimulating activities and as communication partners.

Thus, one of the goals of communication intervention is to create a positive communication environment with stimulating activities and partners. In general, this goal will be accomplished indirectly through educating family and other caregivers and counseling the adult with aphasia regarding both the importance of and how to access socialization activities. Family and other caregivers need to learn the value of socialization and their role in maximizing access to a variety of meaningful social activities for the individual with aphasia. This may be accomplished in educational programs, informal discussion, and counseling. At a time when caregivers are absorbed in meeting the myriad needs of the survivor of

stroke, socialization may not be a priority. In fact, family members' own socialization needs may be neglected.

Remember that a positive communication environment is one that values the communication contribution of its members. Key to being considered a viable communication partner is the understanding that, despite the presence of aphasia, the individual is respected as a valuable adult communication partner. Thus, caregivers and others need to provide real opportunities in which individuals with aphasia can offer their ideas through verbal and other means of communication.

Caregivers also need to realize their critical role in encouraging individuals with aphasia to reengage in old or new favored activities. Caregivers are also catalysts who encourage people outside the immediate family to interact with the person who has aphasia. They may need to model communication-facilitating strategies so that partners feel comfortable in communicating with the patient. Further, caregivers must understand the importance of activities of choice as the basis of communicative interaction. Speech-language pathologists may also use such activities as the foci of individual and group therapy to prepare the client for these interactions.

Caregivers will want to know which activities to suggest and what to talk about with patients. Encourage caregivers to follow the lead of the individual with aphasia. Such choices are likely to reflect prestroke interests and experiences, but they may also involve new activities and partners. The act of soliciting options from patients with aphasia is important socialization in itself. Topics generate from activities, but conversations that reflect reminiscing, philosophizing, and evaluating are also meaningful and adult-like. For example, opinions can be solicited with open-ended questions for those with aphasia and a high level of expressive skills: "What is your opinion on ___?" "What do you think about ___?" For those with more limited expressive skills, yes/no questions or those that contain options can be presented: "Do you think your property taxes are too high?" "Do you think Mr. Jones or Mrs. Wilson should run for mayor?"

Some individuals with aphasia may return to work or leisure activities, and these are natural sources of conversational topics. Others may participate in language stimulation groups at local aphasia centers. Such participation provides a supportive environment in which those with aphasia can demonstrate their communicative competence in a supportive environment. Many provide an array of adult-like activities that stimulate thinking and conversation. Involvement in other types of cognitive stimulation programs available in the community, college training programs, and long-term care settings also encourage interaction. These include reminiscence, remotivation, and cognitive stimulation programs. Many of these programs are geared for those with cognitive decline, but some may be appropriate for those with aphasia. Before suggesting such programs, however, the speech-language pathologist

should try to observe the level of skill needed to participate and the cognitive level of the attendees.

Keep in mind that adults with aphasia should be encouraged, but not forced, to participate in programs. Some individuals with aphasia may be unsure of their ability to communicate in such contexts, and others may perceive some activities as demeaning. A good strategy is to provide information about an array of available activities and discuss those that the patient could attempt on a trial basis. Some individuals with aphasia may attend if they know that they can observe anonymously or participate with a caregiver. Finally, it is good to discuss the parameters of the activity, including length of the program, who attends, cost, transportation, and access to bathroom facilities. Role playing may help as a precursor to actually attending new activities.

Goal 4: Create Skilled and Empathic Communication Partners

Skilled clinicians know intuitively that support from family and other caregivers is critical to the success of speech-language intervention in patients with aphasia. Research on family intervention concretizes this clinical perception. Two studies by Hinckley and Packard (2001) investigated the effects of a family education program on adults with aphasia and their families. Both studies clearly demonstrated that family education improves knowledge, family adjustment, and functional activity level. Fox, Poulsen, Bawden, and Packard (2004) studied the outcomes of a 2-day residential family program held at a rustic camp. Participants identified five intervention outcomes: a sense of hope, a view of support from a social support network, an ability to monitor emotional and physical well-being, acceptance, and the creation of a new social support network.

The most typical approach to creating skilled and empathic communication family partners is to provide information in some type of education program. Avent and colleagues (2005), in focus group interviews of family members, found that they needed different information depending on the poststroke stage (acute initial rehabilitation or chronic phase). Michallet and colleagues (2001, p.734-5) found that spouses of patients with severe aphasia identified six needs: (1) need for information, (2) how to communicate more effectively, (3) how to have better interpersonal relations with their family and others, (4) need for a partnership relationship with professionals, (5) need for emotional and practical support, and (6) the need for respite. Thus, a one-time approach to counseling and education is not likely to meet the needs of most caregivers.

Stroke Education

When designing an education program for families, several things need to be kept in mind. First, the time or phase

poststroke is critical to what information the family needs and how ready they are to participate meaningfully in the programming. Figure 12-2 illustrates the needs and ways to meet these needs by stages.

During the crisis and early recuperation stages, the focus is on providing family members with emotional support and beginning the process of engaging them as part of the therapeutic process. Support is generally provided through communication between the speech-language pathologist (or other professional) and the family. Emotional support involves letting the individuals know that someone in the unfamiliar world of the hospital knows who they are and understands the trauma they have experienced. Generally, this is a time when simple introductions, active listening, and comforting nonverbal communication are important. Such supportive counseling helps to establish an atmosphere of trust whereby individual family members can eventually express their feelings and concerns to the speech-language pathologist (Ziolko, 1991).

Emotional support may also be offered by other professionals, volunteers, peer visitors, and the family's own support network. Some families may be ready at this time for a limited amount of information regarding stroke and aphasia, but it is important not to overwhelm them. Stroke/aphasia packets or brochures may be provided that include easy-to-read information and clear directions to further resources. The American Stroke Association and the National Aphasia Association are good sources for such materials. Generally, families will want information about physical problems at this stage (Michallet et al., 2001).

The recuperation stage may be a time when the speech-language pathologist can model some simple communication facilitating strategies for the family members to use. Simple strategies include (a) alerting the patient with aphasia that conversation will begin, (b) maintaining eye contact during conversation, (c) using well-formed short utterances, (d) pausing frequently and using a slow to moderate speaking rate, and (e) including the individual with aphasia in conversation even if his or her responses are limited to single words, gestures, or eye gazes.

As the patient moves into the rehabilitation stage, more formal and extensive education may be provided to families. In fact, most family education will be done during this phase. This is the time to solidify the family as active members in the communication rehabilitation process. This involves soliciting their goals for therapy and enlisting them in the therapeutic process itself. The speech-language pathologist should discuss both goals and expectations and how these coincide with neurologic and communication diagnostic findings. The family can also be an excellent source of information regarding the strategies they have developed to facilitate interaction.

Families will also want specific information about a range of topics during this time. Evans and colleagues (1994)

found that the most important constructs for families to understand are physical loss, cognitive and perceptual disorders, language impairment, and sexuality. Specifically, the nature of the communication problems, prognosis, how to facilitate communication, and how to make the transition to home and the postrehabilitation stage should be discussed in some depth. Family members should be encouraged to participate in therapy sessions and practice communication facilitating techniques with their family member. Encourage a problem-solving approach to repairing communication breakdowns with the patient. Practical issues, such as financial coverage of therapy and transportation needs, should be addressed. This is also the time to continue to provide emotional support as family members assume new responsibilities. Family members may be reluctant to discuss their feelings of stress and burden associated with caregiving. Many are grateful to express their emotions in a safe environment. This is a prime time to encourage participation in a support group.

It is not always easy to incorporate families in therapeutic activities or counseling programs because of limited time for therapy and the personal schedules of family members. To work effectively with the family during rehabilitation, we must be available during nontraditional times for therapy, such as evenings and weekends. Such availability demonstrates our commitment to helping family members maintain active participation in rehabilitation.

A smooth transition to the postrehabilitation stage is critical for the carryover of therapeutic techniques and family adjustment. The chronic stage presents long-term challenges for family members. This is a time when family members and the individual with aphasia no longer have the expectation that rehabilitation will result in improvement. Now, they must truly rely on their own internal and external resources. Michallet and colleagues (2001) found that if information needs were not met soon after the stroke, spouses experienced increased needs, worry, and difficulties in their interpersonal relationships with the patient and with others. Evans and colleagues (1988) found that families showed significantly less deterioration when they participated in a combination of education and counseling at 6 to 12 months poststroke. The results were sustained even after a year.

The individual with aphasia and the family members should not be surprised when therapy is terminated, and they should be well-prepared during the rehabilitation stage to assume their role as communication problem solvers. Avent and colleagues (2005) also suggest that this is a time to present information regarding long-term planning, travel and finances, living options, vocational retraining, volunteer opportunities, alternative therapies, and support groups. Referral to other rehabilitation counselors and support groups may be beneficial. With careful planning and guidance, the family should be able to reintegrate the

individual with aphasia into the family and their extended social network in former or newly created roles.

Some individuals with aphasia may need to relocate to some level of long-term care, ranging from an assisted-living to a skilled nursing facility. The decision to relocate from the family home may be made during the recuperation stage or some time after the individual has returned to the community. This decision is difficult for everyone involved, because it will change the nature of the relationship between the person with aphasia and his or her family. The decision is usually made because family caregivers are unable to provide the extensive physical care needed by some persons with aphasia. For some families, acceptance of permanent institutionalization may instill feelings of guilt; for others, institutionalization may bring a sense of relief. In either case, families continue as an important source of cognitive and social stimulation for the individual with aphasia. Counseling for the family should concentrate on helping them to understand the meaning of institutionalization, their role in the communication life of their loved one, and strategies for communicating in that setting. Teamwork with the social worker and nursing staff can facilitate adjustment to the new setting. Finally, families should be encouraged to join support groups and participate in family-focused activities within the settings.

Aphasia Family Groups and Self-Help Groups

One of the best ways to provide long-term support to the family is through involvement of the family in group programming, including language stimulation programs, aphasia family support groups, and self-help groups. Language stimulation groups may be formed as part of formal communication therapy or as a post-therapeutic strategy. These groups help individuals with aphasia to practice communication skills in a realistic context. This is also an excellent opportunity to have family members serve as communication partners and reinforce their use of facilitating strategies.

A natural adjunct to the language stimulation group is the aphasia family support group. This group can be a combination of individuals with aphasia and family members, or it can be family members alone. Family members may appreciate having their own reference group, in which they can openly exchange ideas and feelings. Such groups may be organized by speech-language pathologists or other mental health personnel. Some groups are organized by family members themselves and become self-help groups. A "self-help group" is composed of peers who share a common problem and unite to form a collective identity.

Speech-language pathologists may be asked to present one or a series of talks on aphasia and related disorders to such family groups. McCormick and Williams (1976) organized a 17-week program that covered such topics as the etiology of stroke, rehabilitation services, physical and medical

management, psychological/emotional changes, environmental barriers, diet, relaxation, and role changes. Pasquarello (1990) evaluated a similar type of program and found that family members specifically appreciated the opportunity to share feelings with others and find out how other families coped with a stroke. In another study on the effectiveness of support groups, Halm (1990) found that families perceived such groups as reducing anxiety and instilling hope. Support groups may assist families in locating available services and in advocating for services where they do not exist. Thus, topics chosen for such groups should be less didactic and include more open discussion and problem solving.

Another creative approach to supporting the family is family-to-family programs (Williams, 1991). Bissett, Haire, and Nelson (1978) designed a spouse advocate program, in which a family member of a person with aphasia assisted other individuals with aphasia and their families. By their unique kinship and empathy with the problem, these individuals can offer families special support. Such family-to-family programs are based on the premise that individuals with intimate knowledge of a problem can be excellent resources for other families while gaining a positive reward themselves from the helping experience. Such programs are not intended to replace professional counseling, but the families can help to relieve feelings of isolation and offer practical information about the logistics of obtaining funding and other assistive services. Williams (1991) states that family-to-family programs give families a “sense of control, predictability, and opportunity” (p. 305).

Family advocacy groups offer yet another dimension. Family members may wish to affiliate and become involved with local, state, and national family advocacy groups, such as the National Stroke Foundation and the National Head Injury Foundation. These groups serve important functions, such as affecting legislation on issues related to stroke and head injury and helping to change health-care and rehabilitation policies. Some families assume prominent roles in such organizations.

The speech-language pathologist should be available to these extended groups as a consultant, leader, counselor, or presenter. The goal in working with such groups is to provide strategies for facilitating communication with the individual with aphasia and informational resources regarding stroke and aphasia. Role playing and problem solving focused on difficult communicative interactions, rather than on didactic information regarding aphasia, are the most effective means of participation with family groups. Speech-language pathologists who feel competent in leading counseling sessions should also offer this service.

Respite and Wellness Programs

One of the most important programs to suggest to families of individuals with aphasia is a respite program. Known as

the gift of time, “respite” is short-term, temporary care that allows families to take a break from the daily routine of caregiving. Respite care may extend from a few hours to overnight to a longer period of time. Respite helps family to attend to their own needs and take vacations while knowing their loved one is safe and comfortable. Use of respite programs may actually forestall institutionalization and prevent abuse or neglect. Some family members may perceive respite and wellness programs as an abrogation of their devotion to the person with aphasia when, in fact, use of these programs is a healthy approach to caregiving. Respite may be offered by other family members or by formal, paid caregivers. Such services may be offered in the family home, in long-term care settings on a temporary basis, or through adult day-care programs associated with senior centers or settings. Van den Heuvel and colleagues (2002) suggest that long-term family programs that focus on coping and providing information should be combined with respite programs for maximum effect. Good sources of information about the availability of respite programs in a community include senior citizens centers, discharge planners in health-care settings, self-help groups, and respite locators on the Internet (e.g., www.respitelocator.org). Families should check the credentials of the centers or personnel who provide respite services.

A second option to suggest to families falls under the rubric of “wellness” programs. Such programs encourage individuals to assume responsibility for their own physical and emotional health through self-education, active participation in a healthy lifestyle, disease management programs, and attention to preventive measures for reducing risks to health. Some wellness programs are comprehensive; others focus on special areas of concern, such as physical health, walking, emotional health, and nutrition. Such programs may be offered at senior citizens centers, workplaces, hospitals, YMCAs, and other community centers. Caregivers should check with their insurance plans for information on funding for participation.

Staff Inservice

Paid caregivers play an enormous role in the success of speech-language intervention. Such caregivers include medical staff (e.g., physicians, nurses, and nursing assistants), rehabilitation staff (e.g., occupational, physical, and recreational therapists), housekeeping and personal-care aides, social work staff, and others. The primary responsibility for therapy rests with the speech-language pathologist, but the staff, particularly in the hospital-rehabilitation-nursing home contexts, have intense daily contact with the patient. These are the folks who make therapy functional. Staff-patient communication can be therapeutic if it facilitates the communication skills of the individual with aphasia and serves to stimulate and reinforce his or her communicative attempts.

Staff education may be done in several contexts, including orientation programs, traditional lecture-type inservice programs, role-playing inservices, self-instructional written or computer packages, video demonstrations, discussions, and modeling by the speech-language pathologist. How and when education is provided to the staff depends on the setting. For example, some settings may have orientation modules on topics such as communication problems for new employees. Others may schedule periodic inservices that are attended on a voluntary basis. Keep in mind that informal modeling of communicative strategies during everyday interaction is a natural way to show the staff successful ways of facilitating communication with those who have aphasia.

Traditional didactic inservices tend to focus on three major topics: (1) the nature of speech, language, and comprehension problems of the patient with aphasia and any associated disorders, such as apraxia and dysarthria; (2) the concept of a positive communication environment for the patient and other patients/residents; and (3) strategies for understanding and speaking with the patient. Aphasia inservices traditionally have some content devoted to defining aphasia and its symptomatology. When conducting this portion of the inservice, it is important not to overwhelm the staff with technical detail and jargon but, rather, to focus quickly and primarily on those topics that will help the audience to communicate more effectively and create a positive communication environment.

Staff are specifically interested in how they can communicate more easily during the delivery of care. Some clinicians may choose to present a list of “do’s and don’t’s” for communicating (e.g., speak slowly and clearly, talk about concrete topics, pause, check for comprehension, and ask questions that require forced choice responses). A more fruitful inservice technique, however, is to elicit facilitating techniques in role playing that focuses on solving communicative dilemmas. The clinician should role play various types of aphasia (e.g., predominantly expressive, receptive, and global) and have the staff role play themselves in these contexts. Following the role playing, the staff and clinician should discuss the scenario, which strategies were successful, and which strategies were not. Such an inservice fosters a problem-solving mentality in the staff and makes them active learners in the process. Two possible scenarios for role playing include:

Scenario 1 The staff member must convey to the patient with aphasia that he or she will be going to the podiatrist in 1 hour and must get ready.

Scenario 2 The staff member must respond to an unintelligible request by an individual with aphasia for something that is not obvious.

In addition, a second focus of an inservice should be on the importance of a rich, meaningful communication environment for all patients, including those with aphasia.

Staff-patient communication will be enhanced when staff members understand the value of successful communication and strategies for creating and maintaining a positive communication atmosphere. Examples of guidelines to suggest to staff include:

1. Staff should talk with the patient during medical and routine daily life care. Staff should talk about what they are doing during care, seek input from the patient regarding care, and solicit information about the individual’s interests. In addition, staff members should offer some information about themselves. Persons who know something about each other are more likely to identify with each other and communicate more frequently.
2. Provide the patient with clear, specific information about his or her status, the routine for the day, and other information that helps the patient to understand his or her care and setting.
3. Encourage the patient to talk or communicate through any verbal or nonverbal means possible about his or her needs and ideas. Providing positive reinforcement to the patient for communicating will generate more frequent attempts.
4. Provide the patient with active listening or supportive attention. Encourage staff to maintain eye contact while communicating and reflect on the content and underlying meaning of the patient’s communication. Other strategies include slowing or stopping an activity while talking, asking follow-up questions that demonstrate active listening, and reinforcing attempts at communication.
5. Encourage the individual with aphasia to participate in and talk about activities of interest.
6. Encourage other patients/residents to talk during the day with the patient who has aphasia. This may involve modeling communicative strategies and forming buddy/friendly visitor dyads.
7. Use positive humor during interactions. Humor can generate conversations and promote a positive atmosphere.
8. Value the communicative contribution of the patient. Remind staff that regardless of the communication difficulties that are present, the person with aphasia deserves adult-like respect.
9. Create a physical environment that promotes easy access to activities and persons of choice and facilitates hearing and vision while communicating.
10. Limit formal or informal rules that restrict communication attempts or topics.

Goal 5: Develop Self-Efficacy and Self-Actualization Skills for Client and Communication Partners

One of the goals of the environmental approach to therapy for aphasia is to develop self-efficacy and self-actualization

skills in our clients and their communication partners. Self-efficacy is defined as what people believe they are capable of doing (Kricos, 2006). If therapy is to be successful, persons with aphasia and their communication partners must view themselves as capable communication problem solvers. It is unrealistic that communication intervention will meet all the long-term needs of adults with aphasia, particularly in a time of limited financial support for extended therapy. From the very first interactions in diagnostic and therapeutic contexts, the speech-language pathologist needs to cultivate the concept that the individual with aphasia and his or her communication partners must independently define their own communication needs and solve communication dilemmas. When they accept responsibility for self-evaluation and continued problem solving, they will be better able to resolve new communication problems. This attitude of “I think I can” leads to self-empowerment and an attitude of long-term self-therapy.

Similarly, communication intervention should help to maximize the client’s self-actualization skills. Maslow (2006) states that self-actualizing people are realistic, accept themselves and others, act spontaneously and naturally, and have a mission in life. Clinicians have a responsibility to discuss how to access communication opportunities of choice. Other examples of self-actualization include asking for help when needed, discussing communication difficulties to relieve frustration, and self-advocating with policy makers for continued intervention.

Participation in community-based aphasia centers and in aphasia and family support groups are two long-term programs that promote opportunities for interaction, counseling, and continued communication problem solving (e.g., Kagan, 2003). They may also serve as a context for social programs as well as for political and social advocacy programs for those with aphasia. Families and patients with aphasia may unite to influence local and other governmental agencies about the needs of those with disabilities in the community. Such grass roots campaigns may influence social movements and promote social changes that reverberate across society.

As individuals with aphasia and their families move further away from direct rehabilitation, many will seek opportunities to reintegrate meaningfully into the community. Some may be able to return to work, and others may seek volunteer positions through their religious and community organizations, hospitals, and schools. One program that capitalizes on the unique knowledge of stroke is the Peer Visitor Program offered by the American Stroke Association.

Goal 6: Develop Greater Societal Awareness of Aphasia

The average person does not know what aphasia is or its short- and long-term impact on survivors of stroke and their caregivers (Code, Simmons-Mackie, Armstrong, & Armstrong,

2000). Unawareness leads to indifference and lack of support. Unless they have had a personal encounter with someone who has aphasia, most individuals are oblivious to the physical and social barriers that face such persons in the larger community. This is one reason why so many families, when faced with a stroke, are naïve regarding rehabilitation services and options. They may rely on their physicians and third-party payers for education and counseling, which may or may not be offered. Few persons with aphasia or their caregivers have a clear conception of what intervention is available at each stage of recovery, and most do not fully understand the difficulties that persons with aphasia will have in reintegrating meaningfully into their communities.

Third-party payers in particular have a vested interest in providing intervention at the least financial cost. Third-party payers such as Medicare and Medicaid are well aware of the increasing number of elderly, many of whom are at risk for stroke. These numbers translate to increased rehabilitation costs for the insurers, which want quality outcomes in the least amount of time and, hence, at the least cost. Long-term intervention is usually not an option with most insurance programs.

A number of efforts can be made to increase societal awareness of aphasia. It is essential that speech-language pathologists, both individually and through their professional organizations, accept responsibility for increasing social and political consciousness regarding this communication problem. Speech-language pathologists can articulate the dilemma of aphasia and argue for innovative programming to meet the needs of patients and their families. As stated previously, aphasia community groups have the potential to create social and political changes through the creation of organized lobby groups.

Research and Public Dissemination

The increased emphasis on functional and outcome-based research into aphasia should be made available to the public through local media, popular reading materials, and the Internet. Researchers and clinicians should take every opportunity to share their findings with the public and with colleagues. We cannot expect the public to search our literature or attend our conferences for information on innovative and effective approaches. We have the responsibility to share our knowledge base and, thus, educate the public on intervention options and outcomes.

Community Awareness Programs

Professional groups, rehabilitation programs, and individual professionals should participate in community awareness programs. This might involve programming during Aphasia Awareness Month. For example, rehabilitation programs might do special staff and family inservice programs or design bulletin boards or Microsoft PowerPoint programs

devoted to aphasia. Interviews and articles in local newspapers and television programs that describe aphasia services will have a broad circulation. Local malls are often willing to provide display space for community-oriented projects. Other community centers that support such presentations include senior centers and public schools. Key to each of these options is a personal approach to which the audience can relate. The audience wants to know what aphasia is and how to talk to someone who has it. Many communities have local newspapers or senior citizen-focused circulars featuring periodic special inserts on health-related topics. An article on aphasia and programs for those with aphasia and their families in such publications would be highly visible to the public.

College and university programs need to build this type of awareness and responsibility into training speech-language pathologists at the pre-professional level. For example, a consortium of college programs in Boston organized graduate students to educate hotel staff and local merchants about aphasia before the Speaking Out! Conference in that city in 2006 (National Aphasia Association, 2006). Undergraduate and graduate student organizations or aphasia classes can also assume responsibility for educating some facet of their community.

Clinicians should take every opportunity to do presentations on aphasia to community groups, including professional physician, nursing, and pharmacy groups as well as political, third-party, and policy-maker groups and service and religious organizations. The word needs to go out!

The Internet provides a relatively new and increasingly popular medium for sharing information about aphasia. VanBiervliet and Edwards-Schafer (2004) found increasing reliance on the Internet across all age groups, demographic groups, and geographic regions. Internet use is growing the fastest among older persons. Such information is assumed under the rubric of consumer health informatics. Rehabilitation centers can highlight their specific programs, technologies, and outcomes and offer vignettes of success cases. Aphasia associations and support groups can also advertise programs and disseminate research findings in everyday language. It is important that clinical practitioners keep abreast of the nature of aphasia information on the Internet, because this is where older persons and their caregivers are now turning for information.

Aphasia Centers

An increasing number of aphasia centers have been established in Canada, England, and the United States. Kagan (2003), who started the Aphasia Institute of Toronto, states that these centers provide an aphasia-friendly community and reflect a life participation approach to long-term intervention. Interestingly, Kagan states that participants in her center prefer to be called “members” rather than “clients” or

“patients.” In England, the Connect program (www.ukconnect.org) has opened the community to those with aphasia. Such centers focus on creating a positive communication environment where individuals with aphasia can use their communication abilities in meaningful, adult-like interaction. Many also offer programs that help caregivers to communicate more effectively and understand the challenges of living with a survivor of stroke. In addition to innovative and traditional interventions, these centers often have outreach programs that provide education on how persons with aphasia can be integrated into the physical and social community.

Volunteer Programs

Survivors of stroke, including those with aphasia, and their caregivers may want to help others who have incurred a stroke. Benefits of formal volunteerism for seniors in general include decreased depression (Li and Ferraro, 2005), slower decline in self-reported health and functioning levels, and improved mortality rates (Lum & Lightfoot, 2005). One example of a volunteer program is the Peer Visitor Program (Insalaco, Sellers, & Lubinski, 2004). After a seven-session training program, survivors/caregivers visit survivors of stroke in acute and rehabilitation settings. Originally designed by the American Stroke Association, the program has been modified and trained more than 30 individuals who have provided hundreds of visits to survivors of stroke and their families in a hospital during the past 2 years. Initial visits are supervised by the training staff, but visitors soon become independent. Problem areas are discussed at quarterly meetings. Peer visitors frequently comment on the “transformative” benefits they receive, including having a new purpose in life. Many add that they wish they had had such a visit when they were in the early stages after a stroke. Several of the original peer visitors have assumed leadership positions within the volunteer program during the past 2 years. Even those who have aphasia are able to communicate effectively with patients and families. Another volunteer program is Speaking Out!, a 10-week functional communication program delivered by trained volunteers (Worral & Yiu 2000). Undoubtedly, numerous other volunteer programs exist in which adults with aphasia and their caregivers can participate. Major problems in establishing volunteer programs with older persons include the cost of formal training, finding optimum training times, and the attrition rate of volunteers over time.

FUTURE TRENDS

This chapter challenges us to think outside the traditional aphasia intervention box and toward the physical and social environment of the person with aphasia. This chapter encourages you to choose between a narrow, skill focus to

your therapy and a broader ambition—one that includes the creation or reinforcement of a positive communication environment. The environmental philosophy presented in this chapter is perhaps the most holistic of those presented in this text in that it encompasses the individual with aphasia, the family and other caregivers, the physical and social milieu, and the broader sociopolitical community.

Fortunately, much has been done in the past 25 years that has implemented many of the ideas presented in the original environmental approach to aphasia (Lubinski, 1981). The World Health Organization framework for functioning, disability, and health has done much to focus on the relatedness of communication and participation for those with aphasia. The study of communication disability and quality of life continues to grow and creates an important database. Outcome measurement is becoming more inclusive of a variety of potential outcomes for both the person with aphasia and the caregivers. More documentation of environmental outcomes is needed. Innovative aphasia centers and community volunteer approaches offer a growing range of programming for persons with aphasia and their families. Increased finances to support the creation of such centers are needed. Political action groups that emanate from these programs are needed to influence governmental funding sources of the value of long-term, community-based communication programs. The challenge now is to sustain the momentum of creativity and promote greater societal understanding of, and support for, innovative aphasia programs across the community.

KEY POINTS

1. Clinicians must be aware that their therapeutic efforts often extend beyond the individual with aphasia to the broader social and physical environment and that these outcomes should be documented and provided as evidence of the value of speech-language intervention.
2. “Environment” is defined as the spectrum of influences that impinge on and are influenced by an individual during his or her life cycle. These forces emanate from the external physical and social environment together with those that arise from the unique internal contributions of each individual. The combination of these external and internal stimuli forms a “total environment” for each person.
3. The external environment is comprised of the physical world, the immediate social milieu in which an individual resides, and the social, political, and economic values, norms, and institutions of the larger

society. The internal environment created by the individual’s own characteristics include the total and evolving array of physical, sensory, psychological, cognitive, communicative, and emotional traits and needs.

4. The environmental systems approach is based on the philosophy that effective and functional therapy emanates from a comprehensive rehabilitative management model that takes into consideration the interrelatedness of individuals, their communication abilities, the effectiveness of communication partners to facilitate communication, and the physical and social environment.
5. Communication is a dyadic process. Therefore, by its very nature, aphasia creates problems for both members of that communication team. Although one individual incurs a stroke, each individual with whom that person communicates will face a predicament that must be resolved if communication is to continue successfully.
6. The environmental philosophy complements current thinking on disability, including empowerment philosophy, social and capabilities models of disability, and self-efficacy.
7. A positive communication environment is one where individuals have plentiful access to communication opportunities of choice and are valued as meaningful communication partners. At the core of this intervention is the belief that, even in the face of severe communication disability, individuals with aphasia need and want to communicate and that the physical and social environment can be a catalyst to promote successful communicative interaction.
8. A communication impaired environment is characterized by:
 - a. A lack of sensitivity to the value of communication as a cornerstone of effective functioning.
 - b. The idea that communication is a by-product, not a goal, of care.
 - c. Restrictive stated or unstated rules that limit communicative interaction.
 - d. Few or no communication partners of choice.
 - e. Limited physical accessibility to activities and partners.
 - f. Few reasons to talk that emanate from meaningful activities and interaction.
 - g. Lack of private places to talk that are easily accessible.
 - h. Sensory dimensions that confound communicative interaction.
 - i. Cognitively boring.
 - j. Limited or no support for communication partners.

9. Environmental goals within a comprehensive therapy program include:
 - a. Developing communication skills and those sensory and cognitive skills that underpin communication to the highest degree possible so that meaningful communication can occur.
 - b. Creating a physical environment that promotes successful communicative interaction.
 - c. Creating a positive communication environment that contains stimulating activities and a variety of interesting communication partners of choice.
 - d. Providing communication partners with techniques for facilitating and reinforcing communication through a variety of communication channels.
 - e. Developing self-actualization skills for individuals with aphasia and their significant others so that rehabilitation becomes a realistic and effective process.
 - f. Developing greater societal awareness of the nature and impact of aphasia as well as a philosophical and financial commitment to supporting communication intervention within the community.
10. Central to enacting an environmental approach is working effectively with family and other caregivers. This may involve inservice education, working with support groups, creating aphasia community centers, and encouraging those with aphasia and their families to participate in community volunteer programs, particularly ones that enhance aphasia awareness.

need improvement? What would you do to create a more positive communication environment in each setting? What obstacles might you have in implementing your plans? What might you do to reduce or eliminate these obstacles?

4. Create an outline or a Microsoft PowerPoint presentation for nursing staff in a long-term care setting that discusses the topic “Creating a Positive Communication Environment.” Present this to your peers, and ask for their feedback.
5. Working with families is an essential component to creating a positive communication environment. Consider the following questions regarding working with families:
 - a. What resources do families bring that will facilitate success in therapy?
 - b. What demands might family members have on them that might impede the success of therapy?
 - c. What strategies might be used to incorporate productively family members in therapy and help them to create a positive communication environment?
6. An important issue in all therapies is outcome measurement. How would you document changes in the communication environment of your client with aphasia?
7. One of the key points in this chapter is the need for greater societal awareness regarding adult aphasia.
 - a. Design a program for your agency that highlights Aphasia Awareness Month.
 - b. How can you incorporate adults with aphasia and their family caregivers in efforts to improve community awareness of aphasia?
 - c. Compare what can and should be done at the grass roots level versus the state and national levels to improve awareness of aphasia. Who should be involved, and what are the expected outcomes of such awareness programming?

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Third-party payers may be skeptical that environmental intervention will enhance the communication of an adult with aphasia. Provide an argument to justify an environmental approach as part of a comprehensive program of therapy for aphasia.
2. Make a visit to each of the following venues where therapy for aphasia might be done. How would you describe the way the physical and social environment either creates a positive communication environment or a communication-impaired environment?
 - a. Medical rehabilitation unit in a hospital.
 - b. Outpatient rehabilitation.
 - c. Home health care (patient's own home).
 - d. Long-term care.
3. After making the visit to each of the settings listed in the second activity, what physical and social characteristics

Chapter 13

Focusing on the Consequences of Aphasia: Helping Individuals Get What They Need

Linda J. Garcia

OBJECTIVES

The objectives of this chapter are (1) to introduce the reader to fundamental principles of disability models, (2) to illustrate how these can be used to structure intervention programs focused on the consequences of aphasia, and (3) to review existing programs that can be incorporated into a life consequences approach to intervention. It is hoped that the reader will better understand better the complexities of a life consequences approach to intervention while, at the same time, adopt a concrete framework for organizing this information.

Approximately 1 million Americans live with the consequences of aphasia at any given time, with approximately 80,000 new cases every year (National Stroke Association, 2006). In addition, an estimated 4.5 million Americans have Alzheimer's disease (Alzheimer's Association, 2006), and 1.4 million sustain traumatic brain injury each year (National Center for Injury Prevention and Control, 2006). If one adds to these numbers those who live, work, and interact with the individual who has the disorder, the human impact of these conditions on everyday life can take on incredible proportions.

You may have wondered how you or someone you know might react to becoming aphasic or how this would affect your life. You might have wondered what your priorities for intervention would be. Likely, you would want to regain as much of your language as possible and do as many of the same life activities you did before your stroke, or, as some, you might see this as an opportunity to set different goals and develop other skills. Do you think your priorities would be different if you became aphasic at age 20 than if you became aphasic at age 75? How about if you worked as a

speech-language pathologist or a lawyer versus a heavy machine operator? Do you think the impact of a language loss might be different? How about if you were living with a spouse and children, or just with your spouse, or living alone? Would the life priorities be different? What *would* be your priorities? In light of these questions, would you prioritize mobility, communication, pain management, or dealing with your incontinence? The point here is that even though two people might have exactly the same linguistic impairments, the impact on each of their lives could be completely different. Interventions focused on life consequences are preoccupied with exactly this impact.

THE NEED FOR A MODEL TO GUIDE INTERVENTION: A FRAMEWORK

No recipes exist for helping individuals return to their lives or redefine new ones following disease, disorder, or trauma. One solution may be adequate for one situation or one person but not for another. Likewise, one solution might work at one specific time in the person's life and not at another. Because aphasia is generally a chronic disorder, its impact may be felt differently at its onset as opposed to 10 years later. The only way to understand the interaction of these many factors is to use a framework that explains the relationships among the person and his or her abilities, environment, and life goals. Disability models can do this. Traditionally, our interventions have been guided by medical ideology. More modern models are based on social ideology (Byng & Duchan, 2005; Mackay, 2003).

To couch aphasia within the context of disability models is to accept that communication is only part of the story. To illustrate this point, let us use the analogy of the six blind men and the elephant (Saxe, 1963). This legend recounts the story of six blind men who, wondering what an elephant looked like, each touched a different part of the elephant's anatomy. The first touched its side and concluded that the elephant looked like a wall. The second touched its tusk and compared it to a spear. The third touched the trunk and

decided it was a snake. The fourth touched the leg, which seemed to be a tree without leaves. The fifth found the ear and concluded the elephant looked like a fan, and the sixth touched the tail and imagined it to look like a rope. Each was convinced of the truth of his conclusions, yet each one of them was wrong.

How might this apply to our knowledge of the consequences of aphasia? Not unlike the six blind men, the foremothers of speech-language pathology relegated communication to the speech apparatus without necessarily considering the other aspects of communication (Duchan, 2006). With increasing scientific knowledge, we came to see communication as a complex system of interrelated abilities. We might use the analogy of the six blind men and the elephant to compare the phonetic system, phonology, syntax, semantics, pragmatics, and discourse as different parts of the elephant's anatomy, with the elephant itself representing the system of communication. No clinician or researcher today would argue against the fact that communication involves at least all of these elements. In terms of guiding intervention, for instance, we know that if we intervene on the syntactic aspects of language, we must be cognizant of the impact of the semantic system. We have theories as to how these elements function together and how we might use one aspect to facilitate the other during intervention.

Let us take the analogy one step further by considering communication as part of a cognitive system, with elements such as memory, attention, vision, and audition being the other components. Again, few would argue against the fact that all these elements are important to understand how one communicates. As in the first example, one might intervene and focus on the receptive aspects of communication while being cognizant of the impact of sensory systems, such as vision or audition, or other components, such as attention. We have conceptual frameworks with which to understand the interdependence of these elements so that we can better intervene on the communication aspects.

What happens if we use this same analogy yet again to understand and intervene on the impact of a communication disorder on an individual's life? Let us say that the elephant represents the person's integration into different aspects of his or her life (e.g., work integration and interpersonal relationships). In this context, communication is only one part of the elephant. The others might include culture, a supportive spouse, and disability laws. We would be foolish to consider looking at just one aspect of the elephant (e.g., communication) and assume that this is the only thing that influences a person's functioning. Disability models give us the framework from which to understand the interaction of these larger-scale elements (Byng & Duchan, 2005). Variations of international disability models have been around for more than 25 years and, as Ross and Wertz (2005) have pointed out, they are likely to stay. Although it can be argued that much work remains to be done, the basic

philosophies behind these models provide a useful framework from which to understand the possible relationships among components of individual functioning that go beyond the communication patterns per se.

The ICF: Getting a Framework to Guide Intervention

Use disability models such as the International Classification of Functioning, Disability, and Health (World Health Organization, 2001), or ICF, to capture the impact of aphasia on everyday life is a growing trend (Simmons-Mackie, Kearns, & Potechin, 2005; Threats, 2006; Threats & Worrall, 2004). This framework has been widely diffused to both clinicians and researchers, and reference to this model is almost routine for those who are interested in psychosocial functioning.

Although an argument exists over whether the ICF can be used as part of an appraisal of aphasia (Ross & Wertz, 2005), the American Speech-Language-Hearing Association (2001), or ASHA, encourages the use of the ICF "to describe the role of speech-language pathologists in enhancing quality of life by optimizing human communication behavior, swallowing, or other upper aerodigestive functions regardless of setting." (p. I-22a-b). Travis Threats, a speech-language pathologist, is currently working with colleagues to develop a clinical manual to help prepare clinicians to use the ICF framework and classification (Reed et al., 2005). A better understanding of the historical development of the ICF may help the clinician to evaluate the relevance and importance of a framework such as the ICF in planning therapy.

The ICF is part of what the World Health Organization (WHO) considers to be a "family of classification systems." The intention is that these classification systems be used, as much as possible, in a complementary fashion. The International Classification of Diseases (WHO, 1999), or ICD, which is in the process of being updated, classifies health conditions. The ICF was developed to classify human functioning as a result of these health conditions. The impetus behind the ICF was to develop a common international language to describe the consequences of disease, trauma, and disorder. The WHO wished the classification to be used (1) for **scientific** reasons to look at the impact of health conditions, (2) for improving **services** by offering a framework for designing interventions and outcomes, (3) for helping individuals specify their **needs**, (4) for **economic** planning, and (5) for helping in the defense of the **rights** of individuals with functional limitations. The classification is not an evaluation system, nor is it meant to be a list of discipline-specific functions. Its aim is to capture an individual's level of functioning through use of a common language that includes a series of codes and categories.

Since its publication, researchers have offered preliminary applications of the ICF framework to the area of aphasia (Davidson & Worrall, 2000; Howe, Worrall, & Hickson,

2004; Threats, 2006; Threats & Worrall, 2004; Worrall, McCooey, Davidson, Larkins, & Hickson, 2002). As early as 1980, the WHO had already given us the International Classification of Impairments, Disabilities, and Handicaps (WHO, 1980), or ICIDH, and speech-language pathologists later applied these concepts to aphasia (LeDorze & Brassard, 1995). Today, however, neither the ICF nor the ICIDH has yet been proven to be useful in terms of its classification categories. In a pilot study, Garcia and colleagues (2003) used the categories from the ICF to describe the level of functioning of two individuals with aphasia. They found the classification to be incomplete in its ability to describe language functions as well as difficult to code in terms of environmental influence. Most uses still tend to focus on the philosophy rather than the classification per se.

The ICF was developed as an improvement over the original ICIDH, which was a linear model (Fig. 13-1). In the ICIDH, the model basically suggested that a disease or disorder (e.g., cerebrovascular accident [CVA]), would lead to impairments (e.g., a brain lesion), which in turn would lead to disabilities (e.g., aphasia), which in turn would lead to handicaps (e.g., not being able to work). Although the international community was pleased to see that we now considered the impact of “disabilities” such as aphasia, it was concerned about the linearity of the model. Individuals with functional limitations, clinicians, and disability researchers were dismayed that this model portrayed individuals with functional limitations as being “doomed” to have handicaps in the real world. The unidirectional impact (as suggested by the direction of the arrows in Fig. 13-1), indicated the likely effect on a handicap, suggesting that the disorder dictated the outcome. In this model, neither the physical environment nor society was held to be even partly accountable for creating obstacles to integration. It followed from this model, then, that if we worked on the impairments (e.g., brain lesion) and/or the disability (e.g., the aphasia itself), we would prevent the person from living with a handicap and from being “handicapped.” The bottom line was that if the language impairment could be reduced, the consequences could also be reduced.

Newer models of disability encourage us to put these impairment-based therapies in a larger context. After many years of international consultation and the development of alpha and beta versions of the ICIDH-2, the WHO pro-

Figure 13-1. The International Classification of Impairments, Disabilities and Handicap (ICIDH) model (World Health Organization, 1980).

Figure 13-2. Model of the International Classification of Functioning, Disability and Health (ICF) (World Health Organization, 2001).

posed the newer ICF. One of the main differences between the ICF and the original ICIDH is the recognition that environmental factors (both physical and social) play a role in determining the level of functioning. Figure 13-2 provides a graphic representation of the ICF framework.

In this newer framework, the three key elements—Body function, Activities, and Participation (roughly the neutral versions of the three ICIDH domains)—are influenced by environmental factors and by personal factors. The premise here is that each of these three basic elements can be classified within an environmental context. Therefore, functioning can be interpreted in the context of a supportive spouse, a facilitative conversational partner, or access to an electronic communication board. Functioning can also be interpreted in the context of personal factors, such as age, sex, and cultural background.

The ICF has been criticized on many levels, including having a framework that remains more medically based than socially based (Fougeyrollas, 2006; Hilari, 2005; Whiteneck, 2006). Part of this criticism is that no clear distinction is made between the domains of Activities and Participation. As Worrall and Cruice (2005) clarify, the differences are more in relation to the levels of context. Activities refers more to what the person can do and Participation to what the individual actually does in his or her real environments. Because the environmental factors interact with all elements in this model, however, the distinction between Activities and Participation remains nebulous. In fact, the list of Activities and Participation elements are actually all in one list in the ICF. It is understandable, therefore, that the clinician may have difficulty distinguishing the two. Nonetheless, the principles of the ICF help us to see all

components of functioning. If we see ourselves as focusing on only one aspect of the model, we are back to the six blind men and the elephant.

An Alternative: The DCP Model

The current discussion surrounding these frameworks may appear to be academic to some, but it is important for the clinician to use some type of framework to guide consequence-based therapy. Interventions using a life consequences approach are not new, but clinicians might find it hard to understand how all the components fit together. For this reason, I would like to introduce an alternative model that might help clinicians to focus on an integrated approach—the Disability Creation Process model (Fougeyrollas, Cloutier, Bergeron, Côté, & St. Michel, 1998), or DCP. Both the ICF and the DCP models are closely related and use similar concepts. I find the DCP to be easier to interpret, however, and the reader is therefore encouraged to see the remainder of this chapter as a possible application of the ICF principles through use of the DCP conceptual model (1998).

Fougeyrollas and colleagues were very much involved in the ICIDH revision process and were instrumental in the inclusion of environmental factors in the WHO framework. The primary difference between the ICF and the DCP is the exclusivity of the components. In the DCP model, a clear distinction exists between the Activities, which is called Capabilities, and Participation, which is called Life Habits (Fig. 13-3). Capabilities do not include environmental factors, but participation necessarily includes the influ-

ence of the environment. This is much more than an academic distinction and is extremely important, because it helps the clinician to distinguish what belongs to the person (personal factors) and what belongs to the environment (environmental factors). Hence, intervention strategies can be geared toward one, the other, or both. The model acknowledges that if the therapist chooses to work at the Capabilities level (e.g., working on the linguistic aspects of aphasia), improvement is likely to influence performance in life activities and roles. If the therapist chooses to work on the environmental factors (e.g., partners), however, reduction of environmental obstacles, in and of themselves, can impact participation.

Teasing out the environmental factors is important for advocacy, because it offers the opportunity to identify those factors that belong to the society and to the individual's milieu. Hence, comparisons across nations and health-care systems are more easily made. For instance, the impact of managed care versus universal health care in rehabilitation can be easily explained using these principles. CVAs or aphasia (personal factors in the DCP) can affect individuals in very similar ways across countries, because human bodies function, overall, in similar ways. The health-care system in one country can be a facilitator, and in another, an obstacle, when it comes to allowing people with aphasia to receive therapy. Environmental factors themselves constitute a separate component and should be viewed as such by therapists. This concept allows us to identify society's responsibility and acknowledges the role that it plays in facilitating integration (Kagan & Leblanc, 2002).

Figure 13-3. The Disability Creation Process (DCP) model. (From Fougeyrollas et al., 1998; with permission.)

Another important concept supported by the proponents of the DCP model is that the model applies to all human beings. The DCP model, in its historical development, was derived from anthropological theories of human development (Fougeyrollas being an anthropologist himself by profession). Hence, the proponents of this model stress that it can be applied to all individuals with or without perceived “disabilities.” The premise is that all of us live with the consequences of some type of health disorder, disease, or trauma. Whether you struggle with relationships because of a lack of self esteem or you need reading glasses or you live with aphasia, you are at risk of living in a situation of handicap. A clinician who gives you reading glasses (an environmental factor) or a surgeon who performs corrective surgery (impacting on body structure) can remove this situation of handicap and allow you to function in your selected life activities or roles. Likewise, if you are the parent of a child with a health disorder or the adult child of an ailing parent, the model can be applied to your situation. Your own life activity or role (e.g., work) may be affected by someone else’s (your child’s or parent’s) health condition. You are then the person who can be seen to live the consequences of your ailing parents’, spouse’s, or child’s health condition. Take, for instance, the case of dementia. Informal caregivers who live with individuals who have dementia live the consequences of their loved one’s disorder each and every day. Seeing the consequences through the disability model helps us to appreciate how the loved one’s health condition (dementia) impacts the spouse’s life activities. Helping the individual with dementia through programs such as respite care helps the caregiver to return, momentarily, to some of those life activities. This reasoning could and should be applied to aphasia as well.

Later in the chapter, you, the reader, will be asked to apply the model to yourself. Seeing yourself in a human developmental model will help you to recognize the impact of health conditions and, perhaps, better prepare you for understanding the possible consequences of aphasia.

Bottom line: Environment should be considered as an independent component capable of influencing integration and, therefore, as a potential focus of intervention, regardless of your preferred model.

Operational Definitions

The following section will help the clinician to understand conceptually the different elements of a disability model by way of the DCP definitions. The choice of the DCP model for this discussion is to help clinicians operationalize the concepts of Activities and Participation to guide intervention.

The Life Activities and Roles

The logical place to start is the Life Participation component—or “life habits” in the DCP model. A life habit is “a daily

activity or a social role valued by the person or his socio-cultural context according to his characteristics (age, sex, socio-cultural identity, etc.) which ensures his survival and well-being in his society throughout his lifetime.” (Fougeyrollas et al., 1998, p. 131). This can include anything from being involved in your personal self-care (physical and mental) to taking part in community activities or interpersonal relationships. A person’s success in his or her life activity or role can be measured on a scale going from full social participation (meaning no problems at all with this activity or role) to a situation of handicap. A “situation” of handicap should be understood conceptually as something that might be temporary. It is influenced by the individual’s abilities and by the support of his or her environment. Hence, the more the individual’s abilities improve (i.e., less aphasia) and the more the environment becomes supportive, the less the individual lives with a situation of handicap, and the more his or her performance “slides” along the continuum toward social participation.

The key, then, clinically is to determine which daily activities or social roles are valued by the person at that point in time in his or her life. The activities or roles that appear to cause problems are not likely to be permanent. An individual can live a situation of handicap at some point in time and not at another, despite having the same functional limitation (e.g., same degree of aphasia). Because some situations can disappear (e.g., no longer need to return to work) and other situations can be created (e.g., planning more leisure activities), speech-language pathology services should be available throughout the life span. For instance, someone who wishes to reintegrate the workforce at age 45 following a stroke may be faced with a situation of handicap; however, at retirement, this may no longer be an issue. This person may also be experiencing situations of handicap in some leisure activities that may warrant different interventions from a speech-language pathologist. An approach to therapy based on life consequences would start by identifying the life activities and roles that are (1) important to the individual and/or to his or her culture or society and (2) done frequently by the individual at a certain point in time. Examples of creative ways for identifying these goals will be discussed later.

The Personal Factors

Assuming that the individual you are seeing is experiencing a situation of handicap with an activity and/or social role, the model suggests that this is the case because the person (1) has limitations related to personal factors (body structure or mental or physical capabilities) and/or (2) is subject to obstacles in the environment that prevent the achievement of higher participation levels. The next step to intervention will then be to identify these contributing factors.

Personal factors include a person’s characteristics and capabilities. In addition to age, sex, culture, education, and the like, it includes how the body structures function and how

limited or accomplished the individual is in terms of physical, sensory, mental, and cognitive abilities. The actual aphasia as well as motivation levels or attention are part of these personal factors. Some conceptualize these factors as “within the skin” (what the individual brings to the situation of handicap). If it was felt that the situation of handicap could be helped by intervening at the level of body structure, interventions that target body systems would be warranted (e.g., surgical procedures for aneurysms). If it was felt that the situations of handicap were caused by specific functional limitations in the individual’s physical, sensory, mental, and/or cognitive capabilities, therapy for these capabilities would be warranted. A “capability” is defined as “the potential of a person to accomplish mental or physical activities” (Fougeyrollas et al., 1998, p. 69) without taking any environmental factors into account. Therapy focused on capabilities, when applied to aphasia, might involve linguistic or neuropsychologically based therapies as well as therapies aimed to improve other psychological components, such as motivational levels. Within a team context, it would also include other therapies, such as physical therapies or psychological therapies. It is important to note that the link is always made with participation levels in life activities and roles.

At the personal factors level, the clinician looks for what the person can do *without* environmental obstacles or environmental help. This gives the clinician a clearer perspective from which to identify the impact of environmental factors as an independent, equally important component.

Environmental Factors

The situation of handicap experienced by the individual is also likely to be the result of environmental barriers. An “environmental factor” is “a physical or social dimension that determines a society’s organization and context” (Fougeyrollas et al., 1998, p. 111). It can create an obstacle to integration, or it can facilitate integration. These factors can include physical barriers, such as noise; social barriers, such as an unsupportive spouse; or organizational barriers, such as lack of services. The clinician’s goal here is to help reduce the barriers and increase the number of facilitators. So, if it was felt that the environmental obstacles contributed to the situation of handicap, intervention at this level would be warranted. Examples of how to apply these strategies to aphasia are given later in this chapter.

Summary of Disability Models

In summary, disability models can be used to offer a framework for planning team interventions. Whether one impacts on personal or environmental factors or both, intervention has the potential to help achieve the ultimate outcome, which is to improve quality of life and integration into society. The premise is that an individual may have few functional limitations but face environmental factors that create enormous

obstacles to intervention. Likewise, a person may have very significant functional limitations yet, because of a facilitative environment, succeed in participating in his or her life activity or role. Hence, intervention on environmental factors can be just as important as focusing on language skills.

Applying a Disability Model to Your Own Functioning

If clinicians are to apply disability model concepts to help people with aphasia and their loved ones better integrate their lives, what better way to understand the philosophy than to apply these concepts to their own lives? As stated earlier, the concepts underlying disability models are meant, conceptually, to be universal. The following exercise is geared to helping the reader learn the concepts through personal applications. Similar questions will arise with those who seek our services.

First, pick a life activity or role that you feel you are not achieving to your fullest but that is important to you and/or your culture. Make sure this is something that you normally do or would like to do, and make sure it is something that you want to do frequently enough for it to be considered important to you. You might consider nutrition (e.g., diet), fitness (e.g., both mental and physical fitness), housing (e.g., finding lodging and/or decorating it), financial and family responsibilities, sexual activities, affective and social interpersonal relationships, community and spiritual involvement, education or employment, or leisure (e.g., sports or arts) activities. Just pick one life activity that impacts your quality of life.

Let us call this your “unfulfilled life activity,” and for illustrative purposes, let us say that this activity falls into the Fitness category. You feel that you would like to take part in more physical activity so that you can keep in shape. To help you, we must identify the reasons why you are unable to take part in activities that keep you in shape. First, is there a body structure or system that prevents you from fulfilling your life activity? Perhaps a past knee injury prevents you from doing many of the physical activities you once did or would like to do. If so, is there anything you can do about this body structure or system? Would surgery help? Would medication help?

Next, take a quick inventory of your personal capabilities and see if any might limit your ability to take part in your unfulfilled life activity. These might include your intellectual capabilities (e.g., consciousness, memory, and thought), language capabilities, behavior capabilities (e.g., volition and affectivity), sensory and perceptual capabilities, motor activity capabilities (e.g., voluntary body part movements and manual activities), as well as capabilities related to breathing, digestion, excretion, reproduction, protection, and resistance (e.g., tolerance to sound and humidity as well as mental endurance).

We are basically looking for the contribution these capabilities might be having on your inability to fulfill your life activity. In the example given above, you might find that you

are unable to perform your life activity of keeping in shape because of a lack of motivation on your part or, again, because of limited motor capabilities (e.g., perhaps because of a previous injury). Can something be done about these capabilities? Whereas intervention based on body structures might come in the form of knee surgery, one based on capabilities might come in the form of physiotherapy, for instance.

Your inquiry does not stop here. According to models such as the DCP, fulfillment of your life activity is the result of two elements: personal factors, and environmental factors. We examined your body structure as a possible cause for not keeping in shape. We looked at what you can or cannot do (capabilities) as a cause for the unfulfilled activity. We must also, however, look at the environmental factors. Consider again your specific situation. Does your physical environment, such as where you live or elements related to nature (e.g., too much snow or too much heat), contribute? Are these things preventing you from taking part in your activity or role? Also, think of social environments, such as family and friends and work colleagues, or yet again, you might look at organizational or governmental rules and regulations. For instance, in the example given above, there may not be many activities available to people in your age group or geographic area, thereby diminishing the chances you will be involved with these types of physical activities. To resolve your problem, you might think of finding a friend who can do a physical activity with you, starting a local activity yourself, or lobbying the municipal government to develop other activities for your age group.

In conclusion, to help you take part in your selected life activity or role, you might need to work on the body structure (e.g., knee surgery), work on the capability (e.g., improve movement through physiotherapy or work on your motivation), or get a facilitator (e.g., find a friend to join a physical activity program with you). The challenge is to find which of these parameters is most efficient over the short and long term in helping you to integrate your life activity or role. Basically, the disability models, whether you espouse to the DCP or the ICF, stress that the individual's functioning is not solely the result of a series of reduced functional limitations (e.g., aphasia + hemiplegia + lack of motivation) but, rather, interact with social and physical environments.

Bottom line: Current disability models are meant to use concepts that are applicable to all human beings. The number and level of severity of the situations of handicap will vary as a function of personal and environmental factors.

APPLYING THE FRAMEWORK TO APHASIA

The First Component: Identifying Disrupted Life Activities and Roles

As has been said, any clinician wishing to use a framework that takes into account the consequences of aphasia must

identify the very consequences that might need intervention. The challenge in applying a life consequences approach is to identify the life activity or social role that the individual would like to address with the help of the therapeutic team. Whereas in more traditional approaches the therapist examines the results of the linguistic evaluation to determine the goals of therapy, the life consequences approach requires the therapist to obtain information from individuals regarding their involvement in life activities and roles as well as their perceptions of the successes they feel they are attaining.

A Question of Perspective

A key element in successful identification of life participation activities and roles is the perception of the individual with aphasia. The clinician should make every effort to include the individual with the disorder in identifying the perceived level of accomplishment of life activities and roles as well as the level of satisfaction. Not only should the individual be instrumental in choosing the goal, he or she should indicate the level of importance as well as the frequency with which the life activities are performed. This will influence the clinical decision to incorporate these activities as target goals for therapy. Only as a last resort should a substitute decision maker be requested to help identify the life participation goals for the person with aphasia.

The aphasia literature contains considerable evidence that proxies are not good substitutes for respondents with aphasia. The paper by Byng and Duchan (2005) on the application of social model philosophies to therapy for aphasia stresses the importance of involving the person with aphasia in all decisions that concern therapeutic interventions. An excellent study by Cruice, Worrall, Hickson, and Murison (2005) compared patients' own ratings of quality of life to those of family and friends. These ratings were taken from (1) a global quality of life measure ("How would you rate your quality of life?"); (2) the Short Form 36 Health Survey, which is a scale of functional outcome; (3) a short, usable quality-of-life scale called the Dartmouth COOP Charts; and (4) the condensed Ryff Psychological Well-Being scale. The authors found that, overall, the perceptions of proxy respondents could not be assumed to be interchangeable with those of the individuals with aphasia. This, of course, depended on the nature of the questions being asked—the more subjective the category, the larger the discrepancy in ratings between the groups. Sometimes, it might be difficult to obtain this type of information from persons with aphasia, but Engell, Hütter, Willmes, and Huber (2003) found an effective way to evaluate quality of life in aphasia using a pictorial self-rating procedure. They, too, found differences in ratings between persons with aphasia and their relatives.

Using a more qualitative interview approach, Parr, Byng, and Gilpin (1997) interviewed 50 individuals with aphasia

and reported on their experiences in living with aphasia. In a subsequent paper, Parr (2001) reflected on the importance of the perspective of these individuals with aphasia and highlighted how this might affect an “outsider’s” view of the consequences of aphasia. She pointed out, for instance, that a person with aphasia may view the impact of aphasia on his or her inability to return to work as being much more invasive compared with the perceptions of the outsider clinician.

In conclusion, it is important to adopt a person-centered approach when identifying the primary areas of life participation that are most problematic. Doing so elevates our level of professionalism as clinicians.

Bottom line: Include the person with aphasia when identifying the goals based on life participation.

Getting Help from Formal Measures of Quality of Life

The therapist has several options, none of them ideal, for obtaining quality-of-life information. Options include generic or disease-specific quality of life measures, informal questionnaires and interviews, and participation=level assessment scales.

The WHO Quality of Life (WHOQOL) group (1998) defines “quality of life” as “individuals’ perceptions of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns” (p. 551). This description of quality of life includes many components of what has been reviewed so far under life participation. Because aphasia can affect an individual’s capacity to understand and/or express written or oral language, it is no small task to obtain this information using formal measures (Hilari & Byng, 2001).

In aphasia, many of our measures of functioning focus greatly on communication (Frattali, 1998), and when communication is impaired, we assume quality of life is also impaired. Hence, the measures we have of communication and conversational abilities become central to the measure of functional outcome. In her chapter on social approaches to aphasia intervention, Simmons-Mackie (2001) offers a comprehensive list of measures used to assess functional communication, either through scales such as the ASHA Functional Assessment of Communication Skills for Adults (Frattali, Thompson, Holland, Wohl, & Ferketic, 1995), or ASHA-FACS, or through judgment ratings such as the Communicative Effectiveness Index (Lomas et al., 1989), or CETI, in which, using a brief scale, families and friends rate how effectively the person with aphasia communicates in various daily communication activities. These are not meant to be quality-of-life scales, nor are they meant to be scales of overall functioning. Unfortunately, some clinicians interpret the results from these scales as outcome scales of overall functioning.

Simmons-Mackie, Threats, and Kagan (2005) surveyed speech-language pathologists on their practice of outcome assessment. In that study, the majority of respondents viewed outcomes as changes in therapy or intervention, with only a few viewing outcome as a change in life participation. In fact, only four respondents even referred explicitly to the term “participation” despite the increasing use of models such as the ICF in the literature. Close to half of the respondents stated that they used some model or theory to guide their choice of outcome assessment methods. The authors concluded, “There appeared to be no general consensus regarding how one measures or reports improvement after intervention or what constitutes improvement” (p. 12). If clinicians are not in agreement about what constitutes outcome despite half of them using some model of functioning, how can we hope to document and effect change on the life consequences of aphasia?

The ASHA guidelines (ASHA, 2001) stress that speech-language pathologists should have, as an outcome goal, the overall improvement of quality of life for the individuals in their care. Outcome cannot be limited to communication skills alone, and it does not appear to be the case that clinicians have access to a ready-made, universally accepted way of measuring perceived quality of life or participation of individuals with aphasia (Simmons-Mackie, Threats, & Kagan, 2005). This is where disability models can help. In disability terms, and for the purposes of the current chapter, the goal of intervention might be the outcome that improves the client’s perceived quality of life by improving participation in life situations or decreasing the number of situations of handicap. As explained previously in this chapter, the focus might be on linguistic intervention, behavioral intervention, elimination of environmental obstacles, or adoption of new life goals. Whatever the approach, however, the outcome goals per se may not, in and of themselves, be communication goals.

In other words, whether one aims to improve cellular activity poststroke, improve naming ability, or facilitate conversations in real-world settings, agreement hopefully exists that our ultimate outcome is improved quality of life. Further, we can assume that quality of life encompasses much more than communication despite the important effect of communication on quality of life (Cruice, Worrall, & Hickson, 2003). Although quality of life is closely linked to participation in life activities and goals, they are not one and the same (Hirsh & Holland, 2000). From this perspective, functional communication assessments are not sufficient. Hirsh and Holland (2000) point out that although quality-of-life measures were originally used for economic reasons and to obtain population-level information regarding health status, most quality-of-life measures now include some assessment of the individual’s perception of how he or she is getting along with his or her life. A recent DVD video developed by McWreath (2005) helps the public and others

with aphasia understand, through words and pictures, the impact of aphasia.

Throughout the quality-of-life literature, much discussion is found about its measurement and whether scales (McDowell & Newell, 1996) are disease specific or generic. All can be useful, and the choice depends on the clinician's goals. This discussion extends beyond the scope of this chapter but is intrinsic to the clinician's understanding of participation, so a brief discussion is warranted. The proponents of disease-specific scales take the position that, as a group, the lived experiences of individuals with similar health conditions will also be similar. For instance, people with aphasia may find similar difficulties in the realization of their life activities that are not usually problematic for people with other types of health conditions. The underlying assumption is that the health condition is directly influencing the quality of life. These scales will be most sensitive to linguistic change following intervention, because the very design of the scale includes language-dependent items. In the area of aphasia, very few quality-of-life scales have been designed specifically for people with aphasia. The Stroke and Aphasia Quality of Life Scale-39 (Hilari, Byng, Lamping, & Smith, 2003), or SAQOL, is an adapted version of the Stroke-Specific Quality of Life Scale (Williams, Weinberger, Harris, Clark, & Biller, 1999), or SSQOL. The SSQOL includes 49 items within 12 domains (energy, family roles, language, mobility, mood, personality, self-care, social roles, thinking, upper extremity function, vision, and work/productivity), which must be self-evaluated on a five-point scale. The SAQOL includes four additional items specifically related to communication. Figure 13-4 gives a sample of the scoresheet used in the SAQOL; a more aphasia-friendly presenter's sheet is available with the test. Psychometric data on the use of the SAQOL with the stroke population at large will be available shortly. As with the SF-36 Health Survey (Ware, Kosinski, & Gandek, 2000), the scale evaluates functional limitations in the way of abilities as much as it does participation levels. The role of environmental factors, however, is not looked at specifically. Many of the domains that are included are actually "personal factors" (using DCP terminology). In fact, some items are actually perceptions of how well individuals feel they are doing on capabilities (e.g. "Do you have trouble seeing things off to one side?") rather than life activities or roles. Other scales, such as the Burden of Stroke Scale, or BOSS, by Doyle, McNeil, Hula, and Mikolic (2003) will offer an interesting tool for looking at the limitations stroke might have on different activities and psychological states. Once again, however, this scale mixes activity limitations with participation levels. This tool was also specifically designed for survivors of stroke. Both scales try to make links between the health condition (in this case, stroke) and success in various life activities.

Another point of view in assessing quality of life is that generic measures are preferable if one wants to bring about

policy changes. Generic scales permit comparisons across diagnoses, whether across individuals with different diagnoses or within one individual who lives with the impact of several diagnoses (McDowell & Newell, 2006). Generic measures of quality of life may allow clinicians to discover other areas of life participation that might have been affected by the disorder but not been identified *a priori* as a potential area of difficulty. Likewise, they may discover that conditions other than the aphasia are contributing to the situation of handicap. The proponents of generic quality-of-life measures hold that the purpose of these measures is to look at the impact on overall functioning, not to obtain more information about the health condition itself. They believe that a ripple effect exists in terms of impact and that the health condition can affect other parameters of functioning not previously foreseen.

Generic quality-of-life measures allow us to compare the life consequences of aphasia to other conditions—for example, rhinitis, which has a much higher prevalence in the population but life consequences that may be very different. Such generic quality-of-life measures include the WHOQOL (WHOQOL Group, 1998), which is quite comprehensive and evaluates many life domains. The WHOQOL comes in a long version (100 items) and an abbreviated version (26 items) and is available in 20 languages. It looks at six domains: (1) physical health (energy, pain, and sleep), (2) psychological (negative and positive feelings, self esteem, and thinking), (3) level of independence (mobility, activities of daily living, and work capacity), (4) social relations (including support), (5) environment (financial, home, leisure, and transport), and (6) spirituality (religion and spiritual beliefs). This scale is quite lengthy and, like many others, might be difficult to administer to people with aphasia. One of the attractive features of this tool is that it is standardized across many different countries and languages.

Other generic scales focus on life satisfaction. The Life Satisfaction Questionnaire (Carlsson & Hamrin, 2002) evaluates the level of functioning and the respondent's perceived satisfaction with life areas. For instance, it looks at the impact of various symptoms, such as tiredness, lack of fitness, loss of appetite, pain, how happy the respondent is with work, financial situation, health, where the respondent lives, level of activity, and relationships. The astute clinician might want to look at the relationship between the ratings from those with aphasia on certain of these items and (1) the severity of their aphasia and (2) the support they are receiving.

Two other scales based on disability models also merit consideration. The Craig Hospital Assessment and Reporting Technique (Whiteneck et al., 1988), or CHART, and the Life-H scale (Fougeyrollas et al., 1997; Noreau et al., 2004; Noreau, Fougeyrollas, & Vincent, 2002) were designed using disability models as a theoretical underpinning (the CHART from the original ICIDH and the Life-H from the DCP model). Participation scales rate the life

Item ID	During the past week: Did you (repeat before each item or as necessary)	Definitely yes	Mostly yes	Not sure	Mostly no	Definitely no	Physical	Communication	Psychosocial	Energy
T4	Have to write things down to remember them (or ask somebody else to write things down for you to remember)?	1	2	3	4	5				
T5	Find it hard to make decisions?	1	2	3	4	5				
P1	Feel irritable?	1	2	3	4	5				
P3	Feel that your personality has changed?	1	2	3	4	5				
MD2	Feel discouraged about the future?	1	2	3	4	5				
MD3	Have no interest in other people or activities?	1	2	3	4	5				
MD6	Feel withdrawn from other people?	1	2	3	4	5				
MD7	Have little confidence in yourself?	1	2	3	4	5				
E2	Feel tired most of the time?	1	2	3	4	5				
E3	Have to stop and rest often during the day?	1	2	3	4	5				
E4	Feel too tired to do what you wanted to do?	1	2	3	4	5				
FR7	Feel that you were a burden to your family?	1	2	3	4	5				
FR9	Feel that your language problems interfered with your family life?	1	2	3	4	5				
SR1	Go out less often than you would like?	1	2	3	4	5				
SR4	Do your hobbies and recreation less often than you would like?	1	2	3	4	5				
SR5	See your friends less than you would like?	1	2	3	4	5				
SR7	Feel that your physical condition interfered with your social life?	1	2	3	4	5				
SR8	Feel that your language problems interfered with your social life?	1	2	3	4	5				
	SAQOL- 39 mean score	Add all items and divide by 39								
	Physical score	(SC items + M items + W items + UE items + SR7) / 17								
	Communication score	(L items + FR7 + SR8) / 7								
	Psychosocial score	(T5 + P items + MD items + FR7 + SR1 + SR4 + SR5) / 11								
	Energy score	(T4 + E items) / 4

activities and roles in which individuals participate and generally do not mix activity-level items with participation-level items, like some of the quality-of-life scales. The CHART asks respondents to indicate the number of hours they spend performing a specific activity (i.e., frequency). For instance, respondents note the frequency with which they got out of bed or the number of hours involved in active homemaking or working, hobbies, and so on. The Life-H scale (some items from the short form are shown in Fig. 13-5) is an

assessment tool that includes 58 items based on the life habits section of the DCP classification. Respondents are required to score three aspects for each item: (1) level of accomplishment, (2) type of assistance needed, and (3) level of satisfaction. For example, an individual may no longer be able to do housework following a stroke; however, this individual might have hired help with this life activity (performed by substitution) and may be very satisfied with this arrangement. For level of accomplishment, the respondent

Answer the following 2 questions (check the appropriate boxes). Question 1: For each of the following life habits, indicate A How the personal generally accomplishes it and B The type of assistance required to accomplish it Question 2: For each of the following life habits, indicate the level of satisfaction with the way it is accomplished. Note: Keep in mind that answers should reflect the person's usual way of carrying out the habits.		Question 1					Question 2									
		Level of accomplishment (check only 1)					Type of assistance (check all that apply)				Level of satisfaction (check only 1)					
		No difficulty	With difficulty	Accomplished by a proxy	Not accomplished	Not applicable	No assistance	Assistance device	Adaptation	Human assistance	Very dissatisfied	Dissatisfied	More or less satisfied	Satisfied	Very satisfied

Figure 13–5. Items from the Life-H scale. (From Fougereyrollas et al., 1997; with permission.)

can score *No difficulty*, *Some difficulty*, *Realized by substitution* (meaning someone else is carrying out this activity for the respondent), *Not performed*, or *Not applicable*. For type of assistance to achieve the life habit, respondents can indicate *No assistance*, *Assistive device*, *Adaptation*, or *Human assistance*. This allows clinicians to identify what environmental help, human or otherwise, is helping the individual take part in his or her life activities. The last category is level of satisfaction, which can be rated on a five point scale from *Very dissatisfied* to *Very satisfied*. Taken as a whole, these participation rating scales allow the respondents to identify problematic areas of life participation.

The clear advantages of these tools are that they track the perception of the impact of environmental factors as well as level of satisfaction for each and every participation item and that they do not mix activity-level items. Unfortunately, they, too, may be difficult to apply to the area of aphasia. For instance, the visual presentation of the Life-H tool itself makes it difficult for individuals with aphasia to score the items themselves. The response forms may need to be adapted for use with this population. The Life-H scale was used in a pilot study comparing caregivers' responses to those of their loved ones with dementia (Wright, Garcia, Neault, & Fergus, 2002) as well as to those of individuals with traumatic brain injury in evaluating the environmental factors that contribute to workplace integration (Laroche et al., 1999). In both instances, the clinician asked the participant the questions.

In short, all of these scales can help the therapist identify how persons with aphasia perceive their level of functioning in daily life. No ideal tool is currently on the market that captures all the elements necessary for therapeutic planning using a life consequences approach, and the clinician will need to examine these clinical tools more closely. McDowell and Newell's book (2006) on measuring health is an interesting start.

In a pilot study using the DCP and ICF models to describe functioning in the area of aphasia, Garcia and colleagues (2003) preferred to use an interview format to identify the life participation areas. Questions were devised based on the participation domains found in the ICF and DCP. The questionnaire may be found in Appendix 13.1. Others also preferred to use tailor-made interviews and questionnaires with individuals with aphasia (Parr, Duchan, & Pound, 2003; Pound, Parr, Lindsay, & Woolf, 2000; Simmons-Mackie & Damico, 1995) to capture individuals' perceptions of the impact of their disorder on overall life participation.

Byng and Duchan (2005) give an excellent overview of how one can construct interventions based on life participation roles. Lyon and Shadden (2001) have also stressed the importance of looking at global life goals. In fact, successful participation in leisure activities has been shown to correlate most with quality of life and overall well-being poststroke (Bays 2001; Sveen, Thommessen, Bautz-Holter, Wyller,

& Laake, 2004). Level of linguistic functioning is not always the predictor of overall functioning (Ross & Wertz, 2002).

Bottom line: Whatever method is used by the clinician (quality-of-life scales, participation scales, or interviews), what is important is to identify those life participation areas that pose problems for the individual with aphasia.

The problematic life participation areas may or may not be reflected in explicit communication goals. In fact, it is very difficult, if not impossible, to tease out communication as a separate entity from life participation (Penn, 2005). Further, identifying areas of life participation as a goal for therapy may seem too global and unmanageable to some clinicians. In addition to using participation scales such as the Life-H and the CHART, or using informal questionnaires, those who are more systematic in their approach may choose a technique such as Goal Attainment Scaling (Schlosser, 2004) to evaluate progress in life participation. This technique (described in greater detail in the section entitled "Fitting it together: interprofessional strategies for rehabilitation, p. 366) involves assigning a numeric value to therapeutic goals as per the individual's priorities. A continuum of outcomes is identified pre-intervention using a five-point scale, and each goal is then defined in terms of this scaling. At the end of the intervention, together with the clinician, the person with aphasia can see which goals, if any, have been attained. Goal Attainment Scaling can be used with any therapeutic goal, including those based on life participation.

The Second Component: Intervention on the Personal Factors

Once the life activity or role has been identified in collaboration with the individual with aphasia but before a therapy plan can be designed, an inventory of the individual's capabilities must be made. These skills will normally be identified through discipline-specific evaluations. In speech-language pathology, this includes a comprehensive appraisal of the speech and language skills. Therapies designed for these skills are the subject of many chapters in this text. All of these techniques can impact the life participation of individuals with aphasia provided the links are made with life domains.

Although most, if not all, clinicians are concerned with the impact of language abilities on their clients' lives, the missing step is often the direct correlation of these abilities with improvements on subsequent life activities and roles that are important to the person with aphasia. Further, the clinician must not ignore the behavioral personal factors, such as level of motivation, and their correlation with life activities and roles. These correlations will allow the clinician to identify those life habits that likely are mildly affected, those that are compromised, and those that are at risk of being compromised (Castelein, Noots-Villers,

Buxant, & Spicher, 1994). For instance, a reading problem could mildly affect the life participation activity of preparing meals (i.e., reading recipe books) but would compromise the job of a lawyer and risk compromising leisure if the person reads for pleasure. Based on this information, the capabilities can be prioritized and incorporated into a cohesive therapeutic plan.

In identifying these capabilities, the clinician should pay specific attention to communication skills as an interactive process. Not only are the linguistic levels of phonology, syntax, and semantics important, but pragmatics becomes a central theme in intervention. Hence, the ability to express one's intention and/or understand others' intentions through language is fundamental to successful life participation. It is so fundamental, in fact, that we often define who we are through communicative interactions.

Verderber (1981) suggests that people communicate on three social levels: (1) For the sheer pleasure of interaction (in these cases, the topic is unimportant), (2) To demonstrate their ties with other people, and (3) to build and maintain relationships. In this sense, the goal of communication is to facilitate social interactions and not necessarily to transmit information. The therapist must remember that individuals may need to communicate with the intention to make relational ties and that this might demand different abilities from those needed to read a book. Luterman (1996) says, "The major means by which we alleviate our interpersonal loneliness is verbal communication, and when that is difficult, we become disturbed" (p. 22). Hence, an approach based on the life consequences cannot focus solely on the transactional aspects of communication (i.e., transmitting a message) (Simmons-Mackie & Damico, 1995). Aside from designing intervention strategies that focus on the linguistic aspects per se, as described in the various chapters of this text, the clinician can also focus on helping the individual with his or her communication skills to function as a social being. Functional communication techniques might include augmentative and alternative communication (McCall, Shelton, Weinrich, & Cox, 2000; Waller, Dennis, Brodie, & Cairns, 1998), drawing (Lyon, 1996; Ward-Lonergan & Nicholas, 1995), or PACE treatment (Carlomagno, Losanno, Emanuelli, & Casadio, 1991; Pulvermüller & Roth, 1991). Cunningham and Ward (2003) used videos to help functional communication by teaching repair strategies to conversational partners so that they become more efficient communicators. Another technique, called reciprocal scaffolding (Avent & Austerman, 2003), uses a reciprocal model of learning where the person with aphasia is in interaction with a student partner. In the reported case, the person with aphasia teaches a science lesson to 25 children. In this situation, the person with aphasia has the opportunity to improve not only in language but also in terms of life participation.

One of the more formal therapeutic interventions designed specifically for conversation is the method devel-

oped by Holland (1991) called conversational coaching. The conversational coaching technique is used to help the person with aphasia transfer the strategies learned in therapy to a more functional context. The first step in this process is to develop a predesigned script that the person with aphasia will practice with the clinician. This script can vary in difficulty depending on the amount of information that needs to be conveyed and on the level of improvisation left to the person with aphasia. The person with aphasia practices the script with the clinician as he or she guides the client in using the most efficient and effective conversational strategies. The person with aphasia will then practice the script with a familiar person, usually a family member, while being filmed on videotape. The therapist will coach both the person with aphasia and the family member in conversational strategies. Other, less familiar individuals can then be called in to make the task a little more difficult. The clinician and person with aphasia will then view the videotape together and discuss what worked and what did not.

Hopper, Holland, and Rewega (2002) looked at the efficacy, both pre- and post therapy, of using a videotaped story as a script. They looked at the number of concepts that were effectively communicated post-therapy and found this therapy to be effective. In another technique using script training, Youmans, Holland, Muñoz, and Bourgeois (2005) used a systematic technique to render scripted phrases more and more automatic in the conversational discourse of two individuals with aphasia. As the participants mastered the scripts, more and more information was added. The scripts were tested for robustness in a contextual conversation, and raters were then used to examine parameters such as speaking rate and naturalness of the conversations.

Any clinician wishing to use these techniques must remember some fundamental principles about communication. Normal speakers do not communicate all the necessary information to communicate their intention, and speakers may not reveal their intentions explicitly. This is important to remember when we engage in techniques that work on turn taking, topic shifting, or conversational repair. How close is the correlation between what is perceived as a breakdown in communication by the therapist (e.g., a breakdown in topic shifting) and the actual breakdown in the person's communicative intention? Which part of the message should be allocated to what is explicit, and which part should be deducted as a function of the context and the links with the speaker? Any approach that focuses on the life consequences must consider the intended goal of the communication event. It is not only about the clarity of the linguistic message. As a reaction to the paper by Ross and Wertz (2005) on the use of the ICF in the appraisal of aphasia, Penn (2005) remarked that communication, in and of itself, is not a life participation domain but, rather, transpires all domains. Nothing could be closer to the truth. What we see (or hear) is not always what is underlying the problem.

Sometimes, linguistic difficulties directly influence other domains, such as self-esteem.

How people feel about themselves and how they feel the disorder has affected them and their loved ones will impact whether individuals with aphasia can take part in life activities and roles. These are equally part of the personal factors of those with aphasia. Because communication affects the very fabric of interpersonal interactions, these feelings cannot be ignored by the therapist. In his book on counselling, Luterman (1996) stated that “the goal of counselling is not to make people feel better, but to separate feelings from non-productive behaviour. The feelings must always be acknowledged” (p. 47). To move ahead in therapy, Luterman suggested that we listen to clients. As with the identification of life participation events, clients can participate with the therapist to switch their focus from what they cannot do to what they may choose not to do. This is a very important distinction to make when one takes a life consequences approach. This perspective suggests that the therapists can use the individual’s state of mind to help the person adopt new life roles by choosing to let go of past roles. The level of motivation and the sense of identity the person has can either facilitate or be an obstacle to full reintegration. Counselling on the other personal factors that interact with communication can be a very important step to recovery.

Assessment tools such as the Code-Müller Protocols (Code, Müller, Hogan, & Herrmann, 1999) or the Visual Analogue Self-Esteem Scale (Brumfitt & Sheeran, 1999), or VASES, are both designed to offer a standardized way of evaluating an individual’s psychosocial adjustment. The VASES will offer the clinician an assessment of the individual’s self-perception (e.g., optimist/pessimist, attractive/unattractive, and so on), whereas the Code-Müller Protocols will evaluate the self-perceptions of individuals regarding how they are doing on items such as ability to work, ability to cope with depression, or ability to follow interests and hobbies. Sometimes, the best way to find out how people are doing is through informal and formal interviews or autobiographies (Parr, 2001; Pound, Parr, & Duchan, 2001). The clinician can use counselling techniques to probe issues of psychosocial adjustment as they relate to communication situations.

As mentioned previously, aphasia affects much more than one’s ability to transmit a message. Kagan (1995) has spoken of aphasia as masking an individual’s competence, whereas Shadden (2005) has written a paper describing how aphasia impacts one’s perception of one’s own identity. No matter how mild the aphasia may seem to the therapist, renegotiation of involvement in life events and roles will need to take place if the therapy is to be successful. Even with mild aphasia, those affected may see an impact on the fact that they can no longer be as witty or have deep conversations with a spouse. The demand placed on communication skills is far greater in real life than in a clinic situation. The individual must process multiple pieces of information—and process

them quickly. Even with mild aphasia, the sequelae of the CVA might affect these subtle aspects, which in turn impact on the individual’s ability to function as he or she did previously. The effect may be withdrawal from these events. As individuals are counselled into reconstructing this new identity with less efficient communication skills, they will need some external validation that they can once again become socially functioning human beings. Validation will come with help from the clinician as opportunities are offered in the form of successful communication situations. Some techniques, such as the conversational coaching technique described above, will help individuals attain success. Other activities, such as group therapy (Kearns & Elman, 2001) and techniques designed to help the conversational partner (see next section), will also help with the validation of a person’s competence as a communicator. The therapist can help to unveil the mask of incompetence caused by aphasia (Kagan, 1995) and reveal who those affected were and may now choose to be (Mackay, 2003) by guiding their involvement in communication situations. The clinician must remember that the individual with aphasia has a premorbid life that comes with a premorbid personality and psychosocial situation. Ignoring these aspects is likely to doom the therapy to failure in terms of life participation.

Bottom line: Capabilities, as assessed by discipline specific evaluations, can be correlated with identified life participation goals.

The level of impairment will contribute to the realization of the life event. Therapy can then be prioritized into work on linguistic aspects and/or social conversational skills. It must not be forgotten that the psychological state of the individual will also play an important role in helping his or her return to past life activities and/or development of new life goals. Counselling will be necessary to guide the individual through these stages.

Improving linguistic, conversational, and psychological skills will most certainly help in improving quality of life (Cruice Worrall & Hickson, 2005); however, a life consequences approach demands that this be considered in the context of other environmental factors that impact real-life functioning. Opportunities for validation and inclusion will most easily occur if the therapist knows how to modify the environment, increasing the number of facilitators and decreasing the obstacles. The life participation goal is modified not only through work on personal factors but also through work on environmental factors. Therapy that focuses on both is more likely to be successful (Ross & Wertz, 2003).

The Third Component: Intervention on the Environmental Factors

To many people, the term “environmental factors” refers only to physical environments and includes such things as

architectural designs, snow-covered sidewalks, or noisy environments. In the disability model approach, however, environment includes much more. It includes social environments, such as family members and colleague support, as well as sociopolitical systems and attitudes. Using the ICF model, Howe and colleagues (2004) offered an excellent review of environmental factors that can influence the life participation of individuals with aphasia, and Lubinski (2001) explained how environmental factors can be seen to interact at the individual, family, and systemic levels.

The most obvious environmental factor influencing the integration of individuals with communication deficits such as aphasia is the conversational partner. For as long as social scientists have studied conversational discourse, the role of the conversational partner has been instrumental in establishing coherent and cohesive interactions (Schegloff, 1987). A conversation cannot occur without a partner. Depending on the words used by conversational partners and their behaviors, this can negatively affect the functional communication levels of the person with aphasia. To reduce these effects, the therapist can use a number of the techniques mentioned previously to help turn negative-impact conversational partners into positive-impact conversational partners. For instance, volunteers were used to facilitate conversations using scripts in the “Speaking out” program of Worrall and Yiu (2000), and Hopper and colleagues (2002) explained how the conversational coaching technique not only benefits the individual with aphasia but also trains family members in how to coach for more fluid communication. Cunningham and Ward (2003) also used videotaping to train couples in conversational repair strategies, and Simmons-Mackie, Kearns, and Potechin (2005) showed evidence for generalization of family training techniques to better, fluid conversations in more naturalistic environments.

Conversational partners do more, however, than just help to construct coherent conversations. As mentioned in the previous section, conversational partners play an important role in validating the competence of the person with aphasia. Supported Conversation for Adults with Aphasia, or SCA, is one of the more formal approaches for training conversational partners. Designed by Kagan, Black, Duchan, Simmons-Mackie, and Square (2001), this program capitalizes on the inherent cognitive and social skills of the person with aphasia to facilitate communication. The program teaches conversational partners to see the person with aphasia as an equal conversationalist, and it encourages the partner to use whatever is at his or her disposal to engage the person with aphasia in a meaningful interaction. Tools that facilitate communication might include visual material (e.g., photographs), writing partial messages to clarify information, drawing, or natural “props” (e.g., newspaper clips). Partners are taught to offer feedback that is as natural and context dependent as possible and focus on the communicative intent rather than the clarity of the linguistic output.

By intervening at the environmental level, the therapist is making the world more accessible to the person with aphasia and helping others to facilitate rather than hinder integration. Nonetheless, environmental obstacles go beyond the individual conversational partner. Kagan and LeBlanc (2002) report on efforts to render health-care services more accessible to individuals with aphasia. Worrall and colleagues (2005) give further examples of how to render written environments more accessible. All environments with which the person interacts, including physical environments (Lubinski, 2001), attitudes (Parr, 2001), and work environments (Garcia, Barrette, & Laroche, 2000), or how health-care teams are structured and function (Golper, 2001), can be examined to see if they are perceived by individuals with aphasia as being obstacles or facilitators to integration.

Much more information is needed regarding the impact of these environmental factors on the life participation of individuals with aphasia. Parr (2001) correctly points out that identifying the exact impact of environmental factors on life participation is far from straightforward. Further, working on the environmental factors alone might be counterproductive. To focus only on the environmental factors minimizes the role of the personal factors (i.e., aphasia) on life participation (Parr, 2001). Just as the traditional medical model might be criticized for not acknowledging the role of environment, a purely environmental approach likewise does not do justice to the role of the impairment. The interaction must be symbiotic.

Lawton and Nahemow (1973) introduced the ecological model of aging (Fig. 13-6) to help articulate the role of personal and environmental factors. The concepts from this model are still relevant today, and they have been improved upon and incorporated into modern disability models. The level of competence of the individual is represented on the *y*-axis of this model. For our purposes, this would include personal factors, such as linguistic and behavioral capabilities. Following evaluation, this can be rated from a low level of competence to a high level of competence. The *x*-axis represents how demanding the environment can be toward the individual. This can be rated as very low in demand value to very high in demand value. The diagonal lines suggest a direct link between level of competence and demand from the environment. If a person has a high level of competence but is in an environment that demands little, the person will lose his or her ability to adapt and will develop negative affect and maladaptive behavior. The individual will not be working hard enough to stimulate development of his or her skills, because the environment demands very little. Conversely, if the person has lower competence skills for what the environment demands, he or she will also be unable to perform, because this individual will not have the skills to respond to the high demands of the environment. Hence, a relationship exists between the person’s level of competence and what is asked by the environment to achieve maximal

Figure 13-6. The ecological model of aging (Lawton & Nahemow, 1973).

performance. This is called “environmental press.” The higher the level of competence, the more the environment can demand—up to a point. To use a concrete example, imagine an individual who can manage some stairs but who cannot manage a full staircase. If all stairs are removed from this person environment, he or she is likely to lose whatever is left of the competence to manage stairs. If this person must manage many stairs in the environment, he or she will likely be overwhelmed and unable to function.

These same principles can be applied to individuals with aphasia. A person with significant residual language must be in an environment that is sufficiently stimulating to reveal competence and enhance development but also not overwhelming enough to elicit discouragement, isolation, and demotivation. Therefore, in addition to stimulating linguistic aspects, the therapist has a role in shaping an environment that will be conducive to the “zone of maximum comfort,” using the model of Lawton and Nahemow (1973).

The clinician’s job, then, is to identify those environmental factors that are contributing to integration, either in a positive or a negative way, and help to impact on these factors. Using the environmental press model, this means that the individual with aphasia must come into contact with communication partners who are stimulating enough to encourage the use of communication strategies on the part of the individual with aphasia yet also facilitating enough not to be overwhelming. The Supported Conversation for Aphasia technique of Kagan et al. (2001) is precisely in line with the Lawton and Nahemow model of environmental press. Here, the clinician facilitates communication sufficiently enough to reveal the competence of the individual.

Two standardized tools may be useful to the clinician for identifying the frequency and impact of environmental fac-

tors. The Craig Hospital Inventory of Environmental Factors (Craig Hospital Research Department, 2001), or CHIEF, and the Measure of the Quality of the Environment (Fougeyrollas, Noreau, St-Michel, & Boschen, 1999), or MQE, are scales used measure environmental factors. The CHIEF helps the clinician identify barriers by asking the individual about the level of the barrier and the frequency with which he or she encounters it. Barriers include items such as the layout of built environments, natural environments, light, and noise, as well as more human barriers, such as human help, attitudes, and policies and rules. The MQE (Fig. 13-7) has similar items and asks the respondent to rate items on a scale going from +2 (very much a facilitator) to 0 (neutral impact) to -2 (very much an obstacle).

The Environmental Partner as an Object of Intervention

Until now, much of this chapter has focused on individuals with aphasia and their interactions with their environments. More and more writings, however, suggest that the clinician should also consider the individuals surrounding the person with aphasia as a focus of intervention. Bakas, Kroenke, Plue, Perkins, and Williams (2006) looked at family caregivers of individuals with aphasia and of individuals without aphasia following stroke. The impact of functioning with an individual who had aphasia was more demanding than with an individual who did not have aphasia.

Just as it is difficult for individuals with aphasia to communicate with their environment, it is difficult for the environment to communicate with an individual who has aphasia. Work on conversational discourse not only benefits the person with aphasia but also the conversational partner.

Measure the quality of the environment									
While taking into consideration your abilities and personal limits, indicate on the scale to what extent the situations or factors generally influence your daily life.									
Social network (support from people around you)									
• Your family situation (living alone, with a spouse, or with children). • Support from members of your family or close friends who take the place of family (presence, physical assistance, household assistance, encouragement). • Support from your friends. • Support from your neighbors. • Support from you colleagues at work, school, or place of principal occupation.									
Attitudes of the people around you.... <i>i can't read this on the reference</i>									
• The attitudes of your family or close friends who take the place of family towards you. • The attitudes of your friends toward you. • The attitudes of your colleagues at work, school or place of principal occupation towards you. • The attitudes of your superiors (professors, supervisors, employees) towards you. • The attitudes of your neighbors towards you. • The attitudes of your service providers (public service agents, salespeople, cashiers, etc.) toward you.									

Influence scale							I do not know	Does not apply
Obstacle ←			No influence	→ Familiar

Figure 13-7. Example of the Measure of the Quality of the Environment (MQE). (From Fougeyrollas et al., 1999; with permission.)

Shadden (2005) brings this point home in the area of personal identity by suggesting a specific burden associated with the impact of aphasia:

Using an identity perspective, it is clear that efforts must be made to understand how each significant other projects his or her identity both now (poststroke), and in the past (prestroke). There is a need to know relational dynamics, to go beyond questions such as "How does he communicate at home?" (p. 219).

In a life consequences perspective, the aphasia almost certainly affects the spouse's, the colleague's, or the friend's life participation. As with the individual who has aphasia, intervention on the aphasia itself or reduction of environmental

barriers might help these partners. Sorin-Peters (2003) used an adult learning model to help couples deal with the consequences of aphasia. Her focus was not only on the communication aspects but also on the impact of the aphasia on the marital relationship. Other members in the person's entourage, such as health-care providers, can also be considered. Although Allan (2006) refers to health workers involved with individuals who have dementia, the same can be said about workers involved with individuals with aphasia:

A system which calls upon workers' humanity in the very delivery of the services it provides cannot simultaneously deny the needs of staff that arise in the course of the work that they do. (p. 191)

Bouchard-Lamothe and colleagues (1999) found that some physicians reported struggling when involved with individuals who have aphasia. Interventions at this level not only help the person with aphasia to obtain better care but also helps the health-care worker to do his or her job and offer better care to all individuals with communication disorders. Using disability models, the therapist can focus on the life participation of the health-care worker, family member, or colleague. This person, who does not have aphasia, has also been affected by it. His or her life habits (e.g., work, activities, and interpersonal relationships), not to mention his or her identity as a spouse or colleague, have likely been disrupted by the partner's aphasia. These are clearly life consequences of aphasia.

Bottom line: Environment is just as important a target of intervention as is linguistic capacity. Environment can include physical environment, social supports, and organizational structures. Those people in the individual's entourage can just as likely become a focus of intervention.

FITTING IT TOGETHER: INTERPROFESSIONAL STRATEGIES FOR REHABILITATION

For a speech-language pathologist to embark on a life consequences approach to intervention is quite challenging. Quickly, the clinician will realize the need for more information from other professionals to understand the full impact of the stroke on the patient's life activities and roles. The best way to facilitate this is to take an interprofessional approach in which the members of the team (including the person with aphasia) work toward common life participation goals. Each discipline can then work on disciplinary elements and keep informed through discussions with the team regarding the progress made on the patient-initiated life activities and roles. This will both save time and be more efficient. Simmons-Mackie, Threats, and Kagan (2005) reported that time constraints were the biggest obstacle to doing outcome measurement in clinic. Using a team approach allows clinicians to concentrate on life consequences goals in a more efficient and effective manner. For a team to be effective, its members must orient their efforts toward a clear, common objective (Golper, 2001), and a model such as the ESOPE (*Évaluation systémique des objectifs prioritaires en réadaptation* [Systemic Evaluation of Priority Goals in Rehabilitation]) will give them this opportunity.

The ESOPE model is one suggestion that might be useful as a guide for operationalizing this approach. It was developed by a Belgian team under the direction of Pierre Castelein and Patricia Noots-Villers (Castelein et al., 1994). These occupational therapists have proposed a model to guide the setting of team rehabilitation goals based on the DCP disability model. The ESOPE program (see Figure 13–8) uses a computer system to help an interprofessional team adopt a life consequences approach. The team first works from a common set

of life participation goals, which are identified based on the frequency with which the client engages in the life habit or role as well as the perceived importance by the client of this life habit or role. A correlation is made between the individual's capabilities and these life habits or roles based on formal or informal evaluation of the life habits and disciplinary evaluations. The clinical rehabilitation team, in collaboration with the individual with aphasia, will (1) target the capabilities that need to be prioritized as a function of life habits and roles, (2) suppress environmental obstacles that prevent integration or augment facilitators, and/or (3) work with the client to adopt new life habits. According to the ESOPE model of intervention, the individual will then be able to diminish situations of handicap and develop a more harmonious interaction with his or her social and physical environments.

To help persons with aphasia determine when they have attained some success in their goals, the therapeutic team can use the technique of Goal Attainment Scaling (Schlosser, 2004) discussed previously in this chapter. This technique offers a systematic way to determine progress on an individual goal. Here are the steps as outlined by Schlosser (p. 218):

1. **Specify a set of goals** In our case, these goals can be the life participation goals set by the team and the person with aphasia in the section entitled, "The First Component: Identifying Disrupted Life Activities and Roles (p. 355)" of this chapter.
2. **Assign a weight for each goal according to priority** The priority given to these goals will be influenced by the frequency and the importance of the goal to the person with aphasia.
3. **Specify a continuum of possible outcomes** Each goal is assigned a worst expected outcome (–2), a less than expected outcome (–1), an expected outcome (0), a more than expected outcome (+1), and a best expected outcome (+2). This is where the Goal Attaining Scaling is most useful; however, this is also the most difficult stage of the process. The team, always in conjunction with the client, will operationally define what each of the levels might be for each of the chosen goals.
4. **Specify the criteria for scoring at each level** The team will then clearly identify what is operationally needed to conclude that the goal has been attained.
5. **Determine current or initial performance** This could be determined through measurable evaluations of life participation or quality of life, environmental factors, and/or disciplinary clinical measures.
6. **Intervene for a specified period** As mentioned above, intervention might take the form of therapy aimed at (a) improving abilities, including linguistic and psychosocial adjustment abilities; (b) reducing environmental obstacles; or (c) helping define new life goals.
7. **Determine performance attained on each objective**
8. **Evaluate extent of attainment**

Figure 13–8. The ESOPE (*Évaluation systémique des objectifs prioritaires en réadaptation* [Systemic Evaluation of Priority Goals in Rehabilitation]). EF = environmental factors. (Adapted from Castelein et al., 1994; with permission.)

Regular meetings with the team will ensure that the over-all life participation goal is being met and that each member is facilitating the person with aphasia's integration in the best possible way as defined by these goals. The professionals involved in the team will be able to focus their own therapeutic plans on the disciplinary items that offer a continued improvement of life participation goals. Like the elephant in the legend of the six blind men, the composite picture is more than the sum of its parts.

It is also important to remember that these goals will change over time (Parr, 2001; Shadden, 2005). As environmental factors change (e.g., the death of a spouse or the pur-

chase of an electronic device) and personal factors improve (e.g., more motivation or improved language skills), the consequence on the life participation goal will also be affected. Further, as Shadden (2005) so eloquently states, the self-identity of the person will also change, and this will be influenced by his or her life experiences. Hence, the chronic condition of aphasia will have differing effects depending on this context. The clinician is therefore encouraged to continuously evaluate the extent of participation in life activities and roles as well as the extent to which the current personal skills and environmental factors are influencing the achievement of these goals.

TABLE 13-1

Applying The Philosophy

	Acute Care	Rehabilitation Settings	Long-Term Facilities	Community-Care Settings
Enhancement of life participation	• Unable to express needs/wants	• Return to work • Return to day living (shopping, cooking, homekeeping, driving, computer, telephone talking) • Return to social network	• Person with aphasia cannot communicate basic needs • Group/recreational activities (in-house and outside facility) • Using communication boards	• Participate in some community activity • Specific work goals • Social participation
All those affected are entitled to service	• Nursing staff • Family • MDs • Rehabilitation team	• Medical staff • Family • Friends • Colleagues • Community workers • Lawyer, insurance personnel • Clergy	• Family • Friends • Caregivers	• Lack of funding for initiating/continuing support services • Family • Friends • Co-workers • Employers • MDs • Rehabilitation team
Measures of success include documented life enhancement changes	• Ongoing evaluation • Staff input/feedback • Improved communication on ward	• Anecdotal information • Family rating scale • Questionnaire • Formal assessment tool • Client interview	• Feedback from staff • Improvement in goals • Diagnostic measures • Documentation of room restorative programs • MDs • Nursing documentation	• Ability to return to work • Measures of self satisfaction • Ability to return to previous activities • Ability to learn new participation activities
Personal factors are targets	• Cognitive status • Motivation • Fatigue	• Cognitive status • Motivation • Client awareness/insight • Mental/physical/emotional status • Financial situation • Overall life style/behavior	• Feelings of isolation and depression • Premorbid level	• Age • Previous roles (e.g., managing finances) • Finances • Motivation • IADLs
Environmental factors are targets	• Other testing procedures • PT/OT • Family members • Noise • Roommates	• Living situation • Responsiveness of employer, community, family • Geographic isolation/location • Transportation	• Family attitudes • Privacy issues • Effects of psychotropic drugs • Noise • Lighting • Ventilation • Roommates • Lack of follow-through with strategic staff commitment and turnover • Language barrier • Cultural differences • Age factor	• Family situation • Transportation • Community involvement • Availability of support personnel

TABLE 13-1

Applying The Philosophy (continued)

	Acute Care	Rehabilitation Settings	Long-Term Facilities	Community-Care Settings
Availability of service	• Lack of SLP • Productivity issue • Lack of staff/MD knowledge	• Accessibility to service • Insurance • Transportation • Lack of/shortage of SLPs • Shortage of skilled clinicians • Poor communication of client to express needs/goals	• Insurance • Staffing issues • Time constraints	• Counselling services for adjustment • Aphasia groups
What would prevent SLPs from applying the philosophy?	• Priority given to vital life functions (swallowing, breathing)	• Medicare, availability • Time constraints • Ability • Lack of objective documentation • Lack of funding • Lack of employer support	• Time constraints • Excessive paperwork • Travel time	• Ongoing services (payment)

Key: IADLs = Instrumental Activities of Daily Living; PT/OT = Physiotherapy/Occupational Therapy; SLP = speech-language pathologist. (Suggestions from participants at a New Jersey Speech and Hearing Conference.)

APPLYING THE PHILOSOPHY TO DIFFERENT CLINICAL CONTEXTS

Speech-language pathologists can deliver services in many different contexts, ranging from hospitals to rehabilitation centers to long-term care facilities to independent clinics to home care. The life consequences approach can be applied in all of these contexts and should not be relegated only to home care. Remember that the consequences of aphasia are felt the minute the person has survived the stroke; therefore, a life consequences approach can be just as appropriate in acute care as in home care.

To illustrate this, I will use the suggestions pooled from a conference I gave to the New Jersey Speech and Hearing Association in 2001 on the applications of the new disability models. The participants were asked to reflect on how the principles of the Life Participation Approach to Aphasia (LPAA Project Group, chapter 10, this book), which summarizes principles of practice using disability model notions, could be applied to the different clinical contexts. Table 13-1 summarizes their suggestions.

The Life Participation Approach to Aphasia guidelines mirror the approach taken in this chapter:

1. The explicit goal is enhancement of life participation.
2. All those affected by aphasia are entitled to service.

3. The measures of success include documented life enhancement changes.
4. Both personal and environmental factors are targets of intervention.
5. Emphasis is on availability of services as needed at all stages of aphasia.

The participants in the New Jersey Speech and Hearing Association conference offer clinicians a first look at targets that can be identified across health-care sectors. The life consequences approach to aphasia not only helps us in looking at the impact of aphasia on an individual's life but also has great promise in helping us understand the impact of aphasia as lived by individuals in different cultures. This can only be done through consideration of environmental factors. By helping individuals with aphasia and their loved ones get what they need to participate more fully in life at a certain point in their lives, we may contribute greatly to their sense of meaning and personal identity.

KEY POINTS

1. Disability model principles and frameworks, such as the International Classification of Functioning, Disability and Health (ICF) and the lesser-known

Disability Creation Process Model (DCP), provide a good starting point for understanding the relationship among all the factors that contribute to helping individuals reenter their lives following aphasia. They can help to identify whether the focus of therapy should be on (a) regaining language abilities, (b) diminishing environmental obstacles or encouraging environmental facilitators, (c) helping the individual to define new life goals, or (d) any combination of the first three.

2. Social and physical environments can facilitate integration or create obstacles to integration and, therefore, can be a focus for intervention just as capabilities can. The environment should be challenging enough to foster development yet facilitative enough to reduce frustration.
3. Goals of therapy should be identified in consultation with the person who has aphasia.
4. Problems in life participation should be seen as *situations* of handicap that change over time rather than as permanent states.
5. Current disability models are meant to use concepts that are applicable to all human beings.
6. Intervention aimed at the personal factors, such as capabilities, should also consider the psychological impact of the disorder on the individual.
7. The individual who interacts with the person who has aphasia also lives with the impact of aphasia. Hence, colleagues, spouses, children, and friends should be the focus of intervention when appropriate.
8. The most efficient way to keep life participation goals in focus is to work within an interprofessional team context.

ACTIVITIES FOR REFLECTION AND DISCUSSION

Use the following hypothetical case to help structure your answers to the following activities and thoughts.

S.H. is a 45 year-old woman who fell while skating on the canal (a 7-km skating surface) in Ottawa, Ontario, Canada. She was found to have had a left frontoparietal hemorrhage, leaving her with a hemiplegia and aphasia. She has no remarkable past medical history. She is married and has one adolescent child aged 15 years. She is the parent that is most involved with her daughter, and of late, she and her daughter have been experiencing some parenting conflicts surrounding her daughter's request for independence. S.H.'s husband is present but very involved with his work. When possible, they used to enjoy a variety of outdoor sports, such as skiing and skating. This has now become impossible since the

CVA. Before her CVA, S.H. worked as a policy analyst for the Canadian government.

Her language testing reveals the following:

A. Spontaneous language	6/20
B. Oral comprehension	
i. Questions	48/60
ii. Words	58/60
iii. Commands	41/80
C. Repetition	33/100
D. Lexical access	
i. Naming (Western Aphasia Battery)	6/60
ii. Naming (Boston Naming Test)	Unable
iii. Fluency	0/20
iv. Sentence completion	2/10
v. Responding to questions	1/10
E. Reading comprehension	
i. Sentences and paragraphs	28/40
ii. Commands	8/20
iii. Words	6/6 (×3)
F. Writing	
i. Name and address	6/6
ii. Spontaneous writing (paragraph)	Unable
iii. Dictation (sentences)	3/10
iv. Dictation (words)	7/10
G. Apraxia	46/60

1. Identify the personal factors, environmental factors, and life participation activities and roles in S.H.'s case.
2. How would you design your therapy for the personal factors, considering her participation levels?
3. Think about how you would design your therapeutic intervention if you wished to focus on:
 - a. S.H.'s lexical access problem.
 - b. S.H.'s language and communication skills as a whole.
 - c. S.H.'s difficult relationship with her daughter and her (in)ability to return to work.

Use the elephant analogy in the chapter to help you reflect on this. Use the disability models to help you identify the types of information you would need to plan your therapy. Look at the interview guidelines to see if you have enough information.

4. How are you going to monitor the changes in S.H.'s participation with her daughter and at work?
5. Now look at the daughter's perspective. How is her mother's new health condition affecting their relationship? What impact do you think the aphasia per se is having on their relationship? How much is unrelated or due to non-linguistic factors?
6. What kinds of things/people might be helpful in the environment? What might hinder integration?
7. Are there any other professionals you would like to include? If so, which ones? Design a therapeutic plan using the principles from the ESOPE model.

8. Think about the chronicity of neurologic language disorders such as aphasia, and evaluate how each of the service environments might impact on this chronicity (e.g., rehabilitation versus acute care). Fill out the categories in Table 1 using the hypothetical case above. Think about S.H.'s possible experiences as she takes part in the different levels of care.
9. Do you think your objectives match S.H.'s objectives?
10. Discuss the relevance of health-related quality of life measures and generic quality of life measures for capturing the impact of aphasia in life participation activities and roles.
11. Think about what motivated you to become a speech-language pathologist, and think about the changes you hoped or are hoping to bring about as a clinician. Does a therapy focused on the social consequences of aphasia respond to these aspirations?

► *Acknowledgment*—All of the animals except man know that the principle business of life is to enjoy it. (Anonymous)

► *Acknowledgment*—Above all, as clinicians and researchers, we need to recognize that our knowledge of aphasia provides, at best, a shallow representation of the reality in which our clients and their significant others live. (Shadden, 2005, p. 221)

► *Acknowledgment*—To Juliette, my mother, who became aphasic at the time I was writing this chapter.

APPENDIX 13.1

Interview Guidelines for Looking at Functioning

Notes to Interviewer:

1. It is important to ask, in all areas, whether a person does not do the activity by choice.
2. Items indicated with bullets are suggested areas to explore.

Housing/Living at Home

- Q1. Who do you live with?
- Q2. Are you able to take care of your house/apartment? Any technology help? Any human help?
- Cleaning and laundry
 - Acquisition and adaptation of residence
 - Management of home and possessions (furnishings, animals, pets)
 - Paid home adaptation services?

Nutrition

- Q3. Do you have any difficulty with your daily nutrition needs? Any meal providing services?
- Getting food, buying food (restaurant, school cafeteria, store), preparing food (appliances, recipes)
 - Use of utensils? Feeding aids?
 - Do you eat well?

Personal Maintenance

- Q4. How would you consider your physical and mental health?
- Stress management and behavioral modification
 - Physical conditioning (relaxation, fitness, sleep)
 - Use of health-care services and resources
 - Health promotion (eating well, yoga, etc.)
 - Medication intake
 - Are services available to you?

- Q4.1. Any problems handling different emotional situations?

- Frustration
- Anger
- Sadness
- Happiness

- Q4.2. Does anybody help you with handling emotions?

- Friends
- Therapist
- Family

- Q5. Do you have issues related to your personal appearance and cleanliness?

- Washing (self, teeth, clothes)
- Dressing
- Toileting
- Technical or human aids?

Mobility

- Q6. Can you get around your home and in your neighborhood for short walking distances?

- Walking
- Running
- From sitting to standing
- From standing to lying
- Staying in one position
- Balance

- Q6.1. Do you have physical limitations that require modifications to your environment (accessibility, accommodations, distance to services)?

- Q6.2. Do you require any type of special equipment, or services to help you move from one place to another (walker, wheelchair, special transportation services, etc.)?

- Q6.3. How is your mobility when traveling long distances?

- Using transportation (as a passenger, as a driver)

Communication/Exchange of Information

Q7. To what extent can you communicate with others? When do you encounter difficulties? What strategies do you use to overcome these difficulties?

- Spoken
- Written
- Sign language
- Nonverbal
- Body language
- Public symbols
- Drawings and photographs

Q7.1. Use of communication devices and technologies?

Q7.2. How do people react to you when you communicate?

Interpersonal Relationships

Q8. Describe your relationships with people. Do you have problems initiating and/or maintaining relationships?

Q8.1. Do you receive support or assistance (encouragement) from people?

- Spouse/intimate partners
- Children
- Friends
- Work colleagues
- Family
- Strangers
- Home-care providers
- Health professionals

Community Life

Q9. What is your involvement in all aspects of your community?

- Social life (activities organized by the community)
- Community associations or groups (scouts, self-help groups, political party, etc.)
- Spiritual life or organized religion

Work

Q10. To what extent can you participate in any type of work or employment?

- Work preparation (seeking employment)
- Self-employment
- Remunerative employment (full time, part-time)
- Nonremunerative work

Q10.1. Are you satisfied with your work and work environment?

- Colleague support and attitudes
- Physical environment at work (noise, lighting, number of colleagues, etc.)
- Organization of tasks (workload, change in duties, number of hours, etc.)

Q10.2. Do you need any special technical or human aid?

Education

Q11. How do you manage in school?

- Trouble understanding what's going on in class
- Friends at school
- Organization of class activities
- Problems with any subjects
- Taking notes
- Exams
- Extracurricular activities

Q11.1. Do you like school?

Q11.2. Do you need any special technical or human aid (adapted classroom, hearing aids, etc.)?

- When something is difficult to understand at school, are there things that the teacher can do to help you learn?

Leisure

Q12. Are you involved in any form of leisure activity?

- Sports
- Arts and culture (music)
- Cinema/theater
- Games
- Hobbies
- Travel (including preparing trips)
- Socializing

Responsibilities/Finances

Q13. Do you have problems managing your finances, your civil and family responsibilities? Have your social roles changed?

- Economic transactions and self-sufficiency (budget, going to the bank)
- Citizenship (social, political, and legal role of a citizen)
- Family (care and responsibility of others: parents, children, spouse)

Q13.1. What is your main source of income, and are you satisfied with it?

Q13.2. Do you receive any additional financial assistance from your family, governmental agencies, or private programs?

Q14. Any general comments about attitudes and support from people?

Q15. Are there things in your physical environment, at home, at work, or in other public places that you would like to change.

Q16. Are you satisfied with your quality of life? Is there anything that you would like to change? What would be your priorities?

Chapter 14

Group Therapy for Aphasia: Theoretic and Practical Considerations

Kevin P. Kearns and
Roberta J. Elman

OBJECTIVES

The need to synthesize the group treatment literature, describe current clinical practice, and develop specific treatment approaches that can be both clinically useful and experimentally validated continues to exist. Therefore, the purpose of this chapter is (a) to critically review and summarize the aphasia group therapy literature and (b) to present a perspective on group therapy for aphasia that is consistent with information in the literature on facilitating generalization. Suggestions will also be provided regarding the future role of speech-language pathologists in this area of rehabilitation.

The content and focus of group therapy for aphasia is predominantly a function of the skills and biases of the group leader (Elman, 1999, 2007; Marquardt, 1982; Marquardt, Tonkovich, & Devault, 1976). In general, however, most aphasia groups focus on one or more of the following parameters: psychosocial adjustment, speech-language treatment, and/or counseling (Eisenenson, 1973; Fawcus, 1989). This clinical taxonomy is, of course, somewhat arbitrary, because communication and psychosocial factors are intricately related and improvement of one factor may affect the other (Marquardt et al., 1976). Therefore, the interrelatedness and complexity of therapeutic goals in group treatment of aphasia should be kept in mind during the following discussion of group treatment approaches.

Group therapy for aphasia evolved in the United States as a practical response to the large influx of head-injured veterans returning from World War II. At that time, relatively few professionals were specifically trained to provide clinical services for individuals with aphasia, and burgeoning caseloads neces-

sitated group treatment. Group therapy has remained a common method of treating aphasia both in the United States and abroad (Fawcus, 1989; Pachalska, 1991a; Tsvetkova, 1980).

Ironically, changes in reimbursement and public policy (Frattali, 1992) as well as a renewed interest in psychosocial aspects of recovery from aphasia have stimulated a renewed interest in group treatment (Avent, 1997a, 1997b; Borenstein, Linell, & Wahrborg, 1987; Brindely, Copeland, Demain, & Martyn, 1989; Elman, 1999, 2005, 2007; Elman & Bernstein-Ellis, 1999a, 1999b; Marshall, 1999a, 1999b; Pachalska, 1991a, 1999b; Radonjic & Rakuscek, 1991). Lyon (1992) argued that clinical aphasiologists broaden their clinical perspective by incorporating psychological as well as functional communicative goals into the endeavors and should use treatment plans that facilitate or encourage “participation in life.” The Life Participation Approach to Aphasia (LPAA Project Group, 2000) (see Chapter 10), further articulated this perspective. Similarly, Frattali has noted, “We must remember that human communication sciences and disorders is a discipline dedicated to improving the quality of life of persons with communication disorders” (p. 81). Psychosocial factors are classified in the World Health Organization (WHO) International Classification of Functioning, Disability, and Health, or ICF. The WHO framework seeks to integrate medical and social models of medicine using a biopsychosocial approach. The reader is referred to the WHO publication for a complete description of this framework (WHO, 2001).

Of course, interest in the broader aspects of recovery from aphasia are not new. Descriptive accounts of group therapy and its benefits abound in the aphasia literature (Agranowitz, Boone, Ruff, Seacat, & Terr, 1954; Aronson, Shatin, & Cook, 1956; Chenven, 1953; Gordon, 1976; Holland, 1970; Inskip & Burris, 1959; Nielson, Schultz, Corbin, & Crittsinger, 1948; Schlanger & Schlanger, 1970; Wepman, 1947). Advocates have claimed that group intervention results in widespread changes in speech and language skills as well as increased psychosocial adjustment to aphasia. Unfortunately, few objective studies have supported these claims, and the efficacy of group therapy for aphasia has more recently been established. Although the results of

recent investigations indicate that group therapy is an effective form of aphasia management (Aten, Caligiuri, & Holland, 1982; Avent, 1997a; Brindely et al., 1989; Elman & Bernstein-Ellis, 1999a, 1999b; Radonjic & Rakuscek, 1991; Wertz et al., 1981), aphasiologists have only recently given attention to this important area of clinical investigation. Renewed interest in group therapy for aphasia is reflected in recent publications that specifically address clinical goals and procedures for group intervention (Avent, 1997b; Elman, 1999, 2007; Marshall, 1999a; Vickers, 1998). These texts are a welcome addition to the clinical armamentarium, because clinical aphasiology textbooks contain only brief descriptions of group treatment and minimal discussion of the procedures employed in group therapy (Brookshire, 1992; Darley, 1982, 1992; Eisenson, 1973; Jenkins, Jimenez-Pabon, Shaw, & Sefer, 1981; Sarno, 1981). Before the recent publication of texts that focus on group treatment, few critical summaries of the group treatment literature were available (Fawcus, 1989; Marquardt et al., 1976).

While recognizing the need for empirically based group treatment procedures, recent interest in broader rehabilitation goals has occurred within a conceptual and methodologic framework that heretofore had been lacking. From a conceptual perspective, clinical aphasiologists have begun to appreciate the complexities associated with facilitating generalized changes in people with aphasia (Van Harskamp & Visch-Brink, 1991). More important, an ecological perspective on intervention, which considers the complexity of environmental, personal, social, emotional, and communicative factors on treatment, is finally evolving into specific, testable treatment suggestions for both individual and group therapy (Aten et al., 1982; Davis & Wilcox, 1981; Elman & Bernstein-Ellis, 1999a, 1999b; LaPointe, 1989). Consistent with the trend toward a more ecological approach to intervention, a concomitant emphasis on methodologic issues may provide a procedural framework for group therapy. For example, calls for reliable and appropriate functional (Frattali, 1992), psychosocial (Lyon, 1992), and life participation assessment tools (LPAA Project Group, 2001), as well as the development of a generalization planning approach to intervention (Garrett & Pimentel, 2007; Kearns, 1989; Thompson, 1989), have direct relevance to group intervention for aphasia.

GROUP TREATMENT APPROACHES

Psychosocial Groups

Although psychotherapeutic and sociotherapeutic approaches to group management have been distinguished in the aphasia literature (Marquardt et al., 1976), these approaches share more similarities than differences. That is, despite differing descriptive labels, the purpose and procedures discussed in reports of sociotherapeutic and psychotherapeutic group

therapy are often indistinguishable. Psychosocial groups provide a supportive atmosphere in which individuals with aphasia can ventilate feelings and learn to cope with the psychological impact of aphasia. In addition, the goals and procedures of these groups emphasize interpersonal relationships while providing social contacts with other persons who are “in the same boat.” The primary purpose of psychosocial aphasia groups is to foster the development of emotional and psychological bonds that help group members to cope with the consequences of aphasia (Ewing, 1999, 2007; Inskip & Burris, 1959; Luterman, 1996; Oradei & Waite, 1974; Redinger, Forster, Dolphin, Godduhn, & Wersinger, 1971; Yalom, 1995).

Earliest reports of psychosocial group treatment gave minimal attention to subject description, procedural specification, or evaluation of treatment results (Backus & Dunn, 1947, 1952; Blackman, 1950; Blackman & Tureen, 1948; Godfrey & Douglass, 1959). Aronson et al. (1956), however, provided a detailed description of a “social-psychotherapeutic” approach to group therapy and attempted to evaluate the effectiveness of such a program. They developed a task continuum in an attempt to facilitate group discussion, provide an emotional outlet, and allow patients to develop interpersonal relationships. Tasks in the hierarchy ranged from non-verbal (e.g., music rhythm group) to solely verbal (e.g., group discussion), and they included (a) using rhythmic musical instruments, (b) participating in group singing, (c) listening to short stories read by a group leader, (d) participating in various speech games and discussion of proverbs, (e) taping and replaying speech samples, and (f) taking part in group-centered discussion. Activities from the hierarchy were introduced as needed to maintain motivation and facilitate group interaction whenever adequate group discussion could not be elicited.

The effectiveness of this approach was evaluated for 21 chronic and acute patients who attended an average of 14 hourly treatment sessions. Results of interviews and clinical ratings revealed that the patients and staff reacted quite favorably to the treatment program. The group leaders also observed a reduction in anxiety, an increased level of intra-group, and a heightened ability for constructive self-criticism among group members. Another early report of psychosocial group therapy notable for its attempt to outline specific group treatment procedures was provided by Schlanger and Schlanger (1970). They recommended the use of role playing as a method for reducing anxiety about communication and establishing spontaneous, functional discourse in the group setting. Their primary purpose was to “try to ‘get something across’ both inter- and intra-personally” (p. 230) through the use of (a) gesture and pantomime, (b) role playing one’s self in realistic situations, (c) role playing other individuals, and (d) psychodrama.

As Schlanger and Schlanger (1970), reported gestures and pantomime were employed to enhance the communication

of chronic patients with aphasia who had severely limited verbal abilities. Gestural and pantomime training included the use of descriptive gestures to transmit information about pictorial referents, pantomiming daily activities such as mailing a letter, and using “universal” iconic gestures.

Following gesture and pantomime training, the patients participated in role-playing activities involving nonstressful and stressful situations. Nonstressful situations included activities such as shopping or attending a picnic. Role playing in stressful situations involved having patients interact with a clinician in a “Candid Camera”-like situation. Unexpected events were blended into everyday experiences so that the patient had to problem solve and communicate in a natural situation.

Another aspect of this approach involved having the individuals with aphasia role play other people during simulated situations. During this activity, patients used pantomime and verbal skills to depict people in contrived scenes from a bakery, a florist, and so on.

A final aspect of the group treatment program used psychodrama to act out the problems and frustrations of each group member. During this activity, patients assumed roles that allowed them to vent feelings and release hostility.

The aphasia group members gradually progressed through the four facets of training, and several benefits of the program were noted. Patients demonstrated an increased ability to cope with stressful situations, a reduction in anxiety concerning communication deficits, a feeling of accomplishment, a loss of emotional inhibition, and a better insight regarding feelings and problems. Schlanger and Schlanger (1970) concluded that role-playing activities provide an important means of adjusting to the psychosocial impact of aphasia.

More recent clinical reports have also targeted psychosocial goals within the aphasia group setting. Borenstein et al. (1987), for example, examined the psychological, linguistic, and neurologic effects of a 5-day, intensive residential treatment program for participants with aphasia and their relatives. Eleven participants with aphasia and seven family members attended the group. Sessions were conducted by a speech-language pathologist, a psychologist, and a neurologist. Formal assessments of the family members’ psychological adjustment and of the participants with aphasia’s language ability and neurologic status were conducted. The content of the intervention program included family-centered therapy, social excursions that encouraged functional communication, and group discussions of everyday problems and adjustment strategies. Reevaluations of the participants conducted 1 year after the intensive treatment period revealed some improvements in psychological and interpersonal adjustment but not in neurologic or communicative status. A 10-year follow-up study involving eight of the original participants (Wahrborg, Borenstein, Linell, Hedberg-Borenstein, & Asking, 1997) found the improvements that had been achieved at the end of the course of treatment were

diminished after 10 years. All but one of the participants showed a more severe aphasia at the 10-year follow-up; however, seven of the eight participants reported that their quality of life was improved at 10 years post-treatment as compared with the end of the psychosocial group.

Johannsen-Horbach, Wenz, Funfgeld, Hermann, & Wallesch (1993) reported on their aphasia groups that focused on aspects of coping with aphasia and its consequences. Two groups were described—one for younger participants (eight members, ages 26–51), and one for elderly participants (seven members, ages 60–80). Content of the group treatment included interactional and conversational exchange about psychosocial burden, communication strategies (e.g., PACE [Davis & Wilcox, 1985]), role playing, and tasks from a verbal/visual memory training program. The groups, which were led by a psychologist and a speech-language pathologist, met once a week for 2 hours. The younger group met a total of 22 times, and the elderly group met a total of 16 times. The authors reported that participants had higher degrees of self-esteem following participation in the group treatment and were able to use “new behavioral strategies.” The authors stated that younger participants had more difficulty accepting their deficits as compared with the elderly clients and wanted to focus their efforts on communicative deficits. The authors concluded that their observations support the usefulness of psychosocial groups and reinforce their belief that separating participants by age is a useful clinical strategy.

Hoen, Thelander, & Worsley (1997) reported on psychosocial changes following participation in their community-based program offered to people with aphasia following stroke and head injury. Their study evaluated changes on a condensed form of psychological scales of well being (1989). Thirty-five clients with aphasia attended volunteer-run communication groups twice weekly for half-days. In addition, a social worker led caregiver support groups with 12 family members. Although improvement was measured over a 6-month period, treatment time in the program before enrollment in the study was not controlled. In addition, total treatment time for each subject was not reported. Results indicated that clients with aphasia showed positive changes on the scales, which measure autonomy, environmental mastery, personal growth, purpose in life, and self-acceptance. The scale designed to assess positive relations with others did not show significant change. The results for family members were also encouraging; family members showed significant change on all scales except for “environmental mastery.” Despite these positive findings, the authors note that the design of this study is flawed and does not permit an objective assessment of the benefits of group intervention.

Penman and Pound developed a short-term, self-advocacy group for people with aphasia at the City Dysphasic Group at City University in London (Pound, 1998; Penman,

2007). The course ran for 10 weeks with 2-hour sessions. The focus of the group was twofold: (1) to identify disabling barriers in the environment, and (2) to develop a positive personal identity that was inclusive of aphasia and disability. Two people, a speech-language therapist and a person with aphasia, facilitated the groups. Eight individuals with chronic aphasia participated. Group discussion was used as the vehicle for working on many different issues, including communication, self-esteem, autonomy, leisure life, and financial status.

The outcomes of the therapy were evaluated by examining personal interviews and personal portfolios that had been developed by each group member. Post-treatment evaluations suggested that group members felt more confident, had improved self-esteem, and were more positive about living with aphasia. Participants also reported feeling an increased sense of social participation and “belonging.”

Shadden (2007) described an ongoing monthly support group, the Stroke Support Group of Northwest Arkansas (NWA), originally established in 1982. She noted how the group has evolved into a community in which members exchange life stories, thereby renegotiating “self and identity.” The NWA includes survivors of stroke, both with and without aphasia, as well as family members or others who are dealing with the impact of stroke. No formal agenda is followed; instead, group sessions start with a sharing time, followed by breakout sessions for survivors of stroke and significant others. Shadden listed 12 core values of the group: (1) respect for the concerns and competence of each member; (2) acceptance, (3) affirmation and validation, (4) actions speak louder than words, (5) feelings are okay, (6) reflection and problem solving are encouraged, (7) flexible goals, (8) a clean slate, (9) participant oriented, (10) focus on the story, (11) interaction oriented, and (12) celebration of change. The rules and routines that characterize the NWA include putting the survivors of stroke first, focusing on new members, and sharing updates and life stories.

Useful supplements to the specific psychosocial treatment programs outlined above are provided by Elman (2000), Ewing (1999, 2007), and Luterman (1996). These authors summarize information regarding group process, group dynamics, and other group considerations that speech-language pathologists must be aware of when facilitating treatment groups. Both authors emphasize group techniques that need adaptation when working with members who have neurogenic communication disorders.

Summary and Observations

The literature contains a general consensus that psychosocial group therapy provides psychological, emotional, and social benefits for individuals with aphasia. Specific benefits that have been reported include an opportunity for increased socialization; a supportive atmosphere in which individuals

with aphasia can express anger, hostility, and other emotions; and the development of skills that allow patients to cope with emotional and life-style changes resulting from aphasia (Aronson et al., 1956; Backus & Dunn, 1947; Blackman, 1950; Blackman & Tureen, 1948; Byng et al., 1998; Eisenson, 1973; Friedman, 1961; Godfrey & Douglass, 1959; Hoen et al., 1997; Inskip & Burris, 1959; Johannsen-Horbach et al., 1993; Marquardt et al., 1976; Oradei & Waite, 1974; Pound, 1998; Redinger et al., 1971; Schlanger & Schlanger, 1970; Shadden, 2007). Despite near-unanimous agreement regarding the benefits of psychosocial group treatment, it should be cautioned that the findings of most reports in this area are based on subjective assessment and anecdotal observations. Data-based studies are practically nonexistent in the psychosocial group literature, and those that have been reported have not been rigorous (Aronson et al., 1956; Godfrey & Douglass, 1959; Oradei & Waite, 1974). Although the psychometric difficulties involved in measuring psychological and social parameters are substantial, a pressing need exists to begin evaluating the psychosocial impact of group treatment for aphasia.

Prerequisite to the establishment of a solid database for this approach to aphasia management is the development of specific, replicable treatment procedures. Unfortunately, with few notable exceptions (Aronson et al., 1956; Schlanger & Schlanger, 1970), investigators have not delineated specific treatment principles or procedures for conducting psychosocial group therapy for aphasia. Descriptions in the literature do not provide the procedural detail necessary to translate them into clinical practice (e.g., Friedman, 1961; Oradei & Waite, 1974; Redinger et al., 1971), and psychosocial group therapy remains largely an undefined entity. Moreover, when attempts have been made to document the effectiveness of psychosocial treatment groups (e.g., Borenstein et al., 1987), failure to meet minimal psychometric standards limits the usefulness of these efforts.

Family Counseling and Support Groups

In addition to the psychosocial adjustment difficulties of individuals with aphasia, the emotional, psychological, and life-style changes for family members of individuals with aphasia have also been documented (Friedland & McColl, 1989; Johannsen-Horbach et al., 1993; Kinsella & Duffy, 1978, 1979; Lafond, Joannette, Ponzio, Degiovanni, & Sarno, 1993; Lyon, 1998; Malone, 1969; Parr et al., 1997; Rice, Paul, & Müller, 1987). More than 30 years ago, Malone (1969) observed that “in most cases the family as a closely knit unit no longer existed” (p. 147) once a family member was stricken by aphasia. He concluded that family counseling programs are needed to help spouses and family members learn about aphasia and cope with its devastating consequences. The group setting is frequently used for

counseling and educating both patients with aphasia and their families.

Brookshire (1997) notes that the primary objective of family support or counseling groups is to educate patients with aphasia and their families about the nature of aphasia and to explore the impact of aphasia on family dynamics. Counseling groups provide a medium for discussing physical, psychological, and social consequences of brain damage. They also serve as a forum for expressing feelings and learning to adjust to newly acquired family roles and life-style changes. Brookshire observed that patient-family and spouse support groups also function as a social or recreational outlet for individuals with aphasia and their families.

Examples of family counseling groups abound in the aphasia literature (Davis, 1992; Derman & Manaster, 1967; Friedland & McColl, 1989; Gordon, 1976; Johannsen-Horbach et al., 1993; Kisley, 1973; Mogil, Bloom, Gray, & Lefkowitz, 1978; Newhoff & Davis, 1978; Porter & Dabul, 1977; Puts-Zwartjes, 1973; Redinger et al., 1971). Turnblom and Myers (1952) provided one of the earliest examples of group counseling for families of individuals with aphasia. Following this early report, the area of rehabilitation was virtually neglected for approximately 20 years. Redinger et al. (1971) subsequently described a multidisciplinary discussion group for patients with severe aphasia and their spouses. The purpose of the group was to facilitate emotional adjustment and to help the group members work through family and social issues using problem-oriented discussions. The group, which met on a weekly basis for 1 year, consisted of several co-leaders (a speech-language pathologist, a psychiatric nurse, and a psychiatrist), six patients with aphasia, and four spouses. Participation of the spouses was viewed as a critical element in rehabilitation, because problems discussed in the group inevitably involved adjustment difficulties that were shared by the patients with aphasia and their spouses.

Redinger and colleagues (1971) observed that the group evolved through several stages during the course of therapy. Initially, a period of anxiety occurred, and group members experienced difficulty communicating with one another. During the second stage, the members expressed regrets about their condition and complained about various factors associated with rehabilitation. Finally, during the third stage, the group evolved into a friendly, understanding, and supportive unit. As the group evolved through these stages, participants gradually became better adjusted to home and social environments, and they developed a more realistic view of family problems. In addition to these benefits, the counseling group also provided a social outlet for patients and spouses.

Many reports of spouse counseling groups highlight the importance of planning treatment to meet the specific needs of individual patients with aphasia and their families. The spouse counseling group of Gordon (1976), for example,

developed in response to the needs expressed by wives of patients with aphasia. The group provided an atmosphere in which spouses acquired a better understanding of aphasia, felt free to express feelings and share their reactions, and worked through problems that occurred as a result of the aphasia. The ultimate goal of the group was to improve the interpersonal relationships of the individuals with aphasia and their spouses.

A speech-language pathologist and a psychiatric social worker acted as co-leaders for the group. Meetings were held on a weekly basis, and attendance ranged from 4 to 10 spouses per session. The duration of individual spouse participation in the group varied from several months to 3 years. The co-leaders adopted a nondirective counseling approach, in which wives increasingly assumed more responsibility for the content and direction of the group while the leaders provided information and guidance as needed. Psychosocial aspects of adjustment addressed by the social worker included feelings of resignation, guilt, and loneliness; shifts in family roles; and the need to maintain interests outside the home. The speech-language pathologist discussed the nature of aphasia, the prognosis for recovery of language skills, and strategies for improving communication with their partners who have aphasia. Wives were encouraged not to demand verbal responses from their husbands, to accept nonverbal communication, and to modify their input to their partners with aphasia.

Gordon (1976) concluded that wives' emotional problems hindered communication with their husbands who had aphasia before participation in the group. The group, however, helped to alleviate many of the wives' emotional problems, and formal psychotherapy was seldom required. Still, Gordon cautioned that multiple repetitions were often needed before the wives comprehended group-counseling information. Some redundancy may, therefore, be necessary for spouses to receive maximum benefit from group treatment.

Bernstein (1979) also described a multidisciplinary spouse group that evolved out of concern for the emotional needs of family members. He stressed that interpersonal problems between patients with aphasia and their wives may interfere with speech-language treatment. More important, Bernstein believed that the family unit itself may be endangered if we ignore the emotional and psychological trauma suffered by spouses and other family members. He stressed that we cannot meet the complex emotional needs of spouses simply by providing a list of "do's and don'ts" and then discussing them. Bernstein also indicated that the team leaders benefited from the group as well; he stated, "We are all better clinicians for the experience" (p. 35).

Recognizing the scarcity of studies in the aphasia counseling area, Newhoff and Davis (1978) reported their attempt to objectively plan and implement a spouse intervention program. Four spouses, two male and two female, participated in this study. Spouses were individually interviewed to determine target areas for intervention, and a questionnaire was

administered both before and at the termination of the study to evaluate the effectiveness of the program.

The questionnaire examined seven areas: (1) communication strategies, (2) changes in life style and social pursuits, (3) spouses' feelings regarding their partner's disability, (4) spouses' perceptions of how well they understood their partner's problems, (5) actual level of spouse understanding, (6) spouse-partner independence, and (7) advice sought by spouses. The items in the questionnaire were all "Do you . . ." questions. For example, one item asked, "Do you talk with your spouse as you did before the accident?" (Newhoff & Davis, 1978, p. 320). The spouses circled appropriate answers on a seven-point rating scale that ranged from "very often" to "never."

The spouse intervention group met for a 50-minute session once a week for a period of 7 weeks. A speech-language pathologist served as group leader, but the spouses provided the direction for the group. The leader served as a catalyst for discussions and provided information as needed. The purpose of the group was to accomplish the following "counseling functions": (a) provide information to the spouses, (b) receive information from spouses that might be useful during their partner's rehabilitation, (c) facilitate the spouses' acceptance of their own feelings and help them to accept and understand their partners with aphasia, and (d) effect change in the spouses' behavior.

After 7 weeks of group counseling, the questionnaire was readministered to evaluate the effectiveness of the intervention. A comparison of responses to pre- and post-study questionnaires revealed considerable variability in the spouses' responses, and no discernible pattern of change was apparent. However, Newhoff and Davis (1978) concluded that they had accomplished their primary counseling objectives. They also concluded that, although the measurement problems involved in evaluating group counseling are difficult, they are not insurmountable.

Rice et al. (1987) also described their social support group for the spouses of 10 patients with aphasia. The purpose of this 12-week group was to provide information and social support, enhance psychosocial adjustment, and facilitate communication between persons with aphasia and their spouses. The authors reported significant improvement on scales of psychological adjustment for those individuals who consistently attended the group. No significant differences were found in the post-treatment functional communication ability of patients with aphasia whose spouses regularly attended versus those whose spouses did not regularly attend. Although this report is noteworthy for its attempt to evaluate the psychosocial effects of the spouse counseling group, the results must be interpreted cautiously given the small number of participants in the evaluation and the lack of appropriate experimental control.

Friedland and McColl (1989) attempted to operationalize the definition of social support for their spouse program.

Their model conceptualizes social support as having three dimensions: (1) source of support, (2) types of support, and (3) how satisfied the patient is with the support received. Common sources of support may include personal, friend/family, community, and professional resources. Relatedly, the type of support received may include emotional and informational support. Their parsing of social support has potential as a taxonomy for future studies of counseling and support groups.

A number of comprehensive aphasia programs offer caregiver and family support groups as part of their regular programming (Beeson & Holland, 2007; Bernstein-Ellis & Elman, 2007; Hersh, 2007; Kagan, Cohen-Schneider, Sherman, & Podolsky, 2007; Penman & Pound, 2007). Kagan and colleagues (2007) provided a detailed description of a 12-week program support and education program that included a "family and friends" group. The family and friends group consisted of 15 to 25 individuals. The primary goals of the group included the following: (1) sharing experiences of living with aphasia, (2) increasing understanding of aphasia as well as ways to overcome communication breakdowns, and (3) finding new ways to live and find hope for the future.

Summary and Observations

Patient and family counseling groups have been widely advocated in the aphasia literature. The primary purpose of patient-family and spouse groups has been to provide educational information regarding aphasia and to provide emotional support for individuals with aphasia and their families. At times, speech-language pathologists and psychologists have acted as group co-leaders for aphasia counseling groups. Their primary function has been to lead topic-oriented discussions that center on issues of communication and emotional adjustment. The emphasis in counseling groups for individuals with aphasia and their relatives has been on "working through" the communication, emotional, and life-style changes that affect family dynamics.

The devastating effects of aphasia on interpersonal relationships and the family unit are well documented, and the need for counseling persons with aphasia and their families is unassailable. Little documentation, however, exists regarding the best format for accomplishing counseling objectives in the group setting. Although not specifically mentioned in most reports of group counseling, topic-oriented discussions should be accompanied by printed counseling information and/or appropriate audiovisual materials. Bevington (1985), for example, described an educational program that included the use of videotaped educational materials, lectures, and printed materials. The National Aphasia Association is a nonprofit organization that promotes public education, research, rehabilitation, and support for people with aphasia and their families. The National Aphasia Association Web site (www.aphasia.org)

provides access to a variety of counseling and educational materials, including *The Aphasia Handbook* (Sarno & Peters, 2004), that can be used to support individual or group counseling efforts. Web sites for other professional organizations, such as the Aphasia Hope Foundation (www.aphasiahope.org), the National Stroke Association (www.stroke.org), and the American Stroke Association (www.strokeassociation.org), also provide an invaluable resource for the clinical management and counseling of persons with aphasia.

Information provided in the counseling packets can be supplemented with counseling films. Printed information provided in patient-family counseling can be supplemented with videotaped material, such as *Pathways: Moving Beyond Stroke and Aphasia* (Ewing & Pfalzgraf, 1991a) and *What Is Aphasia?* (Ewing & Pfalzgraf, 1991b).

Films and printed materials can be shared with individuals who have aphasia and/or with spouses before their participation in counseling and support groups. This common information base allows new members to immediately interact with the other group members if they wish to do so. Clinical experience indicates that this approach alleviates some of the anxiety that may be present before entering the group. Discussions generated from the counseling materials may also help clinicians to determine if a client or spouse might benefit from individual counseling. For example, spouses can be referred to a clinical psychologist for evaluation if they do not appear to be psychologically ready to share their feelings and emotions in the group setting. Similarly, spouses who discuss sensitive issues such as divorce or suicide may also be referred for individual counseling.

The invaluable contributions of professionals specifically trained in psychological assessment and counseling emphasize the importance of an interdisciplinary approach to family counseling for aphasia. Group counseling sessions are often very emotionally laden, and speech-language pathologists require specific training to manage the psychological and emotional impact of disability (Ewing, 1999, 2007; Kearns & Simmons, 1985; Luterman, 1996). Group counseling for aphasia may be best conducted within a multidisciplinary approach that recognizes and treats emotional and psychological difficulties arising from disordered communication (Friedland & McColl, 1989; Pachalska, 1991a; Radonjic & Rakuscek, 1991).

Speech-Language Treatment Groups

Speech-language treatment of patients with aphasia has been conducted in group settings for nearly half a century, yet despite this history, group therapy for aphasia remains a controversial area. Many authors have viewed group therapy as being an “adjunct” to, or a substitute for, individual therapy (Chenven, 1953; Eisenson, 1973; Makenzie, 1991; Marquardt et al., 1976; Schuell, Jenkins, & Jimenez-Pabon, 1964; Smith, 1972), rather than a substitute for it. Schuell

et al. (1964), for example, noted that “we are unable to have confidence in group therapy as a basic method of treatment for aphasia” (p. 343), because benefits derived from group treatment are likely to be emotional or social in nature. Similarly, although he acknowledges potential speech-language benefits, Eisenson (1973) states, “The first and most important [objective] is providing psychological support for individuals within the group” (p. 188). The prevalent attitude has been that group treatment methods may not facilitate speech-language recovery in aphasia but are not, at least, detrimental to recovery.

In opposition to the stance that group therapy for aphasia is merely palliative, a number of authors have indicated that group intervention is an effective means of treating speech-language deficits (Aten et al., 1981, 1982; Avent, 1997a; Beeson & Holland, 2007; Bloom, 1962; Elman, 2007; Elman & Bernstein-Ellis, 1999a, 1999b; Fawcus, 1989; Garrett & Ellis, 1999; Graham, 1999; Hersh, 2007; Makenzie, 1991; Marshall, 1993, 1999a, 1999b; Penman & Pound, 2007; Penn & Jones, 2007; Van der Gaag et al., 2005; Walker-Batson, Curtis, Smith, & Ford, 1999; Wertz et al., 1981; Worrall, Davidson, Howe, & Rose, 2007). Although the data are not yet available to conclude that individual and group therapy for aphasia are equally effective, recent data and opinions that support this conclusion are stimulating investigative interest in the group treatment approach. In the sections that follow, we will examine the speech-language treatment group literature and explore emerging trends in this area.

Advocacy Reports

For our purposes, the term “advocacy reports” is used to designate articles that advocate the use of group speech-language therapy for aphasia without clearly delineating treatment procedures or presenting data to support their position. Johnston and Pennypacker (1980) originally described an advocacy research style as one in which the experimenter’s prejudices interfere with his or her objectivity. That is, the experimenter “has taken the role of an advocate who defends a cause, not a scientist who searches for understanding” (p. 424).

Advocacy reports may reflect, in part, a paucity of efficacy research, a strong clinical bias toward unproven techniques, and a genuine interest in sharing clinical ideas. Clinicians are often more influenced by teachers, colleagues, and nondatabased presentations than they are by clinical research. This has often been the case with clinical aphasiology, in which few data existed regarding the efficacy of group therapy approaches. Unfortunately, discussions of group therapy for aphasia continue to be based primarily on clinical experience and bias. Some descriptions of group therapy approaches have attempted to document change in psychosocial skills (Borenstein et al., 1987) and in communication skills (Radonjic & Rakuscek, 1991) following intervention. Few

studies, however, have incorporated appropriate experimental controls, such as the use of control groups and reliable measurement techniques. These limitations may negate the contributions of such efforts, making them comparable to earlier advocacy reports.

The current emphasis on intensive, multidisciplinary, functional aphasia treatment groups is reminiscent of approaches that have been advocated for decades (Borenstein et al., 1987; Pachalska, 1991a; Repo, 1991). Sheehan (1946) was among the earliest advocates of group speech-language therapy for aphasia. Her initial writings described “group speech classes,” in which small groups of patients with aphasia worked on everyday vocabulary. Five or six patients usually participated in the group at a given time. The specific content of “lessons” included greetings and farewells, personal identification information, money, calendar use, right-left orientation, and body part identification. As Sheehan noted, “The list is endless—a product of a little imagination and ingenuity and of observation of the things needed by the patients in their daily living” (p. 152). Sheehan (1948) was also an early advocate of establishing individualized goals for each patient with aphasia in treatment groups.

Wepman (1947) described a model program for inpatient rehabilitation of individuals with aphasia. This program was carried out by a multidisciplinary team that included speech-language pathologists, psychologists, occupational and physical therapists, social workers, and special education teachers. Both individual and group speech therapy sessions were included in the program. The speech-language pathologist directed speech-related groups, and special educators taught writing, spelling, reading, and arithmetic in a group setting. Wepman outlined an intensive program that included 6 to 8 hours of treatment per day, 5 days per week. He concluded that an intensive, multidisciplinary approach is necessary if patients with aphasia are to make maximum gains in therapy. A similar approach for patients with “motor aphasia” was outlined by Corbin (1951).

The earliest writers in this area emphasized the importance of functional communication therapy in the group setting, but the rationale for this approach was not fully developed for several years. Bloom (1962) was the first to clearly articulate a pragmatic philosophy of group therapy for aphasia. Her rationale for group treatment combined an awareness of contextual influences on communication and meaning with an appreciation for the power of operant training techniques.

Although several treatment groups were conducted in her setting, Bloom emphasized the feasibility of group treatment for patients with severe impairments. Individuals with aphasia who participated in her rehabilitation program attended one session of individual treatment, one session of auditory stimulation, and an hourly group session each day. The primary goal of group treatment was to improve functional communication abilities. All treatment activities were directed toward improving performance of activities of daily

living. Unlike many of the previously reported group treatments, however, this approach did not segment sessions into classroom-like activities according to separate language modalities.

Bloom emphasized a situational group approach, one in which language stimulation was provided in meaningful contexts. Situations that occurred in daily experience were recreated in the naturalistic group environment; role playing and rote memorization of scripts were avoided. Verbal tasks were used to practice greetings, directions, ordering from a menu, and handling money. In addition, auditory stimulation was provided during group sessions.

Summary and Observations

To summarize, advocacy style treatment reports promoted the use of group therapy techniques as a primary method of intervention for aphasia. These reports described ongoing group treatment programs and presented a sampling of tasks employed in the group setting. A consensus existed that group speech-language treatment was efficacious, although data to support this claim were lacking.

Despite their shortcomings, advocacy reports of group treatment for aphasia were farsighted in several respects. They were, for example, ahead of their time in recommending a multidisciplinary treatment approach (Nielson et al., 1948; Sheehan, 1946; Wepman, 1947). Sheehan (1946) held regular team conferences that included speech-language pathologists, occupational therapists, and physical therapists. An effort was made to coordinate these services so that an overall plan of rehabilitation could be developed. Wepman (1947) also strongly advocated the multidisciplinary approach; he indicated that “only by this overall cooperative approach can the maximum recovery level for the brain injured aphasic adult be achieved” (p. 409). Advocacy reports laid the historical foundation for current group therapy approaches that incorporate a multidisciplinary format (Pachalska, 1991a; Radonjic & Rakuscek, 1991; Walker-Batson et al., 1999).

In addition to establishing a multidisciplinary approach to aphasia management, early advocates of group therapy were nearly unanimous in their call for an intensive therapeutic regimen (Corbin, 1951; Huber, 1946; Sheehan, 1948; Wepman, 1947). Wepman (1947) and his contemporaries suggested daily treatment, and many advocated several sessions per day. Huber (1946), for example, indicated that most patients with aphasia could participate in 3 to 6 hours of therapy daily if appropriate rest periods were scheduled. Perhaps the most impressive aspect of the early group treatment literature is the consistent emphasis on functional, real-life treatment activities (Agranowitz et al., 1954; Bloom, 1962; Corbin, 1951; Huber, 1946; Sheehan, 1946, 1948). During the embryonic stages of group therapy for aphasia, clinicians developed treatment tasks that were based on the patients’ communicative needs in the living environment.

Treatment approaches included a consideration of contextual factors despite the lack of a supporting theoretic basis for “pragmatic” aspects of communication.

The previous examples of advocacy reports are primarily from the post–World War II era. Recent reports considered below, however, are also advocacy reports in nature (Borenstein et al., 1987; Friedland & McColl, 1989; Radonjic & Rakuscek, 1991; Rice et al., 1987). These authors present data obtained from uncontrolled group treatment studies to support the effectiveness of their approaches. Whereas earlier advocacy reports presented detailed clinical information and subjective clinical impressions, more recent descriptions of group therapy have included relatively less detailed information regarding clinical techniques and quasi-experimental results.

Taken together, early and more recent advocacy reports appear to have had a subtle and, perhaps, negative impact on the cumulative growth of objective information in this area. That is, the legacy of advocacy reports has been the tacit acceptance of the efficacy of group therapy for aphasia despite meager evidence to support this claim. Initial reports of group therapy provided convincing, albeit unsubstantiated, testimonials as to the effectiveness of this method of patient management, and more recent efforts have included clinical data that provide an appearance of scientific legitimacy. Acceptance of subjective reports and uncontrolled treatment data as evidence for the efficacy of group treatment, however, may have had the deleterious effect of retarding legitimate investigative efforts in this area. More than 20 years ago, Gilbert et al. (1977) stated that “repeated weakly controlled trials are likely to agree and build up an illusion of strong evidence because of a large count of favorable studies. Not only does this mislead us into adopting and maintaining an unproven therapy, but it may make proper studies more difficult to mount” (p. 687). It seems that advocacy reports of group therapy have seduced clinicians and researchers alike into uncritically accepting this approach, and the cumulative effect of this literature has been an “illusion of strong evidence.” Recent data-based clinical efforts represent a legitimate initial effort to examine the effectiveness of treatment, but these efforts must be followed up with more rigorous studies of efficacy that examine specific treatment approaches for clearly defined groups of patients with aphasia.

In the section that follows, we will examine contributions to the group treatment literature and explore the current status of research in this area. Five types of aphasia treatment groups—direct, indirect, sociolinguistic, transition, and maintenance—will be considered.

Direct Language Treatment Groups

Davis (1992) has distinguished “direct” from “indirect” treatment approaches. He states:

Direct approaches focus the clinician-patient interaction on the exercising of specific language processes. They are referred to as stimulus-response training, in which the clinician elicits specific language responses from the patient. They are structured . . . so that the patient is using discrete functions such as auditory language comprehension or word retrieval. (p. 241)

Brookshire (2003) was apparently referring to “direct” speech-language training groups when he noted that many aphasia treatment groups are didactic, relatively structured, and clinician directed. Tasks that are chosen for direct treatment groups of 10 individuals mimic those used in individual treatment.

Holland (1970) provided an early example of the application of “stimulus-response training” in a direct group treatment program. She applied “shaping and reinforcement procedures to direct language work with aphasics in a group setting” (p. 385). Unlike previously discussed group treatment reports, she established specific treatment goals in an attempt to improve verbal categorization, naming, plurality, subject-verb agreement, and syntactic ordering abilities. Language tasks were arranged in hierarchies of difficulty so that patients with various levels of aphasia could participate in the same group. Although Holland did not report objective data to support her exploratory approach, she did indicate that she was able to arrange treatment so that individual patient needs were met.

Additional examples of direct language treatment groups are also available from studies of specific training techniques. Skelly, Schinsky, Smith, and Fust (1974), for example, combined group treatment with individual treatment in their study of the effects of American-Indian sign on patients’ verbal production. They stated that the sign group was an integral part of their gestural program. Skelly and colleagues did not evaluate the contributions of group training to the acquisition of American-Indian signs. Relatedly, Sparks, Helm, and Albert (1974) used “less structured” Melodic Intonation Therapy (MIT) in direct group treatment of aphasia. Although not specifically evaluated in their study, group MIT therapy was suggested to possibly increase patients’ ability to intone basic, purposeful utterances.

More often than not, group therapy is viewed as an adjunct to individual therapy (Davis, 2000). Makenzie (1991) examined the effectiveness of a combined regimen of direct individual and group intervention. The five subjects in this study had previously been dismissed from nonintensive speech therapy after having plateaued. All participants were at least 9 months post-onset of aphasia. The primary focus of this investigation was to examine the value of an intensive period of therapy.

The stated aim of the aphasia group was “information giving.” All participants were encouraged to use an available modality to communicate effectively during discussions of daily topics. In addition, each individual participated in daily individual therapy in which two verbal goals were targeted

for improvement. In total, subjects received approximately 85 hours of individual and group therapy during a 1-month period, and a 1-month period of no treatment followed the period of intensive therapy. A screening battery for aphasia, a test of verbal naming ability, and a test of functional communication were among the measures used to evaluate treatment gains. The results of this clinical report indicate that all five patients improved on at least one clinical measure. Some decrease in performance was found following a period of no treatment.

Indirect Language Treatment Groups

Indirect treatment approaches are unstructured and may consist of general conversation, social groups, role playing, and field trips (Davis, 1992). Despite the fact that they are largely undefined, many of these approaches are purported to have therapeutic merit for improving deficient language skills. Previously presented examples of psychosocial group therapy for aphasia, which used unspecified or poorly described techniques, differ from indirect treatment approaches primarily in the orientation and general goals of the group leaders. That is, whereas the general purpose of psychosocial groups has been to facilitate emotional and psychological adjustment to aphasia, the orientation of indirect language training groups has been to stimulate language recovery.

Despite the vague nature of indirect treatment groups, reason exists to believe that loosely defined language stimulation and group discussion are commonly applied treatment methods. In a survey of group therapy for aphasia in a Veterans Administration Medical Center, Kearns and Simmons (1985) asked clinicians to estimate the percentage of time spent on various clinical activities during a typical aphasia group treatment session. The respondents indicated that “general, topic oriented discussions” were the most prevalent (31%) activity during group treatment. Considerably less group time was spent on “structured tasks” (e.g., word retrieval [22%]).

As in all areas of group therapy for aphasia, few data are available regarding the effectiveness of indirect language treatment groups. The poorly defined nature of these treatment approaches severely limits the ability of investigators to examine the usefulness of such approaches. A Veterans Administration cooperative study on aphasia (Wertz et al., 1981), however, compared the effectiveness of individual treatment and indirect group treatment. A treatment protocol was developed to help ensure uniform training within both groups. Strict selection criteria were also used in this study, and only patients having a single, left-hemisphere, cerebrovascular accident were included.

Participants with aphasia in both treatment conditions received 8 hours of therapy per week for up to 44 weeks. Subjects in the group treatment condition received 4 hours of therapy in a social setting and 4 hours of recreational

activities. Group treatment activities did not include direct manipulation of speech or language abilities; that is, no specific treatment tasks were presented to improve performance in verbal, auditory, visual, or graphic language modalities. Typical group tasks included participation in discussions of current events or other interesting topics. Subjects in the individual treatment condition received 4 hours of direct “stimulus-response” treatment of speech and language deficits. Specific tasks were presented for the various language modalities, and contingent feedback and reinforcement were provided by the clinician. In addition to individual treatment, subjects also received 4 hours per week of machine-assisted treatment.

The results of this study revealed that subjects in the individual treatment condition improved significantly more than subjects in the indirect treatment group conditions in terms of overall performance on the Porch Index of Communicative Ability (Porch, 1967), or PICA. No significant differences were, however, apparent on other language tests. Further, subjects in both the individual and group treatment conditions made significant gains in their language test scores beyond the recognized period of spontaneous recovery. Wertz and colleagues (1981) concluded that relatively few differences exist in the amount or type of improvement exhibited by subjects in the two treatment conditions. They surmised that “individual and group treatment are efficacious means for managing aphasia” (p. 593).

Sociolinguistic Treatment Groups

Sociolinguistic treatment groups have evolved as a reaction to the highly structured treatment techniques employed in direct treatment approaches. Proponents of sociolinguistic treatment approaches have pointed out that direct treatment approaches may limit the types of communicative exchanges that occur between the clinician and the patient. Wilcox and Davis (1977), for example, found that clinicians primarily produced “questions” and “requests” during direct treatment sessions and that patients responded to the clinicians with assertions. A similar pattern of restricted responding was evident in a social group setting. Clinicians and patients produced a restricted number of “speech acts” in both settings. Wilcox and Davis concluded that individual and group treatment should be less didactic and permit the exchange of a wider variety of communicative interactions, including advising, arguing, and congratulating.

Davis (1992) also advocates a sociolinguistic approach to group therapy for aphasia. Rather than drilling patients on specific treatment tasks that are adapted from individual treatment, he recommended that group sessions emphasize interaction among the patients while minimizing clinician directiveness. For example, principles of PACE therapy (Davis & Wilcox, 1981) can be incorporated into group treatment so that patients “take turns, convey new information, practice

using multiple channels, and provide each other with feedback to overcome obstacles" (p. 263).

As a participant in the panel discussion of group therapy for aphasia conducted by Aten and colleagues (1981), they elaborated on Davis's principles of treatment. They defined the purpose of group treatment as an attempt to "maximize (the patients') communicative strengths in order to improve interpersonal communication" (Aten et al., 1981, p. 146). Her group treatment activities centered around a preplanned task or game, and PACE treatment principles were incorporated into the sessions. Aten et al. (1982) investigated a sociolinguistic treatment approach that was described as "group functional communication therapy." Seven patients with chronic aphasia participated in this study. All subjects had suffered a single, left-hemisphere, cerebrovascular accident at least 9 months before the initiation of treatment. The subjects participated in hourly group sessions twice weekly for a period of 12 weeks, and a total of 24 treatment sessions were administered.

The goal of treatment was to improve functional communication, and a variety of everyday communicative situations from the Communicative Activities of Daily Living (Holland, 1980), or CADL, were selected for training. The "real-life" training situations included (a) shopping, (b) giving and following directions, (c) greetings, (d) giving personal information, (e) reading signs, and (f) gestural expression of ideas. Therapeutic activities included role playing and use of menus, grocery lists, and other materials from the patients' living environment. The results of training were evaluated by examining pre- and post-study performance on the PICA (Porch, 1967) and the CADL. Pre- and post-treatment PICA scores revealed nonsignificant differences, but statistically significant differences were apparent for pre- and post-treatment CADL scores. The authors concluded that group functional communication treatment is efficacious and that functional measures, such as the CADL, should be included in our clinical assessments.

A partial replication of the study by Aten and colleagues was provided by Bollinger, Musson, and Holland (1993). In this study, group treatment was provided using a treatment/withdrawal design, with "structured" treatment followed by a period of no treatment. Ten individuals with chronic aphasia who were at least 18 months post-onset received 3 hours per week of group treatment for a total of 40 weeks. Treatment consisted of 10-week segments of "contemporary group treatment" and "structured television viewing group treatment" alternating with 10 weeks of no treatment. "Contemporary group treatment" consisted of greetings and socialization, a core activity focusing on a real-life activity, and specific communication-related activities, such as group repetition of words and naming activities. "Structured television viewing group treatment" consisted of subjects watching specific television programs with later group discussion of specific communicative elements by

group members. Bollinger and colleagues found significant improvement on both the CADL and the PICA but not on the third measure of language, which tested auditory comprehension. Results did not demonstrate the superiority of either treatment.

Avent (1997a) described the use of cooperative learning methods with eight brain-injured individuals (seven post-cerebrovascular accident and one Traumatic Brain Injury). A single-subject, multiple baseline across behaviors design was used to evaluate the effectiveness of cooperative group treatment on narrative and procedural discourse of participants. Each participant was paired with another for a total of four dyads. The role of the speech-language pathologist was to provide guidance and structure to the treatment. Each participant with aphasia alternated in the role of "recaller" and "facilitator" of 10 narrative and 10 procedural stories having 100 to 120 words each. Initially, the therapist read the target story aloud, with participants listing 8 to 10 key words and/or phrases from the story. Then, the recaller retold the story. Each dyad's facilitator used the key words/phrases to cue his or her partner as needed. The therapist also prompted the facilitator to cue the reteller with the key words. Following a practice period, the reteller once again told the story, followed by feedback from both the facilitator and the therapist. Five procedural stories and five narrative stories were used in treatment, with the remaining stories used as generalization probes.

The outcome measure in this study was an analysis of content units (Nicholas & Brookshire, 1993). Results indicated that following 18 sessions of cooperative group treatment, three of the eight participants improved their narrative and procedural discourse in the treatment stories and the generalization probes. The remaining five participants, however, showed either slight improvement or no change in performance. Avent (1997a) concludes that participants who showed improvement were those with the mildest aphasia as measured pre-treatment by the Western Aphasia Battery and the content unit analysis (i.e., 20% or higher content units per minute).

Graham (1999) described the use of aphasia groups in subacute and skilled nursing facilities. Graham used the American Speech-Language-Hearing Association Functional Assessment of Communication Skills for Adults (1995), or ASHA FACS, as a framework for planning and evaluating treatment in these groups. Following evaluation to determine communicative strengths and weaknesses as well as the ability to use compensatory strategies, patients were enrolled into group treatment. (Group members could also be enrolled in individual treatment sessions.) Both individual and group treatment goals were selected from the ASHA FACS in combination with Hartley's (1995) functional communication goals. Treatment groups consisted of two to six members meeting 5 days per week for 45-minute sessions. Treatment tasks focused on functional and "survival" skills,

and Graham described how she used videotape segments for viewing and discussion by group members.

Garrett and Ellis (1999) described a group language intervention program developed in 1994 at the University of Nebraska–Lincoln's Speech Language and Hearing Clinic. This program continued at Duquesne University (Garrett, Staltari, & Moir, 2007). The primary goal of this aphasia group program is to provide a vehicle for individuals with long-term aphasia to continue to improve their communication skills. In addition, the program provides learning opportunities for graduate students in speech-language pathology. The authors describe the Nebraska treatment program as combining principles of discourse, thematicity, contextual support, and functional use. A continuum of language activities, communication goals, and scaffolding strategies are incorporated into conversation, context building, language mediation, and discourse activities. The authors provide specific communication goals and explicit prompting information. Group sessions are 90 minutes in length, with 6 to 10 people participating in each group. Garrett and colleagues report that group members frequently indicated the groups helped them to become more competent communicators.

Additional data are needed to establish the validity of sociolinguistic group treatment for aphasia. For example, evaluation of the efficacy of discourse exercises (Osiejek, 1991) and other communication-based therapies in the group setting are warranted.

Transition Groups

In addition to the direct, indirect, and sociolinguistic treatment approaches described above, several authors have described transition or maintenance group treatment for aphasia. Brookshire (1997) indicates that transition groups “prepare patients for communication in daily life by giving them training and practice with strategies and problem-solving skills that are useful in daily life” (p. 286). Tasks employed in these groups, such as role playing, are usually selected to help individuals with aphasia adapt to communicative situations that occur in their living environment. Information may also be provided in transition groups regarding community services, such as adult day-care centers and home health services. Transition groups often meet one or more times weekly, and patients usually participate in these groups for a limited and specified period of time before discharge from treatment.

As a member of the group therapy panel conducted by Aten et al. (1981) she described her unique approach to transition groups. Three groups—a discharge-planning group, a community involvement group, and a “stroke club” group—were used to facilitate the transition between inpatient hospital services and release to the home environment. Patients in West's program participated in each of the

groups in sequential order in an attempt to develop an increasing level of functional independence from the hospital staff.
