The overall goals of the transition groups were (a) to help patients accept changes in physical and cognitive abilities, (b) to develop a realistic view of progress and altered ability, (c) to assist patients in finding an alternate life style within available family and community resources, (d) to reinforce gains made in individual therapy, and (e) to help patients with community placement.

In addition to these general goals, each group had a specific purpose. For example, the main purpose of the discharge-planning group was to prepare patients for life-style changes that would occur on dismissal from the hospital. Practical difficulties encountered during home visitations were also discussed in this group.

Once patients were discharged from the hospital, they participated in the community involvement group in an attempt to facilitate emotional and psychological adjustment to their new environment. The emphasis in this group was on helping patients to accept their new life styles and assist them in developing productive alternate life styles. The group also discussed emotional incidents that occurred in the home setting, and it provided an opportunity for emotional venting by the group members. The community involvement group attempted to “confront reality without destroying hope” (Aten et al., 1981, p. 150).

The final stage in West's transition group program was participation in a monthly “stroke club.” This group provided emotional support and education, and it helped patients to maintain the level of communicative ability that had been reached following individual speech-language treatment. In general, West concluded that her three-group transition process was successful, because it reduced dependence on the hospital staff and integrated patients into existing family and community structures.

Maintenance Groups

In the final analysis, West's “stroke club” group appears to be similar in function to a maintenance group. Brookshire (1997) notes that maintenance groups provide regular stimulation so that patients' speech-language skills do not deteriorate once they are dismissed from intensive individual therapy. He indicates that maintenance group activities are frequently social in nature and may emphasize social interaction and communication in social contexts. Participation in maintenance groups may last from months to years, depending on the individual needs of the patient and his or her family. Brookshire observed that maintenance group meetings are seldom held more than once per week; in fact, they may be held only once per month. Maintenance groups continue to be a medium for encouraging retention of therapeutic gains made during aphasia rehabilitation (Springer, 1991).

Hunt (1976) described a language maintenance group that provided support, information, and language stimulation for patients who had been dismissed from individual treatment. From 8 to 12 patients participated in the groups, which met once per week for 2 hours. Family members were excluded from group participation.

The emphasis of this maintenance program was on stimulation of language in a social setting. Group activities were planned around the patients' interests and included movies, slide presentations, and guest speakers. These activities provided an opportunity for using residual language skills. Although specific language goals were not established, all attempts to communicate in the group setting were reinforced.

Hunt concluded that the social language group provided valuable language stimulation, practice of previously acquired abilities, social interaction, and entertainment. The maintenance group also acted as a source of information, support, and referral for the families of patients with aphasia, and it provided a valuable training experience for student clinicians.

Coles and Eales (1999) describe Action for Dysphasic Adults, an organization that provides self-help groups for individuals with aphasia in the United Kingdom. Speech-language therapists work for Action for Dysphasic Adults as regional development advisers. Each adviser supports a number of self-help groups and provides direction as each group is formed. The speech-language therapist also serves as the link to the national body. Ultimately, each group is run by its members, with the speech-language therapist providing assistance only when requested. Because different locales have varied interests and/or needs, each group identifies its relevant goals and sets its own rules, including the number of members permitted in the group.

Multipurpose Groups

Taxonomies of group treatment procedures for aphasia are inherently flawed, because clinicians often identify several purposes for their groups. The results of a survey by Kearns and Simmons (1985) of clinical practices indicate that 80% of the respondents listed multiple goals for their groups. As might be expected, language stimulation, often in combination with support or social goals, was the most frequent aim (84%) of aphasia groups. Following language stimulation, the next most frequently listed goals were emotional support (59%), carryover (47%), and socialization (45%). As previously indicated, attempts to classify types of aphasia group treatment approaches are generally for the sake of convenience alone, and they should not be construed as being a reflection of clinical reality. More often than not, group therapy is undertaken with several aims in mind—even when a primary focus is evident. Most recent reports of group therapy for aphasia reveal that programs are typically multipurpose in nature, often combining psychosocial and speech-language goals into treatment.

Kagan and colleagues (1990, 1999, 2001, 2004, 2007) described a unique, community-based group treatment approach, provided at the Aphasia Institute in Toronto, Canada, that is designed to facilitate functional communication, promote independence, and maintain gains resulting from individual therapy. An important aspect of the program is the use of community volunteers who are trained and supervised by speech-language pathologists to work, in a group setting, on communication goals with individuals who have with aphasia. A comparison of the results of pre- and post-testing for participants with chronic aphasia who participated in the community group versus a group of untreated, community-dwelling control subjects was reported (Kagan, 1990). Results revealed significant improvement in the post-treatment performance of the group participants on a test of communicative effectiveness (Lomas et al., 1989) (see Chapter 6), but not on traditional language testing. A significant between-group difference favoring the treated patients was also found on this measure.

A primary component of this aphasia community program is training agency volunteers and health-care professionals to use supported conversation techniques (Kagan, 1998). Kagan and colleagues (2001) investigated whether these techniques improve the conversational skills of volunteers and, if so, whether the improvements affect the communication of their conversation partners with aphasia. Twenty volunteers received training in supported conversation techniques, and 20 control volunteers were merely exposed to people with aphasia. Trained volunteers scored significantly higher than untrained volunteers on ratings of acknowledging competence and revealing competence of their partners with aphasia. The training also produced a positive change in ratings of social and message-exchange skills of individuals with aphasia, even though these individuals did not participate in the training. These results support the efficacy of supported conversation techniques.

Radonjic and Rakuscek (1991) described a multipurpose group that was established to decrease emotional tension; prevent social isolation; encourage the need for communication; encourage the ability to search for, develop, and use communication in social situations; and develop confidence and self-respect. The group was developed by a clinical psychologist and a speech-language pathologist, and it generally ranged in size from four to seven participants, with a maximum of 10 group members. Group activities included such varied activities as "learning about each other, relaxation techniques, games to strengthen psycholinguistic ability, drawing, pantomime, and therapeutic techniques involving music" (p. 451). A five-point scale of communication was administered at the beginning and end of each patient's participation in an attempt to examine the impact of intervention. A descriptive analysis of difference scores for 108 patients with aphasia revealed improvements on patients' post-treatment communication ratings as compared with

pretreatment ratings. The authors concluded from their analysis that the best results were obtained for patients who participated in at least 10 treatment sessions in small groups (three to five members). Although intriguing, these clinical data must be replicated under more rigorous experimental conditions before they can be considered unassailable.

Pachalska (1991a) reviewed the group therapy literature and presented her treatment approach. Based on her literature review and clinical experience, she suggests making groups as homogeneous as possible in terms of patient type and level of language involvement. Pachalska also recommends that the size of aphasia groups should not exceed four or five members and that treatment sessions should last no more than an hour. A structured treatment approach is also advocated. Pachalska refers to a “holistic” method of treatment, which apparently refers to a multidisciplinary, multipurpose approach, such as her own Complex Aphasia Rehabilitation Model, or CARM. Citing publications in her native language (Polish), she asserts that the holistic approach is “the most effective approach” (p. 547) to group treatment. CARM is described as having both individual and group treatment components, and group therapy is seen primarily as an adjunct to individual treatment. Group sessions are run by a multidisciplinary team of clinicians who provide cognitive physiotherapy, physical therapy, speech therapy, psychotherapy, and sociotherapy. Tasks are directed toward facilitating natural conversation. Pachalska (1991b) also indicates that a goal of CARM is to stimulate transfer of information between the cerebral hemispheres. Consequently, both linguistic and nonlinguistic stimuli are employed in treatment, and special emphasis is placed on “language-oriented art therapy.” Linguistic materials used in therapy include popular poems and word games. In addition to the language emphasis, other aspects of rehabilitation, such as physical therapy and group discussions with family members, are also included. Social activities, such as “car rallies,” are considered to be part of the rehabilitation process as well. Pachalska (1991a) makes the broad claim that “all abilities which underwent training in the program significantly improved, and that the disturbances in the communicative, psychological and social domains were eliminated to a considerable degree; the reintegration was more complete” (p. 551).

The clinical forum that highlighted the work of Pachalska (1991a, 1991b) included commentaries by distinguished aphasiologists (Aten, 1991; Fawcus, 1991; Loverso, 1991; Repo, 1991; Springer, 1991). Fawcus (1991) emphasized that “the whole essence of group work is its flexibility and spontaneity” (p. 555) and cautioned against using overly structured approaches. Others agree that the mechanics of group therapy, such as group size and session length, cannot be dictated by prescription (Loverso, 1991; Springer, 1991). Our clinical experience is consistent with their suggestion that group sessions of longer than 1 hour are possible and that larger groups are manageable and, sometimes, desirable.

Larger, more heterogeneous groups may be particularly appropriate when the emphasis is not on direct communication or language training (Springer, 1991).

Another example of a multipurpose group is provided by Marshall’s (1993, 1999b, 2007) description of problem-focused group therapy for patients with mild aphasia. The goals of this program are to provide a forum for discussing social, vocational, and recreational reintegration into society and assisting members in solving everyday communication problems. Examples of the problem-solving activities used during treatment include communicating in an emergency, meeting new people, and preparing for a physician’s visit. Unique aspects of this program include the fact that it provides one of the few available descriptions of clinical management for patients with mild aphasia as well as a rationale for intervention that focuses on everyday problems and community reintegration. Clinical data are presented that show the range of post-treatment improvements on standardized language test scores of the 18 patients for whom pre- and post-treatment comparisons were available. Marshall recognizes the potential of functional communication assessments for evaluating progress in group therapy (Lomas et al., 1989), and he suggests that seldom-used formats, such as the client self-report, may also provide a measure of clinical accountability. This issue is further considered in the sections that follow.

Walker-Batson and colleagues (1999) describe the Texas Women’s University transdisciplinary Aphasia Center Lifelink® program, which uses theme-based activities to prepare clients for community reentry. Lifelink® is a half-day, university-based program with graduate students in speech-language pathology, physical therapy, and occupational therapy in addition to rehabilitation professionals providing services. Clients are assessed on a battery of measures to evaluate speech and language skills, participation in leisure activities, affect/mood, and quality of life. Speech-language treatment is determined by placement of each client on the “recovery-compensation continuum” (Elman, 1994). Intensity of intervention is based on the client’s severity level as measured by the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983). The most severe clients receive individual as well as group treatment; those with less severe aphasia are discharged from individual treatment, with continuation in group therapy and community activities. The authors describe a “Visual Retrieval Language System” that provides theme-related vocabulary and structure for each client and is used in both individual and group treatment. Group size ranges from three to five members, and groups are 75 minutes in length. Group sessions often focus on themes developed by the clinician; however, higher-level groups can select their own topics.

Beeson and Holland (2007) describe the University of Arizona group treatment program. Treatment here is focused on facilitating successful communication using any

modality in addition to client-specific communication strategies. Groups are 1 hour in length, include between five and seven members, and are facilitated by faculty and graduate students. Beeson and Holland suggest that the Arizona treatment groups serve many purposes including direct and indirect language treatment, modeling of communication strategies, psychosocial support, and continuing education for group members, their families, and the student-clinicians. (Separate groups are conducted for family members.) Holland and Beeson report the Western Aphasia Battery (WAB) scores, before and after group participation, for 40 individuals with chronic aphasia. All had participated in the aphasia group for at least 1 calendar year. More than one-third of the group members showed a positive change of at least five points on the WAB. A regression analysis suggests that individuals who are younger and closer to onset improve more than those who are older and further from stroke onset (Holland & Beeson, 1999; Beeson & Holland, 2007).

Elman & Bernstein-Ellis (1999a) investigated the efficacy of group communication treatment on linguistic and communicative performance for 24 participants with chronic aphasia. Their research design used random assignment to immediate-treatment and deferred-treatment groups, which were balanced for age, education level, and initial aphasia severity. In the treatment condition, all participants received 5 hours of group treatment per week, provided by a speech-language pathologist, for a total of 4 months. The focus of treatment was on increasing initiation of conversation and exchanging information using whatever means possible. Communicative topics were relatively unconstrained, with a wide variety of topics addressed, including psychosocial and poststroke issues. Specific clinical procedures and content are described in detail by Bernstein-Ellis and Elman (1999, 2007). While awaiting group communication treatment, participants in the deferred-treatment group engaged in activities such as support, performance, or movement groups to control for the effects of social contact.

Dependent measures included the Shortened PICA (Disimoni, Keith, & Darley, 1980), or SPICA; the WAB Aphasia Quotient (Kerstesz, 1982), or WAB AQ; and the Communicative Abilities in Daily Living (Holland, 1980), or CADL. All participants received these tests at entry, after 2 and 4 months of treatment, and after 4 to 6 weeks of no treatment. In addition, participants in the deferred-treatment group received an additional administration of the measures just before beginning treatment.

Results revealed that group communication treatment was efficacious. Participants receiving treatment had higher scores on the SPICA and WAB AQ compared with those participants not receiving treatment. In addition, those participants with moderate-to-severe aphasia who received treatment had higher scores on the CADL compared with those who did not receive treatment. Significant improvement was observed

after both 2 months and 4 months of treatment. No significant decline was observed at the time of follow-up. This study was the first to demonstrate that group communication treatment and not social contact alone was responsible for treatment gains.

Elman and Bernstein-Ellis (1999b) also reported on results from participant and caregiver interviews collected during and after group communication treatment. Semistructured interviews were conducted, with questions focusing on the positive and negative aspects of participation in the communication treatment groups. Interview transcripts were transcribed verbatim, and a qualitative analysis (Miles & Huberman, 1994; Strauss & Corbin, 1990) was applied. In this analysis, both positive and negative aspects of group treatment were noted and then coded and grouped into common themes. Finally, all transcripts were reread multiple times to produce a limited number of themes that captured the information expressed in the interviews.

Interview data for 12 participants and their relatives/caregivers were reported by Elman and Bernstein-Ellis (1999b). The positive psychosocial aspects of group communication treatment reported by participants with aphasia included (a) like being with others, (b) like the support of others with aphasia, (c) like making friends, (d) like being able to help others, (e) like seeing others improve, and (f) feel more confident. The positive speech-language aspects included (a) enjoy conversations, (b) improvement in talking, and (c) improvement in reading/writing. The relatives/caregivers reported very similar positive psychosocial and speech-language aspects of their family member's or client's participation in group communication treatment. Psychosocial aspects included (a) more confident, (b) more social, (c) more independent, (d) more motivated, (e) like making friends, (f) happier, and (g) like helping others. Positive speech-language aspects included (a) improvement in talking and (b) improvement in reading/writing. Negative aspects were rarely reported. It is important to note that many of these psychosocial behaviors were not directly treated during group communication treatment. Elman and Bernstein-Ellis posited that many of these changes were a result of increased confidence and motivation that participants gained from attending the groups. They suggested that the group environment can be an extremely powerful one for producing change.

Van der Gaag and colleagues (2005) evaluated the impact of attending a community-based aphasia program on quality of life and communication skills for 28 people with chronic aphasia as well as 14 significant others. Individuals with aphasia attended group treatment either once or twice per week for an average of 1.7 hours a week. Caregivers received an average of 1.4 hours of therapy per week. Group activities included conversation groups, communication skill groups, and self-advocacy groups. Both qualitative and quantitative methods were used to assess the participants before and after 6 months of therapy. Participants were evaluated by semistructured

interviews and two quantitative measures assessing quality of life, the CETI and a caregiver assessment. Results indicated statistically significant improvement in the CETI and one of the two quality-of-life measures but no statistically significant differences on the caregiver assessment. The qualitative interviews revealed similar results, with a majority of the participants reporting improved communication skills. It is not possible to determine which aspects of the therapeutic program contributed to these changes.

Inspired by the Aphasia Institute in Toronto, several independent, community-based aphasia centers were created in the 1990s. These included the Aphasia Center of California (Bernstein-Ellis & Elman, 1999, 2007; Elman, 1998), the Talkback groups in South Australia (Hersh, 2007), and Connect in London (Penman & Pound, 2007; Pound, Parr, Lindsay, & Woolf, 2000). In addition, various university-sponsored aphasia programs were developed (Penn & Jones, 2007; Walker-Batson et al., 1999; Worrall et al., 2007). These programs advocate a social approach to programming for individuals and family members affected by aphasia (Elman, 2005) (see chapter 11) and provide a variety of groups that emphasize successful communication strategies, rebuilding identity, and community reengagement. Several of these programs also provide specialized groups, including Internet training (Bernstein-Ellis & Elman, 2007; Egan, Worrall, & Oxenham, 2004; Worrall et al., 2007) and aphasia book clubs (Bernstein-Ellis & Elman, 2006).

Efficacy of Speech-Language and Multipurpose Treatment Groups

Examination of group treatment as a primary and independent form of patient management has only recently been undertaken (Aten et al., 1982; Avent, 1997a; Elman & Bernstein-Ellis, 1999a, 1999b; Radonjic and Rakuscek, 1991; Van de Gaag et al., 2005; Wertz et al., 1981). In addition, several studies have explored the value of combined individual and group treatment for aphasia (Chenven, 1953; Makenzie, 1991; Smith, 1972). Research evaluating the effectiveness of specific group speech-language treatment is growing, but the scientific basis of clinical aphasiology will not be sturdy unless this investigative effort continues.

Summary and Observations

Recent reports of group speech-language treatment for aphasia were reviewed and five group therapy approaches identified. These included (a) direct language treatment groups, (b) indirect language treatment groups, (c) sociolinguistic treatment groups, (d) transition groups, and (e) maintenance groups. Although each approach is unique, the common denominator is that their primary purpose is to facilitate recovery and/or maintenance of speech-language abilities. Considerable variability, however, exists among

group treatment approaches. Speech-language treatment groups range from structured, so-called “stimulus-response” approaches to essentially undefined, indirect treatment approaches. Group treatment tasks also show considerable variability and include specific techniques, such as MIT (Sparks et al., 1974) as well as group discussions and recreational activities (Wertz et al., 1981). As previously noted, the variety of group treatment approaches probably reflects the training and biases of the clinicians who conduct group therapy (Elman, 1999, 2007; Marquardt et al., 1976).

Obvious parallels exist between speech-language treatment group therapy and individual therapy for aphasia. Direct language treatment groups, for example, often employ tasks similar to those used in individual treatment sessions. Similarly, clinicians conducting sociolinguistic group therapy often adopt recently developed functional treatment approaches, such as PACE therapy (Davis & Wilcox, 1981), to the group format. Given these parallels between individual and group treatment, Holland’s (1975) inquiry about the differences between these two approaches is poignant. If a group leader sequentially treats each individual in a group and little interaction occurs other than individual exchanges between the clinician and a given patient, the result may be inefficient individual treatment in a group setting. To avoid this possibility, group leaders must be aware of the strengths and communicative needs of individual group members. Ideally, tasks should be structured so that all group members can participate (Holland, 1970), but interactive aspects of communication should not be sacrificed (Davis, 1992; Elman, 2000; Ewing, 1999). Moreover, the objectivity of direct approaches should be combined with the common-sense rationales for sociolinguistic group therapy. The development of data-based, pragmatic treatment approaches will be challenging, but clinical aphasiologists have recently demonstrated the feasibility of this approach to program development (Cochrane & Milton, 1984; Davis & Wilcox, 1981; Elman & Bernstein-Ellis, 1999a, 1999b; Kearns, 1986; Osiejek, 1991; Van der Gaag et al., 2005).

Clinicians should eschew indirect treatment approaches that have no explicit communication goals and serve as a social outlet for their patients with aphasia. Socialization can be a legitimate goal of group therapy for aphasia, but clinicians should be leery about letting group treatment deteriorate into totally unstructured activities that neither facilitate nor support identified communication aims. Like individual therapy for aphasia, group intervention should be based on sound clinical logic, and it should be goal directed without being overly rigid (Fawcus, 1991).

CLINICAL ACCOUNTABILITY

Measurement problems encountered in group therapy are significant but not insurmountable, and proper attention

must be given to assessing speech-language treatment gains in the group setting. To date, few authors of group therapy reports have attempted to measure treatment gains, and those who have examined the success of treatment have, for the most part, relied on standardized tests of aphasia (Aten et al., 1982; Wertz et al., 1981). Although tools designed to measure functional communication ability (Holland, 1980; Lomas et al., 1989) may be of particular value, standardized aphasia tests do not measure interactive aspects of communication, and the development and use of reliable supplemental measurement tools, in addition to qualitative methods of investigation, are sorely needed (Elman & Bernstein-Ellis, 1999b; Garrett, 1999; Garrett & Pimentel, 2007).

The importance of measurement issues in group therapy for aphasia cannot be overestimated. Kearns and Simmons (1985) reported that 73% of survey respondents used periodic standardized testing to evaluate group members and that 33% employed standardized testing in combination with “behavioral ratings of task performance.” Surprisingly, 20% of the clinicians indicated that patient performance was *not* routinely evaluated. A recurring problem for clinicians who run aphasia groups is the issue of clinical accountability; finding appropriate measures for assessing the effects of group therapy is problematic. As Aten (1991) pointed out in his commentary on Pachalska’s work, treatment effectiveness will not be easily demonstrated until better assessments of psychosocial changes and conversational language are available. Similarly, Loverso (1991) addressed the need to develop and adopt tools that examine the roles of individuals within aphasia groups and the interaction of these roles during treatment. This novel suggestion is exemplified by the earlier work by Loverso et al. (1982), in which they demonstrated the reliability of a process evaluation form. Loverso, Young-Charles, and Tonkovich (1982) assessed the “roles” of individual group members and classified their interactions. They demonstrated that task (e.g., giving and receiving information), maintenance (e.g., encouraging following), and non-functional (e.g., disruptive) behaviors could be reliably rated in the small-group setting. Other novel, supplemental measures that may be employed in aphasia groups include the use of discourse analyses and interactive coding procedures (Cochrane & Milton, 1984; Garrett & Pimentel, 2007).

Given the nature of the abilities targeted for intervention in group settings, clinicians often must devise their own clinical probes or “mini-tests” to sample skills such as turn-taking ability, initiation of interactions, and other skills, because standard assessments are not routinely available. Garrett and Pimentel (2007) describe numerous outcome measures that clinicians can use to assess basic communication skills, functional communication, quality of life, customer satisfaction, and overall cost/benefit ratios. They state that most of these measures can be adapted for use in medical, outpatient, and/or community settings. Whatever the procedure or outcome measure that is chosen, it is important to evaluate

routinely the communicative abilities of aphasia group members.

GUIDING PRINCIPLES

Thus far, we have considered psychosocial, family counseling and support, and speech-language treatment groups for aphasia. Among the speech-language treatment reports, we distinguished early advocacy groups from more recent speech-language and multipurpose treatment groups. Our review of recent speech-language treatment group reports revealed a number of distinct approaches, including direct language treatment groups, indirect language treatment groups, sociolinguistic groups, transition groups, and maintenance groups. It should be apparent from this brief summary that no single therapeutic model can accommodate the variety of aphasia groups that have been reported in the literature. Recent trends in the generalization literature, however, may serve as a cornerstone for the development of eclectic, principled group treatment approaches.

The ultimate goal of therapy for aphasia is to develop maximum communication ability in non-training settings and situations. In essence, generalization of target behaviors across stimuli, settings, people, behavior, and time (i.e., maintenance) is the desired end product of therapy. Treatment effects are notoriously restrictive, and generalization is the exception rather than the rule in aphasia rehabilitation and other applied fields. A growing generalization literature, however, that provides suggestions regarding specific techniques that may facilitate carryover (Baer, 1981; Horner et al., 1988; Hughes, 1985; Kearns, 1989; McReynolds & Spradlin, 1989; Spradlin & Siegel, 1982; Warren & Rogers-Warren, 1985). A philosophy of group management that is geared toward facilitating generalization may provide an opportunity to empirically test our assumptions about generalization and allow us to examine the efficacy of group therapy for aphasia.

Reviews of the aphasia generalization literature also indicated that generalization of aphasia treatment effects is not an automatic by-product of intervention (Thompson, 1989). More often than not, clinical investigations of aphasia are what Stokes and Baer (1977) labeled “Train and Hope Studies.” That is, investigators attempt to measure generalization of communicative improvements, but they seldom do anything to actively try and achieve generalized responding. Further, when generalization does not occur following intervention, no additional follow-up steps are taken to obtain carryover. If the ultimate goal of therapy for aphasia is to achieve maximum communicative functioning in settings and situations where patients live, work, and interact, we have an obligation to do everything in our power to achieve functional carryover. As Horner and colleagues (1986) note, “[T]here is an ethical obligation, if not a responsibility, to make sure that generalization programming is incorporated

into every program that endeavors to make important social and life-style changes for clients" (p. 16).

Generalization Planning

Clinical practice in speech-language pathology often includes four discrete and relatively independent sequential phases: (a) assessment, (b) intervention, (c) generalization, and (d) maintenance. As is true of other clinical specialties in speech pathology, clinical aphasiologists have attended to the assessment and intervention phases of the clinical process while placing relatively little emphasis on the generalization and maintenance phases. In contrast to the traditional approach to treatment planning, a generalization planning approach to the clinical process is conceptualized as a means of integrating the known clinical phases into a continuous loop that incorporates specific procedures to maximize the possibility of promoting generalization (Baer, 1981; Horner et al., 1988; Hughes, 1985; Warren & Rogers-Warren, 1985).

Kearns (1989) notes the following differences between a generalization planning approach to intervention and the traditional, discrete-phase approach. First, separation of the clinical process into discrete phases encourages the establishment of clinical goals based on performance on clinical tasks within the treatment setting. Thus, within the traditional model, an aphasia test is given during the assessment phase, and the results of this testing are used to establish clinical goals. When these goals are met, clinicians may then begin to examine aspects of generalization and maintenance. By contrast, a generalization planning approach to clinical management assumes that carryover of improvements in functional communicative abilities is the primary goal of intervention, and as a result, assessment, goal setting, and intervention are all influenced by this assumption. The desire to facilitate generalization is foremost from the initial contact with the person with aphasia and his or her family. Within a generalization planning framework, carryover of functional abilities is the clinical glue that bonds all aspects of patient management into an integrated whole. Thus, all steps in the process are woven together for the express purpose of effecting change in a patient's ability to communicate in nonclinical settings as well as with people and in situations they experience in daily life. Whereas generalization and maintenance are too often a clinical afterthought with the discrete-phase model of clinical practice, their attainment is the driving force behind generalization planning.

The distinction between traditional treatment planning and generalization planning is far more than philosophical. After all, most clinical aphasiologists would contend that carryover is a primary goal of group therapy. From a practical viewpoint, however, a generalization training approach is procedurally more complex and, sometimes, more time-consuming than its traditional counterpart. For example,

whereas the discrete-phase approach to assessment of individuals with aphasia may include standard and nonstandard tests of language and functional communication, the generalization planning approach expands the evaluation process to include gathering information that is directly relevant to maximizing the chances of obtaining carryover of treatment effects. Expansion of the traditional assessment may include, for example, naturalistic observations, interviewing significant others to determine communicative needs, and recording and analyzing spontaneous interactions with familiar and unfamiliar partners. Baer (1981) suggests using every available means to make lists of all (communication) behaviors, settings, individuals, people, and actions of significant others that might affect generalization. These lists can then be narrowed down to a reasonable few, which are then prioritized for the purposes of deciding what combination of client behaviors and environmental factors need to be altered to maximize the probability of obtaining generalization.

The primary outcome of an expanded, more ecologically valid assessment is to choose generalization goals. That is, based on the information gathered, the clinician attempts to determine the most critical factors that should be targeted for intervention if improved communicative ability is likely to carry over to real-life settings and conditions. Importantly, the clinician also sets a criterion for evaluating whether a sufficient level of generalization occurs. The clinician is also charged with the task of determining how best to measure progress toward generalization goals. Because specific tests are rarely available to determine if generalization of specific target behaviors improves, clinicians must often develop their own means of assessing performance or adapt nontraditional measures (Garrett & Pimentel, 2007). These clinical probes (i.e., mini-tests) can be given periodically over time to evaluate progress toward generalization goals. This information can subsequently be graphed and used as a visual aid to monitor the effectiveness of treatment (Connell & McReynolds, 1988; Kearns, 1986a). In addition, ongoing assessment and visuographic data presentation also serve as a guide in making treatment decisions. For example, clinical probe data can be examined to determine if generalization occurs to targeted people, settings, and conditions, and appropriate modifications can then be made to intervention strategies as needed. Because generalization of aphasia treatment effects clearly does not automatically occur as a result of intervention, it is imperative that progress toward generalization goals be monitored so that appropriate clinical modifications can be initiated.

Kearns (1986a), Kearns and Scher (1988), Kearns and Yedor (1991), for example, reported a treatment approach, Response Elaboration Training (RET), which has been adopted clinically in group settings. The thrust of this approach is to use a forward-chaining technique to lengthen patient-initiated utterances and encourage response variety. Novel appropriate utterances are encouraged and reinforced.

That is, any patient-initiated response that was relevant for a given stimulus item is acceptable regardless of the form or content of that response. A unique aspect of this approach is that the patient directs the content of treatment. Once treatment stimuli are selected, the patient's spontaneous utterances are used as building blocks for developing more elaborate responses. The clinician combines successive patient responses, models them for repetition by the patient, and then prompts him or her to provide additional information. Each novel elaboration is subsequently added to the chain until the patient's spontaneous responses are lengthened to preselected levels. Throughout RET, an interactive, turn-taking format is maintained so that it can be readily adopted to group treatment. That is, each spontaneous conversational turn during group activities can serve as an opportunity for the clinician to prompt more elaborate verbal (and nonverbal) responses and reinforce the use of novel but appropriate utterances.

Although the RET format has not been tested experimentally in the group setting, a series of studies has examined the efficacy and generalization of this approach for individuals with aphasia. Results to date indicate that generalized increases in verbal response length and variety have occurred following RET (Kearns, 1986; Kearns & Scher, 1989; Kearns & Yedor, 1991). In addition, this approach has also successfully facilitated improvements in nonverbal means of communication (Gaddie-Cariola, Kearns, & Defoor-Hill, 1990) and communicative drawing (Kearns & Yedor, 1991).

Both RET and other "loose training" approaches to treatment are based, in part, on the rationale that loosening and diversifying treatment parameters may facilitate generalization (Baer, 1981; Horner et al., 1988; Hughes, 1985; Stokes & Baer, 1977; Stokes & Osnes, 1986). Attempts to target generalization directly, as a goal of therapy, by incorporating procedures that may facilitate carryover are an integral component of a generalization planning approach to intervention for aphasia. The group setting provides an environment for refining this clinical process, and it also provides a rich arena for future research and development of strategies that promote generalization.

By appropriately targeting generative responding in the group setting, we may increase the probability of obtaining carryover to the natural environment. Generalization training should, however, go beyond simply reinforcing selected responses when they occur. Task hierarchies should be developed to elicit responses under conditions that increasingly approximate the natural environment.

Summary

In summary, a generalization planning approach has been reviewed and related to group therapy for aphasia. It was suggested that group therapy for aphasia may provide a means of

incorporating generalization prompting techniques. The group setting provides an important link between individualized treatment and the natural environment. Only future research can determine the most effective means of using group treatment to facilitate generalization.

FUTURE TRENDS

Group therapy for aphasia is at a crossroads. We can fall back on the worn path of investigative complacency, or we can continue along a newer path of rigorous research to add to the knowledge base regarding group therapy for aphasia (Elman & Bernstein-Ellis, 1999). Although the choice may seem to be obvious, the road to group therapy research will continue to be challenging. Group therapy for aphasia has become strongly entrenched in our clinical repertoire because of historical precedent and practical clinical exigencies. Very few experimental studies of group treatment methods, however, are available to guide our clinical practice. Intensive group treatment research will not be forthcoming unless we overcome the "illusion of strong evidence" (McPeck & Mostellar, 1977) that supports current clinical practices. The future direction of group therapy for aphasia depends on whether clinical aphasiologists will continue to research group treatment methods aggressively. The ultimate goal of research in this area should be to identify specific, replicable, and effective group treatment procedures. Ideally, it would be desirable to be able to predict with reasonable certainty which patients would benefit from which types of group treatment. Thus, future research should eventually compare the relative effectiveness of group treatment methods.

In addition to investigating treatment approaches, the future direction of group therapy for aphasia will bring an increased awareness regarding the training needs of group clinicians. It has been suggested that not all clinicians are appropriately trained to conduct group therapy (Eisenson, 1973; Elman, 1999, 2000, 2007; Ewing, 1999, 2007; Sarno, 1981; Simmons-Mackie, Elman, Holland, & Damico, submitted). We do not, however, have academic or training guidelines to evaluate the skill level of group leaders. Kearns and Simmons (1985) found that 74% of a large sample of clinicians who conduct group therapy for aphasia reported no additional training beyond their speech-language pathology coursework. Only 24% of the survey respondents indicated that they had taken coursework or training in group dynamics, counseling, or related areas. While it is not clear exactly what type of additional training is advisable for group clinicians, this issue must be addressed in the near future. Group therapy for aphasia presents additional challenges that are not encountered in individual sessions, and investigators and academicians alike need to consider clinical training factors relating to group intervention (Elman, 2000; Simmons-Mackie et al., submitted).

Along with research and training, the future direction of group treatment will also be shaped by technologic advances. The rapid development of computer technology, including the Internet, will no doubt have an impact on group treatment methods. Individualized treatment programs may be expanded to allow patients to interact with one another and jointly solve communication problems. Similarly, treatment approaches may be enhanced by expanding technology, and virtual communicative interactions may eventually replace static picture cards as the primary stimulus material used during group sessions.

In the final analysis, the future direction of group therapy for aphasia will depend on people rather than technology. If researchers are firmly committed to this area of investigation and clinicians are willing to challenge traditional assumptions about the effectiveness of group approaches, the benefits of group therapy for aphasia may eventually be fully realized.

KEY POINTS

Given the historical roots, it would be tempting to conclude that group therapy for aphasia is nothing more than “old wine in a new bottle.” It should be emphasized, however, that group therapy for aphasia, while in existence since the post–World War II era, has taken on a new and more important role in clinical practice.

1. The advent of managed care and the resultant decrease in services for individuals with aphasia (Elman & Bernstein-Ellis, 1995; Frattali, 1998; Warren & Kearns, 2000) have forced clinicians and clinical researchers to reevaluate the efficiency and efficacy of their therapy techniques.
2. In the context of reductions in reimbursement for clinical services and less time to treat persons with aphasia, sound group therapy approaches clearly are playing an increasingly significant role in patient management.
3. General trends in rehabilitation, including the emphasis on treating individuals at the level of life participation or well-being rather than on treating their impairments per se, also bode well for the future of group therapy for aphasia.
4. Multipurpose groups that attempt to address the needs of the “whole” patient are rapidly becoming the norm rather than the exception. Importantly, the resurgence of interest in group techniques is not simply a matter of necessity.
5. Clinical researchers have recently developed novel group treatment methods (Avent, 1997b; Bernstein-Ellis & Elman, 1999, 2007; Kagan et al., 1990, 2007) that incorporate clearly articulated treatment ratios,

and long overdue interest has emerged regarding issues relating to the measurement of client progress in treatment (Garrett, 1999; Garrett & Pimentel, 2007).

6. Treatment efficacy is finally being put to the scientific test, and data are accumulating to support the use of group treatment for aphasia (Elman & Bernstein-Ellis, 1999a, 1999b; Marshall, 1993; Van der Gaag et al., 2005; Wertz et al., 1991).
7. Group therapy for aphasia should now be considered an essential component of our clinical armamentarium rather than a convenient supplement to individual treatment.

ACTIVITIES FOR REFLECTION AND DISCUSSION

Interested readers may wish to observe and compare individual and group therapy for aphasia. Attempt to categorize the group intervention into one of the types of therapy discussed in the chapter. What are the important similarities and differences observed between individual and group treatment?

Section IV

Traditional Approaches to Language Intervention

A. Stimulation Approaches

Chapter 15

Schuell's Stimulation Approach to Rehabilitation

Carl A. Coelho, Michele P. Sinotte, and
Joseph R. Duffy

OBJECTIVES

Hildred Schuell's stimulation approach to therapy for aphasia represents one of the main schools of thought in aphasia rehabilitation and has been one of the most widely used treatment approaches employed in this country. This chapter reviews Schuell's definition, theory, and classifications of aphasia as well as the principles, rationale, and specific goals associated with the stimulation approach.

This chapter deals with an approach to the treatment of aphasia that places its primary emphasis on the stimulation presented to the patient. Hildred Schuell was among the most lucid, scientifically minded, and insightful clinicians to propose and offer support for this approach. Because of her major role in its development, the approach described in this chapter is often referred to as "Schuell's therapy" or "Schuell's stimulation approach."

The bulk of Hildred Schuell's work in aphasiology spanned the 1960s and 1970s, and it included significant contributions in the areas of diagnostic testing, classification of patients with aphasia, and theory development regarding the underlying nature of the disorder. It was probably this sound foundation in theory, evaluation, and methods of observing and categorizing behavior that helped Schuell to develop the compelling rationale for the stimulation approach. This sound foundation also helps to explain why the stimulation approach represents one of the main schools of thought in therapy for aphasia and has been one of the most widely used treatment approaches employed in this country (Darley, 1975; Davis, 1993; Sarno, 1981). In this chapter, Schuell's definition, theory, and classifications of aphasia will be reviewed briefly as prerequisites for understanding the stimulation approach. The remainder of the chapter will emphasize the principles, rationale, and specific

goals, procedures, and techniques associated with the stimulation approach to aphasia rehabilitation.

Before proceeding, it is necessary to delimit further the territory to be covered in this chapter. First, virtually all approaches used by speech-language pathologists for the treatment of aphasia must necessarily involve stimulation of some kind (Wepman, 1953); for that reason, the stimulation approach may be thought to encompass all approaches to aphasia rehabilitation. The presence of numerous other chapters in this book, however, makes it clear that this is not intended to be the case. The material presented here is conceptually related to Schuell's specific approach to treatment, and it is her name that signals the scope of this chapter and distinguishes it from other treatment approaches that use stimulation in more broadly, or more narrowly, defined ways.

The second point is intended to qualify the narrowed scope described in the previous paragraph. Although Schuell was a "prime mover" in the development of the stimulation approach, many other clinicians and investigators have contributed to the development or refinement of its rationale, principles, design, and techniques. Wepman's (1951) contribution, for example, is particularly noteworthy, because it was the first complete elaboration of the approach (Darley, 1972). Therefore, although all current approaches to the treatment of aphasia will not be discussed, attention will be given to the contributions of many individuals in addition to those of Hildred Schuell. Receiving special emphasis will be those investigations that continuously help to refine the approach by identifying stimulus factors influencing the adequacy of language performance in persons with aphasia.

PREREQUISITES TO UNDERSTANDING THE STIMULATION APPROACH

Definition and Primary Symptoms of Aphasia

Systematic observation and testing of more than a thousand patients with aphasia led Schuell and her colleagues to define aphasia as "a general language deficit that crosses all language modalities and may or may not be complicated by other sequelae of brain damage" (Schuell, Jenkins, &

Jiménez-Pabón, 1964, p. 113). The language modalities referred to in the definition include comprehension of spoken language, speech, reading, and writing. The “other sequelae”—that is, the nonaphasic disturbances—most often would include modality-specific perceptual disturbances, dysarthrias, and sensorimotor deficits (including apraxia of speech). Also, other complications and secondary symptoms, such as a reduction of communication generated by depression or an altered attitude toward communication, may occur as a reaction to the primary symptoms of aphasia (Jenkins, Jiménez-Pabón, Shaw, & Sefer, 1975).

Schuell consistently viewed a reduction of available vocabulary, linguistic rules, and verbal retention span, as well as impaired comprehension and production of messages, as being the primary characteristics of aphasia (Schuell, 1969, 1974a; Schuell & Jenkins, 1961a; Schuell et al., 1964). In addition, her observations indicate that the impaired ability to retrieve and use the language code not only crosses all modalities but also tends to be evident in all modalities in a similar manner. Finally, “the impairment is regular and orderly, and operates in a manner that is lawfully related to known language phenomena” (Schuell et al., 1964, p. 104). The occurrence of similar deficits across modalities within patients, as well as the predictable nature of those deficits, are important additional characteristics, and they figure strongly in the rationale and procedures used in the stimulation approach.

Underlying Nature of Aphasia

In most scientific clinical endeavors, it is preferable that the rationale for using a particular method precede the application of that method. This is particularly important in clinical aphasiology, because the efficacy of treatment continues to be debated and we cannot always confidently, though superficially, say, “I use this approach because it works!” Until the efficacy of any approach to the rehabilitation of a person with aphasia is unequivocally demonstrated, what we do must at least be defensible on theoretic grounds. Schuell (1974b) supported such a notion with her belief that “what you do about aphasia depends on what you think aphasia is” (p. 138). Therefore, it is important that our methods of treatment be linked to our beliefs about the organization of language in the brain and the nature of that language breakdown that occurs when the brain is damaged. The adoption of such beliefs, however, is complicated by an abundance of choices. In fact, the existence of numerous beliefs about the underlying nature of aphasia has led to the existence of numerous approaches to treatment. Because treatment is subject to such beliefs, it is essential that we have some understanding of the model of language and beliefs about the nature of aphasia that specifically underlie the stimulation approach. If such a model and beliefs are palatable, procedures and techniques become logical extensions of the underlying rationale.

Schuell’s beliefs about the organization of language and the nature of the language breakdown in aphasia can be summarized as follows:

1. Language cannot be thought of as a simple sensorimotor dichotomy or a three-system cortical relay involving reception, transmission, and execution (Schuell et al., 1964). Such classical models ignore the complexity of perceptual and motor processes and view language as an activity bound to sensation and movement. They also allow aphasia to be thought of in terms of isolated, pure disorders reflecting disturbances at different stages of the dichotomy or relay system (e.g., receptive or Wernicke’s aphasia, conduction aphasia, and expressive or Broca’s aphasia). To many investigators, including Schuell, such notions do not correspond to modern concepts of neurophysiology and, more important, to the clinical behavior of most patients with aphasia.
2. Neurophysiologically, language is the result of the dynamic interaction of complex cerebral and subcortical activities. Such complex interactions preclude the existence of simply segregated sensory and motor divisions and, in effect, place the existence of isolated sensory or motor deficits outside the realm of aphasia. Likewise, the various elements of language cannot be separated neurophysiologically. For example, the relationship between the semantic and syntactic aspects of language is so strong that their separation at the physiological level is arbitrary at best (Schuell et al., 1964).
3. The language mechanism contains a system of stored, learned elements and rules, the use and maintenance of which require discrimination, organization, storage, comparison, retrieval, transmission, and feedback control. Like Wepman, Jones, Bock, and Van Pelt (1960), Schuell viewed language as an integrative activity that is linked, but not bound, to sensory and motor modalities. That is, the stored elements and rules are common (central) to all input and output modalities; speech, verbal comprehension, reading, and writing “involve the same referents and the same categorizations of individual and collective experience” (Schuell et al., 1964, p. 104). In the adult, therefore, language can exist unimpaired even in the presence of severe sensory and/or motor deficits, although it might be difficult to receive or express language through an impaired modality. Conversely, the language mechanism can be impaired in the absence of sensory or motor deficits. In such instances, however, the disturbance will be reflected in all modalities, because the same language system is used by (or linked to) all input and output modalities through which language is channeled. Consequently, aphasia is viewed as a multimodality disturbance that is unidimensional in nature. That is, not only do all

modalities tend to be impaired in aphasia, they also tend to be impaired in the same manner and to about the same degree.

4. It is important to recognize that Schuell's unidimensional, multimodality concept of aphasia does not require that patients with aphasia vary only along a severity continuum. Schuell and Jenkins (1961b) wrote that among patients with aphasia, "many dimensions of impairment resulting from language deficit are identifiable, and need to be studied, in addition to the common or general dimension of language deficit" (p. 299). They also stated, "[A]t a given level of language deficit, language tests may be arranged in subgroups which show systematic regularities in aphasic performance in various modalities as well as systematic differences in the performance of various segments of aphasic populations (p. 299)." The point here is that Schuell did not believe that all patients with aphasia were alike, but based on her clinical observations and objective analyses of data, she chose to emphasize the apparent universal feature of the disorder—a general disturbance of language that is reflected in a similar manner in all modalities.
5. In aphasia, the problems of most patients appear to be more related to performance factors than to competence factors (Schuell, 1969). That is, it appears that linguistic elements and rules are not lost or destroyed but that the language system either is working with reduced efficiency or is "swamped in noise, due to faulty connections, disturbed internal signal sources, defective speech analyzers, and the general asynchronous chaos of processes whose mass action can no longer be properly coordinated" (Jenkins et al., 1975, p. 59). Schuell's belief that language is not lost or destroyed in aphasia is an important factor in determining that the stimulation approach does not involve the "teaching" or "re-teaching" of language.
6. Although the language mechanism can exist separately from both input and output modalities, our primary language processes are acquired and organized through complex, interacting sensory systems and sensorimotor processes. Notably, auditory processes are at the apex of those interacting systems that aid in the acquisition, processing, and control of language (Schuell et al., 1964). The importance of auditory processes for language and in the stimulation approach to language remediation will be discussed in more detail later.

Classification of Aphasia

Schuell's classification system for aphasia is unique when compared to most other popular systems. Her view of aphasia as a multimodality, unidimensional impairment clearly precluded categorizing patients according to modality of impairment (e.g., expressive, receptive, agraphia, or alexia) or the element of language involved (e.g., semantic, syntac-

tic, or anomic). Instead, her classification system aimed at descriptive and predictive utility by classifying patients according to the severity of language impairment, presence or absence of related sensory or motor deficits, and prognosis. Originally, Schuell's system contained five categories and two minor syndromes. Later (Jenkins et al., 1975), the minor syndromes were treated as major categories. The seven categories are summarized below.

These classifications are useful in planning treatment with the stimulation approach in two ways. First, the various categories indicate the severity of language impairment and, therefore, give some indication of the level at which stimulation should be directed. Second, the identification of associated non-aphasic deficits indicates those input avenues with the least intact access to the language system as well as those output avenues through which evidence of language processing is least likely to be valid or interpretable. Such input and output problems signal a possible need to modify stimuli or restructure response demands. They also identify non-linguistic disturbances that also may require remediation.

Simple Aphasia

"Simple aphasia" is considered to be relatively mild multimodality language impairment with no specific perceptual, sensorimotor, or dysarthric components. The prognosis for recovery is excellent.

Aphasia with Visual Involvement

"Aphasia with visual involvement" refers to mild aphasia complicated by central impairment of visual discrimination, recognition, and recall. The prognosis for language recovery is excellent, but reading and writing recover more slowly.

Aphasia with Persisting Dysfluency

"Aphasia with persisting dysfluency" is mild aphasia with associated verbal dysfluency as an apparent result of proprioceptive disturbance (Jenkins et al., 1975). The prognosis for recovery from aphasia is excellent, but continued conscious control over speech execution remains necessary.

Aphasia with Scattered Findings

"Aphasia with scattered findings" is considered to be moderate aphasia involving a variety of problems compatible with generalized brain injury (e.g., dysarthria, visual involvement, or emotional lability). Although the potential for functional language exists, the prognosis is limited by the concomitant physiological and psychological problems.

Aphasia with Sensorimotor Involvement

"Aphasia with sensorimotor involvement" is defined as severe language impairment with impaired perception and

production of phonemic patterns. The prognosis is for limited but functional recovery of language with persisting signs of sensorimotor impairment.

Aphasia with Intermittent Auditory Imperception

“Aphasia with intermittent auditory imperception” is usually considered to be severe aphasic impairment with severe involvement of auditory processes. Recovery of some language may occur, but normalcy is not achieved.

Irreversible Aphasia Syndrome

“Irreversible aphasia syndrome” is nearly complete multimodality loss of functional language skills. The prognosis for recovery of functional language is poor.

APPROACH—GENERAL DESCRIPTION

Definition and Rationale

The stimulation approach can be defined as the approach to treatment that employs strong, controlled, and intensive auditory stimulation of the impaired symbol system as the primary tool to facilitate and maximize the patient's reorganization and recovery of language. It is an approach that recognizes the stimuli to which an intact language system can respond may be inadequate for eliciting responses from an impaired system. Because “sensory stimulation is the only method we have for making complex events happen in the brain” (Schuell et al., 1964, p. 338), the approach employs the manipulation and control of stimulus dimensions to aid the patient in making maximal responses.

Although numerous input modalities may be used, the auditory modality is at the foundation of the stimulation approach. The use of intensive, controlled auditory stimulation is supported by the following:

1. Sensory stimulation affects brain activity. For example, sensory input alters the electrical activity of the brain, increasing stimulus strength increases the frequency of firing of neurons and the number of fibers activated, and the threshold of response can be altered by repetitive stimulation (Eccles, 1973; Naeser, et. al, 2005; Thompson, 1967). In addition, repetitive stimulation can increase the firing of neurons in homologous right-hemisphere brain regions in individuals with left-hemisphere cortical and subcortical lesions (Calautti, Warburton, & Baron, 2003, Hillis, 2002). Thus, at the neurophysiological level, stimulation can and does influence brain structure and function.
2. Many lines of research indicate that repeated sensory stimulation is essential for the acquisition, organization, storage, and retrieval of patterns in the brain. Language “patterns” appear to be no exception, because language proficiency is largely the result of linguistic stimulation

and experience. In addition, it is likely that language retrieval works through patterns of excitation laid down during original learning and that appropriate stimuli are required for adequate retrieval (Schuell et al., 1964).

3. The auditory system is of prime importance in the acquisition of language, and ongoing functional language is dependent on the auditory system for processed information and control through feedback loops (Schuell et al., 1964).
4. Numerous studies indicate that nearly all people with aphasia exhibit deficits in the auditory modality (Duffy and Ulrich, 1976; Schuell, 1953b; Schuell et al., 1964; Smith, 1971). It has been suggested that many of the multimodality impairments that patients with aphasia experience stem from these auditory deficits (Schuell, 1953b) and that recovery of auditory functions, for many patients, is a prerequisite to recovery of other speech and language abilities (Brookshire, 1976a; Holland and Sonderman, 1974). Finally, the clinical observations of Schuell and colleagues (1955, 1964) as well as of Schuell alone (1953a, 1969) suggest that the use of intensive, controlled auditory stimulation results in multimodality improvement greater than that when treatment focuses on movement patterns or on each modality separately. Schuell (1974c) considered the notion of intensive auditory stimulation to be “the most important clinical discovery that we ever made” (p. 112).
5. The use of intensive auditory stimulation is consistent with the definition of aphasia as a multimodality deficit that results from an underlying disturbance of language. That is, if the patient's problems in each modality are a reflection of a common underlying language disturbance, it makes sense to channel treatment through the auditory modality because of its crucial link to language processes. In doing so, we should expect that gains made through the auditory modality will extend to all other input and output language channels.

A caveat regarding the primacy of the auditory modality in treatment is in order. Experience tells us that for some patients, the auditory channel is not the most appropriate avenue for stimulation. For example, some patients with disproportionately severe impairment of auditory processes respond, on baseline testing, more favorably to written or gestural input. For such individuals, the primary stimulus channel in therapy may be visual instead of auditory. The use of intensive auditory stimulation in the stimulation approach should therefore be viewed as a rule for which important-to-recognize exceptions exist.

What the Stimulation Approach is Not

The stimulation approach can be further understood by identifying some things that it is not. Wepman (1953, 1968)

argued that patients with aphasia do not recover because they are taught to speak. He indicated that the purpose of stimulation is not to convey new learning but, rather, to focus on “old learning” and stimulate the patient to produce new integrations for language. Schuell and colleagues (1955, 1964) emphasized that aphasia clinicians are not teachers; their role is to stimulate the adequate functioning of disrupted processes. Martin (1975), viewing the stimulation approach as being conceptually related to cognitive theories of learning, indicated that the approach is an attempt “to reorganize a system already reorganized by brain damage” (p. 73). He pointed out that, because the approach is based on a model which views aphasia as an interference with (not a loss of) language processes, therapy does not emphasize memory or the reproduction of stimuli as stimulus-response learning approaches do. Instead, the approach emphasizes the action that is elicited within the patient by the stimuli that are presented. Such an approach treats the patient as an active participant in the reorganization of language and adjusts stimulation to maximize the ability of the patient to participate in the process.

Finally, what Taylor (1964) has called nonspecific stimulation, or the spontaneous recovery approach, is not part of the approach being discussed here. Nonspecific stimulation would include merely talking to the patient as much as possible; working to establish rapport, socialization, or interest; and reducing anxiety. Clearly, such approaches to treatment should be distinguished from the more carefully planned and controlled approach that is the focus of this chapter.

Individuals for Whom the Approach is Appropriate

Relative to Severity

The rationale and general goals of the stimulation approach do not preclude its use with particular degrees of language impairment; however, the approach is not invariant along the severity continuum. The severity of aphasia should—and does—influence the nature of stimulation, the specific treatment goals and procedures, and the frequency and duration of treatment. For example, severe aphasia (Schuell's irreversible aphasia syndrome) may sharply limit use of the stimulation approach and reduce treatment to a short-term program aimed at improving comprehension, counseling of the patient and family, and preventing withdrawal and depression (Schuell, 1969). Variations of the approach as a function of severity will be discussed in more detail later.

Relative to Associated but Non-Aphasic Communicative Deficits

The stimulation approach attempts to improve language or reduce the functional handicap imposed by the disruption of language processes. It is not intended to remediate problems that often co-exist with aphasia, such as perceptual deficits,

apraxia of speech, or dysarthrias; such deficits may interfere with communication but do not disturb language per se. When present, they require treatment that differs significantly from the stimulation approach used therapy for the aphasia. The treatment of concomitant non-aphasic deficits may be secondary to, take precedence over, or coincide with therapy for aphasia. Although non-aphasic deficits often places limits on the application of the stimulation approach and the expected outcome of therapy for aphasia, their presence does not necessarily preclude use of the stimulation approach to treat the aphasia; nor does the presence of aphasia and use of the stimulation approach for its treatment necessarily preclude the use of other approaches to treat the non-aphasic deficits.

Philosophical Underpinnings

Before discussing the general principles and design of intervention, a brief summary of the general philosophy underlying the stimulation approach is in order. This philosophy should temper any desire on the part of the reader for a rigid, universal approach to treatment.

First, Schuell and colleagues (1964) stated, “We believe in a general philosophy of treatment, but not an arbitrary method. There is no room for rigidity in clinical practice . . . If the method leaves the patient behind, or if a patient outstrips the method, the method must be altered” (p. 332). Schuell believed that the main objective of treatment is to increase communication and that techniques merely assist in achieving that end. Therefore, methods should be flexible enough to be discarded if they are not working.

Second, diagnosis is a crucial part of the therapeutic process. That is, treatment must not proceed without some knowledge of the patient's assets and liabilities in each modality and some information about why performance breaks down when it does. Only with such information do we know what to work on and where to begin.

Third, treatment must be relevant. The neurologic, linguistic, and social needs and interests of the patient need to be considered and used (Schuell et al., 1964; Wepman, 1953, 1968). Not only do such considerations reflect the clinician's personal sensitivity, they also help to identify motivating material and pinpoint stimuli that may have very strong associational linkages in the patient's brain. Using stimuli and focusing treatment on skills that have functional relevance to the patient have been demonstrated to show greater gains in restoration of skills and/or increased use of compensatory strategies in individuals with aphasia (Pulvermüller et al., 2001).

Finally, as stated earlier, treatment should be logically related to beliefs about the nature of aphasia. The stimulation approach includes no material to be taught and no student to learn a lost language. Instead, the stimulation approach involves a person whose communication ability

may be improved with appropriate stimulation. Such a philosophy significantly affects the principles and conduct of therapy.

GENERAL PRINCIPLES OF REMEDIATION

The design of intervention used in the stimulation approach is based on a number of general principles, many of which were articulated by Schuell and colleagues (1964). A number of additional, very practical principles that also apply to the stimulation approach have been presented by Brookshire (1997). It should be noted that several of these principles are indigenous to good clinical practice, regardless of the specific approach used. They are addressed here because they have grown out of observations of patients treated with a general stimulation approach. Information pertinent to the validity of the applied principles will be presented when the design of intervention is discussed. The general principles derived from those discussed by Schuell and/or Brookshire are as follows:

1. Intensive auditory stimulation should be used. As noted earlier, this is the framework of the stimulation approach and is based on the primacy of the auditory modality in language processes and the notion that the auditory modality represents a key area of deficit in aphasia. The auditory modality need not be used exclusively. One modality may be used to reinforce another, and combined auditory and visual stimulation may be especially appropriate.
2. The stimulus must be adequate—that is, it must get into the brain. Therefore, it needs to be controlled, perhaps along a number of dimensions. The application of this principle may be highly dependent on baseline data and may involve considerable individualized pretreatment planning. Brookshire (1997) states that the difficulty of tasks should match the level at which patients are working or be just below maximum performance level (i.e., approximately 60% to 80% prompt and correct responses, and task difficulty is increased when prompt correct responses exceed 90% to 95% accuracy).
3. Repetitive sensory stimulation should be used. Auditory material that is ineffective as a single stimulus may become effective after it is repeated a number of times.
4. Each stimulus should elicit a response. This is the only way we can assess the adequacy of stimulation, and it provides important feedback that both the patient and the clinician may use to modify future stimuli and responses.
5. Responses should be elicited, not forced or corrected. If a stimulus is adequate, there will be a response. If a response is not elicited, the stimulus was not adequate.
6. A maximum number of responses should be elicited. A large number of adequate responses indicate that a large number of adequate stimuli have been presented. Numerous responses also provide frequent feedback and reinforcement of language and help to increase confidence and language attempts outside the treatment setting.
7. Feedback about response accuracy should be provided when such feedback appears to be beneficial, and such feedback should show patients their progress. The necessity for feedback may vary from patient to patient, but it is generally advisable. Showing patients their progress may be motivating, reinforcing, and extremely helpful in “proving” that progress is, in fact, taking place or that different approaches or termination of treatment should be considered.
8. The clinician should work systematically and intensively. Treatment requires a sequenced plan of action. It should be implemented often enough to meet the patient’s needs, taking into account their overall condition and prognosis for recovery.
9. Sessions should begin with relatively easy, familiar tasks. This allows an adjustment and “warm-up” time, and it enables the patient to proceed to more difficult activities after experiencing success.
10. Abundant and varied materials (Schuell et al., 1955) that are simple and relevant to the patient’s deficits should be used. Treatment does not involve the learning of vocabulary or rules, so content need not be limited to “items-to-be-learned.” As Wepman (1953) indicated, the specific content of treatment is not as important as the manner in which the treatment is conducted. A variety of material also reduces the frustration often induced by drills on a small amount of material.
11. New materials and procedures should be extensions of familiar materials and procedures. This allows the patient to concentrate on language processing and minimizes the possible disruptive effects of new material and response demands.

DESIGN OF INTERVENTION

In this section, those factors that must be considered in developing a treatment program will be considered. Because the most important component of the stimulation approach is, by definition, the stimulation provided to the patient, those variables that are potentially most important to structuring stimulation will receive primary emphasis. Response demands, feedback, and the sequencing of treatment steps also will be discussed. The reader is cautioned, however, that

the recommendations offered here for implementing the stimulation approach are based on rather broad generalizations derived from a potpourri of research and observation of heterogeneous groups and individual patients. Consequently, few, if any, of the recommendations can be assumed to apply effectively to all patients with aphasia.

Structure of Stimulation

A great deal of information has been acquired about stimulus variables that may affect the performance of patients with aphasia. Such data are largely the result of basic clinical and experimental research and are not primarily derived from specific treatment studies. Nonetheless, the data are invaluable to the clinician who must decide how to make stimulation adequate and effective during treatment. As Holland (1975) and Tikofsky (1968) have suggested, one strategy for designing treatment is to follow leads provided from research by turning the experimental techniques designed to isolate a particular problem into potential treatment tasks. Nowhere in the aphasiology literature are there so many "leads" as in the area related to stimulus variables that affect performance, and these leads have at least three practical applications to patient management. First, knowledge about stimulus manipulations that may maximize performance can be used to ensure that a patient is working at a level where "failure" is minimized. Second, and conversely, knowledge about stimulus manipulations can be applied in the opposite direction to challenge mildly impaired patients or those who respond without difficulty to tasks designed to maximize performance. Third, many of the factors to be discussed may be useful when counseling people in the patient's environment who need information about how best to communicate with the patient in everyday interactions.

The following discussion represents a review of the variables most relevant to the structuring of stimulation.

Auditory Perceptual Clarity (Volume and Noise)

Although Schuell and colleagues (1964) suggested that most patients prefer to hear speech at conversational levels, those authors indicated that an increase in volume (not shouting!) is sometimes desirable. Only a few controlled studies, however, have been conducted to evaluate the effects of increasing volume on auditory comprehension.

Glaser, Stoioff, and Weidner (1974) found that auditory comprehension of persons with aphasia under sound field conditions at the conversational level was superior to comprehension under earphones (binaurally and monaurally) at 25 dB above the conversational level. Because of the interaction between volume level and earphone/sound field methods of presentation, the results are difficult to interpret, but they do suggest that increasing volume above the normal levels does not facilitate comprehension.

McNeil, Darley, Rose, and Olsen (1979a) found no significant improvement in a group of 10 patients with aphasia on a word discrimination and word sequencing task or on portions of the Revised Token Test (McNeil and Prescott, 1978) when stimuli were presented under earphones at 75, 85, and 100 dB sound pressure level (SPL). Group data were representative of individual performance. The authors concluded that simple increases in stimulus intensity do not improve the auditory comprehension of patients with aphasia.

Although little evidence supports increasing the volume of auditory stimulation, reducing noise or increasing the signal/noise ratio does appear to be beneficial. Patients with aphasia often complain about the negative effects of noise on performance (Rolnick & Hoops, 1969; Skelly, 1975). Although Birch and Lee (1955) found that a binaural masking tone improved the naming and reading performance of patients with aphasia, other investigators have not concurred. Weinstein (1959), Wertz and Porch (1970), Schuell and colleagues (1964), and Siegenthaler and Goldstein (1967) found either no difference in performance accuracy in quiet versus noise or found noise to have a detrimental effect on performance on language tasks. Darley (1976) concluded from a review of such studies that "background noise apparently reduces the efficiency of the patient's performance" (p. 4).

These studies suggest that reducing noise or working in quiet generally facilitates language performance. Simply increasing loudness, on the other hand, does not appear to be useful, although such an increase may enhance performance in isolated cases. Many clinicians feel confident in advising patients' families that verbal comprehension is typically better in quiet than in the presence of a variety of distracting or competing auditory stimuli (e.g., television, radio, or background conversation).

Nonlinguistic Visuo-perceptual Clarity (Dimensionality, Size, Color, Context, Ambiguity, and Operativity)

Visual materials are often used as an integral part of the stimuli to which patients are asked to respond. The importance of visual stimulation, in fact, led Eisenson (1973, p. 162) to call Schuell's stimulation approach to treatment a "visual-auditory" approach. Clinical observations suggest that the properties of visual stimuli may influence responses, and the importance of the visual modality to language behavior in general has led to the investigation of visual redundancy as a potential factor influencing linguistic processing in aphasia.

In a study of 21 patients with severe verbal comprehension deficits, Helm-Estabrooks (1981) compared performance on a single-word comprehension task in which stimulus conditions consisted of line drawings, each on

individual cards arranged in rows; smaller line drawings of items, all on a single page; and real objects around the room. For the group as a whole, picture-pointing was superior to identification of objects around the room, but no differences were found between the two picture conditions. Not all patients followed the group pattern, however. Helm-Estabrooks concluded that auditory comprehension can be influenced by variables extrinsic to central auditory processing, such as visual search skills. The posteroinferior frontal gyrus has been demonstrated to be involved in the execution of visual search activities (Manjaly et al., 2005). Given that individuals with Broca's aphasia often present with lesions in this area, these findings support Schuell's notion that the properties of visual stimuli may influence responses during treatment.

Bisiach (1966) compared the naming performance of nine subjects with aphasia in response to pictures of realistically colored objects, line drawings of the same objects, and the same line drawings with superimposed curved or jagged lines. Although no differences were found among stimulus conditions for object recognition, subjects' naming of the realistically colored pictures was 15% to 18% more accurate than their naming of line drawings and of distorted line drawings. The visual redundancy of the realistically colored drawings was felt to facilitate naming.

Benton, Smith, and Lang (1972) examined the naming performance of 18 persons with aphasia in response to real objects, large line drawings, and small line drawings. Accuracy of real object naming was superior to that for small line drawings; accuracy for large line drawings fell between the two. The redundancy provided by three-dimensionality was felt to enhance the conceptual associations underlying word retrieval. Because of the relatively small differences between conditions, however, the authors questioned the clinical significance of their results. The possible insignificance of three-dimensionality was supported by Corlew and Nation (1975), who found no differences in the performance of 14 persons with aphasia when they named the 10 common, real objects used in the Porch Index of Communicative Ability (Porch, 1967), or PICA, than when they named reduced-size line drawings of the same objects.

In a theoretically interesting study, Whitehouse and Caramazza (1978) compared the ability of 10 persons with aphasia to identify line drawings of three objects (a cup, a bowl, and a glass) varying in physical features such as height and width. Stimuli consisted of prototypes (unambiguous representations) of the three objects as well as drawings in which the height-width dimensions were varied to make the perceptual distinction among the objects "fuzzy." In addition, some of the drawings had a handle, and some did not. Context (functional information) was also varied by presenting stimuli either alone or in context with a coffee pot, a cereal box, or a water pitcher. Subjects "named" the pictures by selecting from multiple-choice presentations of the

names of the three objects. Results were not uniform across subjects. Those with a diagnosis of Broca's aphasia performed similarly to normal control subjects in their use of context and in their ability to deal with fuzzy perceptual boundaries. Patients with a diagnosis of anomic aphasia, however, had difficulty integrating and using perceptual and functional cues (dimension and context). These findings, along with those of Caramazza, Berndt, and Brownell (1982), have led to the conclusion that, for some patients, naming difficulty is related to an inability to organize adequately the concepts underlying word meaning in terms of functional and perceptual information, as opposed to difficulty with retrieval of an adequately perceived/conceived lexical item. Although the implications of these findings for clinical practice are neither clear-cut nor universal, it appears that the perceptual characteristics of visual stimuli should be as unambiguous as possible for all patients. Placing a target object in a redundant conceptual setting (e.g., pairing a cup with a coffee pot) may enhance word retrieval when the target is perceptually ambiguous. When pairing a target stimulus with other visual stimuli, however, the additional stimuli should never introduce ambiguity about the nature of the target.

The findings of Gardner (1973) suggest that the number of modalities in which associations may be evoked should be considered when selecting visual materials for treatment. He compared naming pictures of "operative" objects (discrete, firm to the touch, and available to several modalities [e.g., "rock"]) to "figurative" objects (not operative [e.g., "cloud"]), while accounting for the effects of picturability and word frequency. Most patients with aphasia performed more accurately in response to the operative items, and the effects of operativity were most pronounced for patients with difficulty initiating speech. Gardner argued that operative items were superior because they aroused associations in several modalities, whereas the figurative items were limited to visual associations. This perspective is supported by findings of Nickels and Howard (1995), who noted that operativity and imageability (i.e., how easy it is to create a visual or auditory image of the referent) were predictive of naming performance for some individuals with aphasia. The implication for treatment, therefore, is that visual stimuli which also may trigger auditory, tactile, kinesthetic, or olfactory associations are potentially more effective in aiding word retrieval than stimuli which trigger only visual associations.

To summarize, although some data suggest that some properties of visual stimuli are relatively unimportant to the performance of individuals with aphasia, the clarity and redundancy of visual stimuli do not seem to influence linguistic processing (Caramazza and Berndt, 1978). Darley (1976) recommends that we "play safe" and use the redundant and realistic stimuli in treatment. The most potent visual stimuli appear to be characterized by three-dimensionality, color, redundant physical properties, operativity,

and a lack of ambiguity in perceptual characteristics and context.

Linguistic Visuo perceptual Clarity (Size and Form)

Few data suggest that the size or form of reading material affects comprehension, but some clinical observations are relevant. Rolnick and Hoops (1969) reported that patients with aphasia complain about small print for word and sentence stimuli and prefer large print—even when visual field deficits are not present. McDearmon and Potter (1975) observed varying preferences for upper-case, lower-case, or script stimuli. Schuell and colleagues (1955) recommended upper-case print for patients with visual impairments and felt that script should not be introduced until the patient's reading rate for printed material is normal.

Boone and Friedman (1976) examined single-word reading comprehension in response to cursive versus manuscript stimuli in 30 patients with aphasia, and Williams (1984) investigated the same factors' influence on the word and sentence comprehension of 20 patients. Neither study found significant differences between the two written forms. Williams, however, observed that two of her patients reliably responded better to manuscript than to cursive.

No compelling evidence suggests that the size and form of written input are powerful stimulus factors affecting reading comprehension. When providing reading material for patients, however, the clinician should be aware of a general preference for large print and potential idiosyncratic preferences for upper-case, lower-case, cursive, or manuscript format.

Method of Delivery of Auditory Stimulation

Many clinicians have speculated about ways to improve the delivery of auditory stimuli to patients. For example, are there better alternatives to live-voice, binaural, free-field stimulation?

The use of earphones is intuitively attractive because of its potential for reducing extraneous noise and focusing attention. Schuell and colleagues (1964), however, observed that patients usually prefer direct presentation to earphones, because they rely on more than auditory cues or, perhaps, because earphones produce distortions to which they are sensitive. The preference for free-field presentation is supported by the previously mentioned study of Glaser and colleagues (1974), who found that the comprehension under free-field conditions was superior to binaural as well as right- and left-ear monaural presentations through earphones. The superiority of the free-field condition was maintained even when the intensity of the earphone conditions was 25 dB greater than the intensity in the free-field.

It has been suggested that selective left-ear/right-hemisphere presentation of auditory stimuli may improve comprehension. Such speculation is based on the results of

dichotic listening studies that have found a left-ear advantage for patients with aphasia (e.g., Johnson, Sommers, & Weidner, 1977; Sparks, Goodglass, & Nickel, 1970). LaPointe, Horner, and Lieberman (1977) examined the responses of patients with aphasia to portions of the Token Test (DeRenzi & Vignolo, 1962) when presented to the right ear, the left ear, or binaurally and found no significant differences among the three conditions. They concluded that selective monaural presentation of auditory stimuli is not a useful procedure. McNeil, Darley, Rose, and Olsen (1979b) examined the effects of selective binaural SPL variations in which stimuli were presented at 85 or 100 dB SPL to one ear while stimuli to the other ear were presented at 70 dB SPL. Although a trend toward better comprehension on some tasks was noted when the left ear was more intensely stimulated, their general conclusion was that the unilateral intensity increase is not a potent mechanism for improving auditory comprehension.

To date, the data indicate that response adequacy to free-field presentation is not exceeded when earphones are used and that selective stimulation of one ear/hemisphere does not surpass binaural stimulation. It should also be noted that the findings of Green and Boller (1974) and of Boller, Vrtunski, Patterson, and Kim (1979) suggest that live-voice presentation is superior to taped presentation of stimuli. Therefore, we have no compelling reason not to continue presenting auditory stimuli directly with live voice, binaurally, and in the free field.

Discriminability (Semantic, Auditory, Visual)

Verbal responses of patients with aphasia are often characterized by errors associated in meaning or experience. Such errors (e.g., "table" for "chair") are, in fact, the "best" errors a patient can make (Schuell and Jenkins, 1961a; Schuell et al., 1964). These characteristics suggest that response alternatives provided to patients should not promote semantic errors. This is particularly relevant for comprehension tasks, which require the patient to choose from among a set of alternatives (e.g., responding to a verbally and/or visually presented word or sentence by pointing to one of several choices). Assuring that response choices are unrelated semantically will often facilitate speed and accuracy of performance. Conversely, tasks can remain unchanged in nature but often can be made more difficult by introducing semantically related response choices (Duffy and Watkins, 1984; Pizzamiglio and Appicciafuoco, 1971).

Semantic discriminability among response choices is more important than visuo perceptual discriminability. This is illustrated by the findings of Chieffi, Carlomagno, Silveri, and Gainotti (1989). Their patients with aphasia made more errors on a single-word comprehension task when response choices were semantically related (e.g., banana, apple, and grapes) than when they were visually related (e.g., wheel,

button, and lifebelt). Performance on a task in which response choices were both semantically and visually related (e.g., chair, bench, and stool) was poorer than in the semantically related condition, suggesting that semantic and perceptual effects may be cumulative, although the authors argued that the semantic demands of the combined semantic and visual task were more potent than the demands of the visual ones.

Difficulty discriminating between words with minimal phonemic differences (e.g., cake/take or horse/house) is an important aspect of auditory impairment in some patients (Schuell, 1973). In addition, patients with aphasia may confuse letters or words with similar visual configurations (e.g., E/F, p/b, or store/stone).

An investigation by Linebaugh (1986) sheds some light on the importance of semantic, auditory, and visual discriminability in single-word reading comprehension tasks. He presented a picture-to-written word matching task to 25 patients with aphasia under two conditions. In one, all three response foils (written words) were either semantically, auditorily, or visually related to the target response. In the other, the three foils consisted of one semantically, one auditorily, and one visually related word. When all foils were of the same type, the error rates were higher with visually than with auditorily related foils, with no differences among other foil comparisons. When foils contained one of each foil type, both semantic and visual errors were more frequent than auditory errors, with no differences between semantic and visual errors. Considerable variability was found among subjects in their patterns and degree of susceptibility to the semantic, visual, and auditory influences, with a minority of subjects making more than 50% of their errors in one category and only two subjects doing so in both experimental conditions. These findings suggest that semantic and visual discriminability, on average, are more potent than auditory discriminability in single-word reading tasks, but the power of each factor is seldom overwhelming in individual patients.

The discriminability factor apparently is also relevant to word retrieval tasks. The findings of Mills, Knox, Juola, and Salmon (1979), for example, have implications for the semantic distinctiveness of visual stimuli used in naming tasks. (They are also relevant to the information discussed under nonlinguistic visuoperceptual clarity.) These authors examined the effects of “uncertainty” on the naming performance of 10 patients with aphasia, with uncertainty being defined as “the number of equally probable binary choice decisions necessary to achieve a final name selection from one or several correct names available in the lexicon” (p. 75). For example, when shown a picture of a cup, most control subjects respond “cup”; few alternative responses are correct (i.e., little uncertainty). On the other hand, a picture of a country home in winter generates considerable uncertainty, because “winter . . . country,” “cabin . . . house,” and other

words would be reasonable responses, thus requiring a greater number of word retrieval decisions. The patients with aphasia made significantly more errors and had greater response latencies regarding high-uncertainty pictures than regarding low-uncertainty pictures, leading the authors to conclude that uncertainty affects naming performance in patients with aphasia. Their findings suggest that another way to simplify word retrieval on picture naming tasks is to select stimuli to which only a few alternative responses exist. Similarly, reducing the number of response alternatives reduces error probability on point-to comprehension tasks.

Finally, discriminability of task format is important to consider when evaluating a language deficit. To illustrate this point, Breese and Hillis (2004) examined the sensitivity of a word/picture verification task versus a word/picture identification task in identifying an auditory comprehension deficit in individuals with aphasia. For the word/picture verification task, subjects were asked if a picture corresponded to a spoken name—for example, a picture of knife with “Is this a fork?” For the word/picture identification task, subjects were asked to point to a named object in a set of four pictures. Results demonstrated that the word/picture verification task was more sensitive than the word/picture identification task for identifying impairments of auditory comprehension. Clinically, these findings suggest that greater discriminability of stimuli occur in verification tasks versus identification tasks when evaluating auditory comprehension deficits.

In summary, compelling data suggest that verbal comprehension tasks in which several response choices are offered can maximize performance if alternatives are semantically unrelated to the target response. The auditory and visuoperceptual “distinctiveness” of the target from response alternatives may also be important, with visual similarity generally being more important than auditory similarity on written-word comprehension tasks. Although considerable variability exists among patients in their responsiveness to these semantic, auditory, and visual influences, reducing the number of response choices on point-to tasks will usually lead to improved performance. In addition, picture verification tasks show greater sensitivity than point-to tasks in identifying auditory comprehension tasks.

Combining Sensory Modalities

Although the auditory modality is paramount in the stimulation approach, the use of several modalities in combination is often recommended. Schuell (1974b) indicated that various modalities should be used to reinforce one another and, in fact, felt that patients often do better when auditory and visual stimuli are combined. Schuell and Jenkins (1961a) reported that patients do better on single-word comprehension tasks when written and auditory stimuli are used instead of auditory stimuli alone.

Goodglass, Barton, and Kaplan (1968) examined the naming performance of 27 patients in response to auditory (characteristic sound associated with the target item), tactile, olfactory, and picture stimuli. They found a uniformity in performance across all modalities for the great majority of patients, although reaction times were fastest to visual stimuli. By extension, the work of Mills (1977) and Smithpeter (1976) suggest that combining some of those stimuli may enhance performance. Mills found that pairing an environmental sound (e.g., whinny) with a picture to be named (e.g., horse) facilitated naming performance over time, generalized to nondrilled words, and resulted in post-therapeutic improvement in naming without the auditory stimulus. Smithpeter reported that olfaction was effective in stimulating accurate language responses in some patients with aphasia when it preceded or accompanied other stimuli.

Caramazza and Berndt (1978) cite the work of North (1971), who found that the word recall of patients with aphasia improved when information was available through several sense modalities. North argued that various senses may contribute additively to word recall. The previously discussed findings of Gardner (1973) regarding operativity suggest that such additivity of multisensory stimulation need not be overt. That is, performance may be enhanced if visual stimuli, for example, are capable of "arousing" multisensory associations.

Combining the auditory and visual modalities is the most widely used form of multisensory stimulation, and a number of studies support the practice, although with some qualifications. Gardner and Brookshire (1972) found naming and single-word reading performance of eight patients with aphasia to be better during combined auditory and visual stimulation than during auditory or visual stimulation alone. By varying the order in which the stimulus conditions were presented, they also determined that combined stimulation facilitated performance during subsequent unisensory stimulus conditions. Analysis of single subject profiles indicated that combined stimulation may not be best for all patients, but these results generally supported the conclusion that combined stimulation is better than unisensory. They also suggest that combined auditory-visual stimulation should generally precede auditory or visual stimulation alone, at least during treatment tasks that require naming responses. Halpern (1965a, 1965b), reporting similar results, supported the concept of multisensory stimulation but noted that a multisensory approach sometimes can be distracting. Additional evidence related to multisensory stimulation may be derived from the study of electrophysiological activity in the brain during various stimulation activities. Moore (1996) investigated the hemispheric alpha asymmetries (through the use of electroencephalography) of normal male and female subjects and of male patients with aphasia during recall and recognition of high- and low-imagery words presented auditorily, visually, and in a multimodality (combined auditory and visual) condition. Results indicated that the

subjects with aphasia demonstrated higher mean scores on the recall and recognition tasks during the multimodality condition than during either the visual or auditory condition alone. Further, for the subjects with aphasia, the multimodality stimulation appeared to activate the left hemisphere to a greater degree than either auditory or visual stimulation alone. Moore commented that "the multimodality stimulation appears to have facilitated the left hemisphere's participation in language processing, which may have contributed to increased language performance" (p. 683).

Auditory stimulation often involves some potentially useful visual input as well; for example, the patient's visual contact with the examiner may provide a number of facilitatory verbal or paralinguistic cues. Green and Boller (1974) found that the comprehension of severely impaired patients with aphasia was not as accurate or appropriate when stimuli were presented by tape or with the examiner behind the patient as when stimuli were presented face to face. Boller and colleagues (1979) confirmed the superiority of face-to-face presentation over the use of taped stimuli, and Lambrecht and Marshall (1983) showed that the comprehension of severely impaired patients was better when they looked and listened than when stimuli were simply heard. Whether the performance differences in these studies resulted from situational, extralinguistic, or additional visuoverbal input through lipreading is not clear. Such an interpretation is supported by recent studies of the contribution by visual sources of contextual information to speech perception. Records (1994) reported that, as auditory information became more ambiguous, individuals with aphasia and poor language comprehension made greater use of accompanying referential gestures to facilitate their understanding of verbal messages. Similarly, the successful application of therapy focused on auditory discrimination of minimal pairs at the phonemic level, using lipreading, has also been reported (Morris, Franklin, Ellis, Turner, & Bailey, 1996). Regardless, it seems that having the visual and auditory attention of the patient during the presentation of verbal material is important. Other combinations of sensory input have been noted to be facilitative as well. For example, Lott, Friedman, and Linebaugh (1994) successfully paired tactile-kinesthetic cues (i.e., tracing letters on the palm of the hand) with visual cues to improve the reading skills of an individual with aphasia and alexia.

Recent studies have investigated computer-administered auditory and visual stimulation for the treatment of anomia. The results of these studies are consistent and indicate that incorporating computers into stimulation treatments facilitate naming skills (Adrian, Gonzalez, & Buiza, 2003; Pedersen, Vinter, & Olsen, 2001). Other promising approaches have included combining verbal and gestural treatments (Rose & Douglas, 2001; Rose, Douglas, & Matyas, 2002).

To summarize, providing multimodality stimulation can improve response adequacy for many patients with aphasia,

and combining auditory and visual stimulation may be the best and most practical way of doing so. Combined auditory and visual stimulation may facilitate responses to subsequent unisensory stimuli and, therefore, may be employed first when responses to unisensory stimulation are deficient to a significant degree. Other modalities, such as the tactile, or use of a computer may also be helpful. It seems that the effectiveness of multimodality stimulation stems from the redundancy of the information that it provides and the additional associations it might help to trigger. This appears to be desirable for many patients, although the clinician needs to be sure that such multiple inputs improve performance and do not, somehow, overload or exceed the capacity of the patient to use them effectively.

Stimulus Repetition

Repetitive sensory stimulation is a principle of treatment espoused by Schuell and colleagues (1964). They recommended, for example, that, on word recognition or repetition tasks, as many as 20 repetitions of a stimulus word might be appropriate or necessary before eliciting a response. Few studies, however, have directly examined the effects of repetitive stimulation on language comprehension or expression in patients with aphasia.

Helmick and Wipplinger (1975) examined naming behavior in one patient with aphasia under a no-treatment and two treatment conditions, with each condition containing different target words. In a minimal stimulus condition, six “stimulations” (including verbal identification, contextual cue, picture identification/discrimination, tracing, and copying) were provided before eliciting a naming response. In the maximum stimulus condition, the six stimulations were repeated four times for each word. Both conditions were more effective than the no-treatment condition, but no differences were found between the results obtained from minimum and maximum stimulation. The authors concluded that a relatively small amount of stimulation can be as effective as a great deal of stimulation.

LaPointe, Rothi, and Campanella (1978) evaluated the effects of two methods of repetition of Token Test commands on the auditory comprehension of 12 patients with aphasia. In one condition, stimulus repetitions of commands preceded responses; in the other, repetition occurred only following incorrect responses. When items were repeated following failure (to a ceiling of four repetitions of the original stimulus), significant improvement occurred in response to the first and second repetitions, and further but non-significant gains were noted for the third and fourth repetitions. In numeric terms, accuracy was 24% without repetition, which rose to 58% after repetition to ceiling level. Degree of language impairment was negatively correlated with gains from repetition. In contrast, when items were presented two or four times before a response, no significant

group gains over the no-repetition condition were noted. However, some individual subject differences were noted. One subject did “remarkably poorer” when commands were repeated before responses, and another apparently benefited from the prerespone repetition.

Contextual priming, a relatively new concept in treating word retrieval deficits, also incorporates stimulus repetition into its procedures. Contextual priming combines “massed repetition of picture names with context effects, by training pictures in small sets that are related in some way semantically or phonologically” (Martin, Fink, & Laine, 2004, p. 458). During treatment, blocks of stimuli are formed—for example, one group of stimuli that is semantically related, one group that is phonologically related, and one group that is unrelated. In a session, the subject is required to name each item in a block using a massed practice principle—that is, rapid and repetitive stimulation to one class of related pictures. Each block of related stimuli is presented in every session, and the accuracy of performance is recorded. Several recent studies examining the effectiveness of contextual priming have noted that not only was exposure to related stimuli beneficial in realizing treatment gains, the massed practice of each block of stimuli provided further substantial gains in naming skills (Cornelissen et al., 2003; Martin, Fink, & Laine, 2004; Martin, Fink, Laine, & Ayala, 2004; Martin & Laine, 2000; Renvall, Laine, Laakso, & Martin, 2003).

Another relatively new treatment approach that uses stimulus repetition is constraint-induced language treatment, the key principles of which include: (1) massed practice in an enriched, therapeutic, and communicatively relevant environment; (2) constraint of other communication modalities; and (3) forced use of spoken language through the application of visual barriers. Massed practice involves repetitive stimulation provided by the clinician, and the subject is required to practice a new or previously acquired language skill for several hours on a daily basis. During the period of massed practice on a variety of communication tasks, the subject is prevented from using either alternative modalities of communication, such as gesture, or other communicative compensatory strategies, such as circumlocution. Complementary studies have found that both constraining a language modality and requiring massed practice of a language behavior effected positive gains in language functions for individuals with chronic aphasia (Maher et al., 2003; Pulvermüller et al., 2001; Hinckley & Carr, 2005). Further research is required, however, to tease out the individual effects of massed practice and constraint during functionally relevant treatment.

As described above, recent research seems to support the use of numerous repetitions of stimulation as a general principle of therapy for aphasia. Earlier studies identified some individuals who responded differently to prerespone repetitive stimulation, with some benefiting and others deteriorating. In contrast, repetition of stimuli subsequent to errors generally does appear to increase adequate responses, with

maximum benefits being derived from the first or second repetition.

Rate and Pause

It has been suggested that slowing speech rate may aid in auditory comprehension (Schuell et al., 1964) and that this is something experienced clinicians apparently are aware of subconsciously. Salvatore, Strait, and Brookshire (1978) reported that experienced clinicians give Token Test commands more slowly than their inexperienced colleagues by inserting more pause time within commands. They also found that experienced clinicians tend to slow their presentation rate when repeating commands that previously had generated error responses. Such clinician behavior obviously is not desirable during standardized diagnostic testing and some baseline procedures, but it does offer indirect support for the facilitating effect of rate reduction on verbal comprehension.

Gardner, Albert, and Weintraub (1975) examined sentence comprehension in 46 patients with aphasia and comprehension problems ranging from mild to severe. They reported improvement in comprehension—independent of the form of aphasia—when sentences were spoken at a rate of one word per second. They recommended that, when proceeding from single-word to sentence stimuli, words should initially be enunciated slowly.”

Weidner and Lasky (1976) found improved performance in a group of 20 patients with aphasia on four measures of auditory comprehension when the presentation rate was reduced from 150 words per minute (wpm) to 110 wpm. Differences between the two rate conditions were greatest for patients scoring above the 50th percentile on the PICA. Similarly, Poeck and Pietron (1981) induced an 11% to 12% improvement in Token Test scores of a group of 42 patients with aphasia through electronically expanding the speech rate by 25%. Pashek and Brookshire (1982) extended these findings by showing that reducing the rate from 150 wpm to 120 wpm facilitated paragraph comprehension in a group of 20 patients; performance was facilitated in those with poor as well as those with good sentence-level comprehension.

The facilitative effect of reduced rate also has been demonstrated for a patient with aphasia and severe auditory imperception (Albert & Bear, 1974). The authors found that the patient's comprehension improved dramatically when rate was slowed to a third of the normal rate or less.

Liles and Brookshire (1975) examined the comprehension of 20 patients when 5-second pauses were inserted into various portions of Token Test commands. The insertion of pauses facilitated comprehension for many of their patients. Patterns of patient performance led the authors to hypothesize that the pauses aided in the processing of strings of lexical items but not in the processing of syntactic components. In contrast, Hageman and Lewis (1983) inserted 2-second

pauses at major within-sentence breaks of the Revised Token Test and failed to find qualitative or quantitative performance differences compared to a no-pause condition. They suggested that a 2-second pause may not be long enough to facilitate performance.

Salvatore (1976) reported a facilitation of comprehension for a patient with aphasia when 4-second pauses were inserted into Token Test commands. By gradually fading the pause duration, it was also possible to maintain improved comprehension with 2-second and, sometimes, only 1-second pauses. Although no generalization to nonpause stimulation was found, the results do suggest that pause time can be faded, to some degree, while maintaining high levels of comprehension.

Are the effects of rate reduction and pause insertion cumulative? Lasky, Weidner, and Johnson (1976) examined the effects of rate reduction (120 wpm vs. 150 wpm) and the insertion of 1-second interphrase pauses on the sentence comprehension of 15 persons with aphasia. Comprehension improved when the rate was slowed or when the pauses were inserted, and the combination of reduced rate and interphrase pauses resulted in the best performance.

In an effort to examine how slowing rate facilitates comprehension, Blumstein, Katz, Goodglass, Shrier, and Dworetzky (1985) compared comprehension by patients with aphasia of sentences spoken at normal rates to (1) a vowel condition, in which vowel duration in each word was increased (140 wpm); (2) a word condition, in which silences were added between words (110 wpm); (3) a syntactic condition, in which silences were added at constituent phrase boundaries (90 wpm); and (4) a natural condition, in which sentences were read at a naturally slowed rate (110 wpm). In general, reducing rate had a relatively small facilitatory effect and was significant only for the syntactic condition and for patients with Wernicke's aphasia. The authors concluded that it may not be slowed rate per se that facilitated comprehension but, rather, the effect of a syntactically well-placed pause on the processing of preceding syntactic and semantic elements. Although this may be the case, the fact that the rate of the syntactic condition (90 wpm) was slower than any other slowed condition confounds the interpretation and leaves open the possibility that slowing rate to a comparable degree in other ways might also facilitate comprehension.

The positive effects of slowed rate may not be as robust for narrative discourse. Nicholas and Brookshire (1986a) examined narrative comprehension across two test sessions in patients with aphasia and relatively good and relatively poor comprehension; narratives were spoken at fast (190 wpm to 210 wpm) versus slow (110 wpm to 130 wpm) rates. Only the group with relatively poor comprehension benefited from rate reduction, and this held only for the first of the two test sessions. In addition, the facilitatory effect of slow rate was not present for all patients in the poor

comprehension group. The authors concluded that the effect of slow rate was undependable and transitory, and they noted that variables with strong effects on comprehension at the sentence level may have only weak effects at the level of discourse.

To summarize, it appears that slowing rate and lengthening pauses at phrase boundaries can have a facilitatory effect on sentence comprehension. This effect is neither always present nor generally dramatic, and no consistent indications are found across studies that the ability to benefit from rate and pause modifications is tied to either type or severity of aphasia. The positive effects of slowing rate may be less consistent and pervasive at the level of discourse than at the sentence level. From the practical standpoint, however, it is reasonable to accept the advice of Nicholas and Brookshire (1986a) that "it seems reasonable to counsel those who speak with brain-damaged listeners to speak slowly, because slow speech rate does not affect most brain-damaged listeners negatively, and for some it may be beneficial, at least on some occasions" (p. 469).

Length and Redundancy

As previously stated, Schuell felt that reduced verbal retention span is a near-universal feature of aphasia. Although pervasive, she reported that retention deficits are highly reversible with the use of carefully controlled, intensive auditory stimulation characterized by gradual increases in stimulus length (Schuell, 1953a; Schuell et al., 1955).

The importance of stimulus length receives additional support from a number of sources, including patients themselves. Rolnick and Hoops (1969), interviewing several patients with mild aphasia, found numerous complaints about the processing and retention demands imposed by lengthy messages. Patients felt that reduced message length facilitated comprehension and retention.

In addition, numerous studies have demonstrated that, with other factors held constant, sentence comprehension tends to decrease as sentence length increases (e.g., Curtiss, Jackson, Kempler, Hanson, & Metter (1986); Shewan & Canter, 1971; Weidner & Lasky, 1976).

Although Goodglass, Gleason, and Hyde (1970) found that 52 patients with different classical forms of aphasia had varying degrees of success on a verbally presented retention span test, all patients were deficient to some degree. Albert (1976) examined the ability of 28 patients with aphasia on a short-term memory task in which they pointed to objects named serially by the examiner. The results of patients were inferior to those of control subjects and of patients with brain injury but without aphasia on total item retention and in retention of the accurate sequence of presentation. Response patterns indicated that sequencing problems increased as information load increased. Information load and sequencing deficits were both present regardless of the

clinical type of aphasia. The findings of Martin and Feher (1990) suggest that the degree of short-term memory limitation in aphasia affects semantic processing (i.e., sentences with a large number of content words) but is not strongly related to the processing of syntactic complexity. Finally, Gardner and colleagues (1975) found poorer comprehension when length increased from single words to nonredundant sentences containing the same single words.

Length appears to be an important factor in the visual as well as the auditory modality. Siegel's (1959) 31 patients with aphasia had more difficulty reading words of two or more syllables (six or more letters) than single-syllable words of less than five letters. Halpern (1965a, 1965b) compared verbal responses of 33 patients on tasks involving single-word repetition, reading single words, and reading single words with simultaneous auditory and visual stimulation. Stimuli in each task were either long (two or more syllables or six letters) or short (one syllable or less than four letters) and also varied as a function of abstraction level and part of speech. Results showed that long words resulted in more verbal errors—including preservation—compared with short words, regardless of the modality of presentation. Differences between errors on long and short words were greatest for the visual modality. On the basis of his findings, Halpern recommended that, for such tasks, auditory or auditory with visual stimulation should usually precede visual stimulation alone.

Going beyond the word level, Webb and Love (1983) examined the reading abilities of 35 patients with aphasia and found (1) more errors on sentence recognition than on letter or word recognition, (2) more errors on oral reading of sentences and paragraphs than of letters or words, and (3) more errors on paragraph comprehension than on sentence comprehension.

Friederici, Schoenle, and Goodglass (1981) have shown that word length also influences writing. In their group of 12 patients with aphasia, written accuracy was reduced by more than 50% as word length increased from one to three syllables. Increased word length (i.e., number of phonemes in the spoken word) has also been shown to negatively influence naming performance in some individuals with aphasia (Nickels & Howard, 1995).

Wepman and Jones (1961) found that verbal responses to words are easier than verbal responses to sentences whether stimuli are presented auditorily or visually. At the word level, verbal responses to written stimuli were better for one-syllable than for two-syllable words. On the other hand, verbal responses to auditorily presented words did not differ between one-syllable and two-syllable words. In contrast to the findings of Halpern (1965a, 1965b), these authors indicated that the length factor for sentence material is most pronounced for the auditory, not for the visual, modality. It is possible that the different results are caused by the fact that Halpern was dealing with variations of length within

single words but Wepman and Jones were referring to differences between words and sentences. If so, this highlights the fact that differences in the processing and/or retention of words between modalities are not identical to differences in the processing and/or retention of sentences (and discourse) between modalities.

It is important to note that the detrimental effects of increasing message length may vary as a function of message redundancy. For example, the findings of Gardner and colleagues (1975) support the notion that patients with aphasia comprehend redundant sentences better than nonredundant sentences of equal length. Clark and Flowers (1987) demonstrated that increasing sentence redundancy facilitated comprehension even when redundant sentences were longer and syntactically more complex than nonredundant ones (e.g., sentences like "Which one is the book you read?" were easier than sentences like "Which one is the book?"). Also, the remarkable sensitivity of the Token Test to subtle deficits of comprehension is at least partially the result of the nonredundant properties of its verbal stimuli. Clearly, the potent effect of length strongly interacts with redundancy—the two factors can seldom, if ever, be considered separately. (Further discussion of this interaction can be found in the section on grammar and syntax.)

To summarize, there can be little doubt that controlling length at the word and the sentence levels is a potent stimulus factor for most or all patients with aphasia, and most clinicians discuss this factor when counseling families about their verbal input to the patient. Length is an influential factor regardless of whether stimuli are auditory, visual, or auditory and visual. In the visual modality, reducing length at both the word and the sentence levels can be expected to facilitate comprehension. For auditory input, length may be relatively unimportant at the word level, but it becomes highly important when proceeding from the word to the phrase to the sentence level. When controlling length, it seems that nonredundant components are the most crucial elements to control, because increases in message redundancy may limit or even overcome the generally negative effects of increases in message length. This may be particularly true at the levels of paragraph and narrative discourse (to be discussed in the section on context).

Cues, Prompts, and Prestimulation

It is well recognized that, under the right circumstances, the skillful clinician can employ a variety of techniques—often referred to as cues, prompts, or prestimulation—that will facilitate a patient's word retrieval or comprehension. Such techniques are often used following an inadequate response to a less powerful stimulus. When less powerful stimuli are consistently incapable of generating a high proportion of adequate responses, however, the cue (prompt or prestimulus) may become a distinct treatment condition to which

acceptable responses must be generated before proceeding to the less powerful stimuli. In this section, a number of potentially useful cues that have not been covered already under other headings will be discussed.

McDearmon and Potter (1975) offered a number of suggestions regarding representational prompts, which they defined as symbolic or realistic cues that directly suggest the concept being referred to in a response. Prompts are strongly related to the concepts of stimulus redundancy and multimodality stimulation; they suggest that more than one representation of the response be presented and that one representation (i.e., the prompt) gradually be faded. For example, on naming tasks, pictures and their written names may be presented with resultant adequate responses. The written prompts may then be faded gradually by blocking out increasing portions of the word until that word is entirely eliminated. Some other suggested prompts not already implied under other headings include (a) tracing letters to facilitate letter recognition, (b) writing words to aid word retrieval, (c) pantomime or American-Indian sign to facilitate word retrieval, and (d) using pictures in conjunction with corresponding written words to facilitate reading.

Barton, Maruszewski, and Urrea (1969) examined word retrieval of 36 patients under three conditions: (1) picture naming, (2) sentence completion (e.g., "You clean teeth with a ____."), and (3) object description. In order, the most powerful cues were sentence completion, picture naming, and object description. It is important to note, however, that 44% of the subjects in their study did not follow the group's ordering of responses to the three naming conditions. This highlights the importance of examining the individual patient's responsiveness to stimulus cues; a powerful cue for one patient may not be as powerful for another. Along these lines, Marshall and Tompkins (1982) as well as Golper and Rau (1983) point out that careful analysis of individual patient strategies may provide clues about the best cues for the clinician to provide during therapy. Such information may also be used to increase the patient's own use of successful cues.

Freed, Marshall, and Nippold (1995) examined two cueing techniques with 30 individuals having mild to moderate aphasia in associative learning tasks. Real English words were paired with black-and-white, abstract symbols, and subjects were required to label each symbol. During the task, subjects were given either their own previously elicited associations for the word-symbol pairs (personalized cues) or associations developed by the examiner (provided cues). Results indicated that both cueing techniques were equal in terms of yielding correct responses. The authors observed that subjects in the "provided cue" condition were given complete rationales for why the cues were used; thus, the provided cues may have inadvertently become similar to the personalized cues. Freed and colleagues concluded that both the provided and the personalized cues contained components

that might be beneficial to include in a treatment protocol for word retrieval deficits.

Linebaugh and Lehner (1977) have described a cueing program for word retrieval that is based on two principles: (1) that recovery is best served by eliciting the desired response with a minimal cue, and (2) that when a cue is successful, continued elicitation of the appropriate response with less powerful cues is reinforcing and conducive to stimulating the processes underlying word retrieval. When a patient is unable to name a pictured object, the following cues, in order, are given until an adequate response is elicited: (1) directions to state the object's function, (2) statement of the function, (3) statement and demonstration of the function, (4) sentence completion, (5) sentence completion plus the silently articulated first phoneme of the response, (6) sentence completion plus the vocalized first sound, (7) sentence completion plus the first two phonemes vocalized, and (8) word repetition. When an adequate response is elicited, the order of cues is reversed until the patient names the picture without a cue. Linebaugh and Lehner presented data for several patients that demonstrate improved word retrieval and generalization to nontreatment words. Importantly, they indicate that cueing hierarchies must be individually determined.

The effectiveness of personalized cues and self-cues in naming tasks has been investigated in two recent studies. In the first, the nature of information contained in personalized cues for naming of subordinate categories was examined. Personalized cues were elicited from 15 individuals without brain damage and 15 individuals with aphasia and evaluated to determine if the cues facilitated learning of unknown dog breeds. Five different types of cues were identified and evaluated for their facilitatory effect. Results revealed that cues containing semantic information led to greater accuracy of naming for the individuals with aphasia (Marshall, Karow, Freed, & Babcock, 2002). In a related study on treatment of naming deficits, individuals with chronic aphasia were required to generate self-cues characterized by either partial written word information or tactile cues. Results revealed improvements in naming of target items with generalization to performance on standardized language measures (DeDe, Parris, & Waters, 2003). The results of both studies support the value of personalized and self-generated cues in naming tasks.

A facilitatory effect of semantic cues also seems to exist for online tasks (i.e., tasks in which the cues are not necessarily obvious to the patient). Chenery, Ingram, and Murdock (1990) studied the ability of patients to recognize whether the second word in a pair of verbally presented words was real or nonsense when the first word was functionally related to the target (e.g., eat-knife), superordinally associated (e.g., cutlery-knife), unrelated (e.g., door-knife), or nonsense (e.g., lamiel-knife). Subjects were told to ignore the first word. All subjects with aphasia, including a subgroup with severe comprehension and naming deficits, more accurately identified words as being real in response to the functional and superordinate semantic

primes than in the other priming conditions. This led to a conclusion that information is preserved in semantic memory in patients with aphasia. (This online facilitation of semantic processing may partially explain why redundancy can facilitate sentence comprehension.) In a related study, Leonard and Baum (1997) noted faster responses to words preceded by primes that were both phonologically and orthographically related to the target word (i.e., words that shared both spelling and sound-syllable rhyme [e.g., "blood-flood"]) than those that were unrelated (e.g., "dish-room"). Phonologically related primes (i.e., word pairs that shared syllable rhymes but were orthographically unrelated [e.g., "seed-bead"]) alone did not facilitate reaction times, and responses were also slower relative to the primes that were orthographically, but not phonologically, related (i.e., word pairs that shared rhyme spelling but were pronounced differently [e.g., "tough-cough"]).

Podraza and Darley (1977) investigated the effects of three types of prestimulation on picture naming in five patients with aphasia. The prestimulus conditions (i.e., cues presented before picture presentation) included the first phoneme of the target word, an open-ended sentence (three words, one of which was the target word), and three semantically related words. Naming was generally facilitated by the phoneme, open-ended sentences, and three words containing the target word cues, whereas performance decrements occurred for the three semantically related word cues. The facilitative failure of the semantically related word cues is in disagreement with the findings of Weigl (1968) and of Blumstein, Milberg, and Shrier (1982) that such cues may serve a "debblocking function" and facilitate retrieval. Podraza and Darley suggest that their own patients may already have been operating in the appropriate "semantic field" (Goodglass and Baker, 1976, p. 361) and that additional stimuli in that field may have served to confuse the selection of an appropriate response. Similarly, patients with Wernicke's aphasia, who frequently make phonemic errors, benefit less from phonemic cues than patients with other types of aphasia (Kohn and Goodglass, 1985).

Breen and Warrington (1994) have also compared a variety of cues in an individual with severe anomia. Phonologic and semantic cues were noted to be far less facilitative, in a naming task, than were sentence frames (i.e., sentence completion). Further, neither picture frames, associated verbs, nor syntactically correct but semantically meaningless sentence frames were effective cues. The authors suggest that two modes of name retrieval may exist, one that uses a nominative system and one that employs an online language processor involved in propositional speech production. The latter system may account for the preservation of fluent speech in individuals with severe anomia. Similarly, sentence completion cues containing a semantically related word were noted to be more effective than semantically empty sentence frames (e.g., "This is a ____.") or semantic information alone (i.e., associated verbs) in facilitating naming performance in eight subjects with aphasia (McCall, Cox,

Shelton, & Weinrich, 1997). These findings were felt to support the notion that naming is enhanced most by a combination of syntactic and semantic variables.

Stimley and Noll (1991) examined naming accuracy in a group of patients with aphasia when pictures were accompanied by a semantic cue (e.g., "This is something you wear on your foot," for "sock") or a phonemic cue (e.g., "This is something that starts with /S/," for "sock"). Compared to a no-cue condition, the semantic and phonemic cues both facilitated naming, although the average effect was only on the order of 9% to 10%. The authors felt the small effect may have occurred because cues were presented for all items, not just following a failure to name without a cue. They also observed (as have others) that semantic errors were more frequent in the semantic cue condition and that phonemic errors were more frequent in the phonemic cue condition (Li & Canter, 1991, have made similar observations). Thus, although semantic and phonemic cues are generally facilitatory, they also tend to "move" errors toward the cueing category. Along similar lines Wambaugh and colleagues (2004) compared the effects of a phonological cueing treatment and a semantic cueing treatment. Results indicated that both treatments yielded positive increases in naming, with effects being similar across treatments. The authors concluded that both treatments have potential for facilitating action naming in aphasia.

Other recent investigations have examined the effects of only semantic cues on naming performance. Semantic feature analysis (SFA) is an elaborate cueing technique in which the client is encouraged to produce words semantically related to the target. For example, for the target word "pan," the cues might involve questions related to its use (cooking), its properties (metal, copper, and wooden handle), where it might be used (kitchen), what group it belongs to (cookware), and what might be associated with it (stove, spoons, ladles, and pots). SFA is thought to improve the retrieval of conceptual information by accessing semantic networks (Massaro & Tompkins, 1992). By activating the semantic network surrounding the target, the target itself should be activated above its "threshold" level, thus increasing the likelihood that its name can be retrieved. Results have consistently documented improved confrontational naming scores with the SFA technique for treated pictures as well as generalization to untreated pictures (Boyle & Coelho, 1995; Boyle, 2004; Coelho, McHugh, & Boyle, 2000; Lowell, Beeson, & Holland, 1995). Generalization to conversational speech, however, has either been quite modest (Coelho et al., 2000) or not observed at all (Boyle & Coelho, 1995). In a subsequent study, Conley and Coelho (2003) examined the effects of SFA in combination with Response Elaboration Training (RET) (Kearns, 1985) on word retrieval deficits for an individual with chronic Broca's aphasia. The combined SFA and RET treatment improved confrontation naming skills for the individual studied, but the results were equivocal in delineating the individual effects of each type of treatment.

Whether a semantic cue should be accompanied by the referent word has also been investigated (LeDorze, Boulay, Gadreau, & Brassard, 1994). Using a comprehension task format, two types of semantic cues were compared. In the first, the individuals with aphasia were to point to a picture (in a field of three pictures) of the referent word presented, then to match the written word to the corresponding picture, and then to answer a question about the referent word (e.g., "Does an organ have just one keyboard?" for the word "organ"). The other cueing procedure also involved three steps: The individuals with aphasia were to point to a picture of the referent word identified by a definition, then to match a written definition to the corresponding picture, and finally, to answer a yes/no question related to the referent word (e.g., "Does this mollusk have pincers?" for the word "lobster"). Results indicated that naming improved significantly when the semantic cues were accompanied by the referent word. The authors speculate that naming was facilitated because both word form and the word semantics were activated.

Some recent efforts have attempted to tailor the type of cue to the level at which naming tends to break down. Thompson, Raymer, and le Grand (1991) examined the effects of a phonemic cueing treatment program on two patients with Broca's aphasia whose naming deficits appeared to be related to phonologic breakdowns (e.g., they had naming difficulties despite being able to match spoken words to pictures and perform conceptual matching tasks; in other words, they appeared to have access to word meaning but not to the phonologic form of words). The program consisted primarily of providing a rhyming cue (e.g., "It sounds like mat" for the target "bat") or, if that failed, the first phoneme, whenever the patient failed to name without a cue. Both subjects improved in oral naming, and some generalization to untrained items and to oral reading tasks occurred. Li and Williams (1989) examined the effect of semantic and phonemic cues on noun and verb naming after failure to name on picture confrontation. Patients with Broca's and conduction aphasia responded better to phonemic than to semantic cues, and the opposite pattern occurred for patients with anomic aphasia. In general, phonemic cues were more effective than semantic cues for nouns, and the two cue types did not differ for verbs. This suggests that the effectiveness of cue type may vary both as a function of the source of naming failure (semantic vs. phonologic, presumably related to aphasia type) and of word category (nouns vs. verbs). (Li & Williams, 1990).

Are cues presented in combination more effective than single cues? The findings of Weidner and Jinks (1983) say yes. They examined the naming performance of 24 patients who were presented with single cues (e.g., sentence completion, written words, or first phoneme) or with cues in combination. Combined cues were more facilitative than single cues or single cues presented in succession. They suggest that if one cue fails, a combination of cues may help.

Finally, cueing also may facilitate sentence production. Roberts and Wertz (1986) used a contrastive task paradigm to facilitate sentence production in two patients with chronic aphasia. After demonstrating comprehension of sentence meaning, patients imitated the clinician production of a sentence (e.g., "The bed is made.") and then spontaneously produced a minimally contrasting sentence in response to a picture stimulus (e.g., "The bed is not made."). Imitation was then faded over additional steps to the point at which the patient had to produce on their own contrasting sentences in response to picture stimuli. The sentence production of both patients improved, and evidence of some carryover to spontaneous sentence production was found.

It is reasonable to conclude that a large number of cues, prompts, including computer-mediated approaches (Doesborgh, van de Sandt-Koenderman, Dippel, et al., 2004; Fink, Brecher, Sobel, et al., 2005) and preparatory stimuli exist that may facilitate language processing in patients with aphasia. Care must be taken to demonstrate the utility of cues in each case, because even the most widely used facilitators may not be effective for every patient. Careful analysis of the level at which language tends to break down (e.g., semantic vs. phonologic) and the types of successful cues that patients adopt spontaneously can help to identify the type of cueing that is likely to be most successful.

Frequency and Meaningfulness

It has been repeatedly established that the reduction of available vocabulary in patients with aphasia is related to the frequency of occurrence of words in the language. Schuell (1969, 1974d) also predicted a reduction of available linguistic rules and a hierarchy for their recovery, and Schuell speculated that the hierarchy is related to the frequency of occurrence of those structures in general or to individual language usage.

Schuell, Jenkins, and Landis (1961) tested the auditory comprehension of 48 patients with aphasia in response to four word lists varying in frequency of occurrence. Decrements in performance as a function of decreasing word frequency were found, supporting the conclusion that word frequency is an important factor in comprehension. They also reported that single-word comprehension improves in an orderly and predictable manner that is strongly related to word frequency. Relatedly, Gerratt and Jones (1987), in a reaction time task, have shown that individuals with aphasia, like individuals without aphasia, recognize words as real (vs. nonsense) more rapidly when they have multiple meanings and high frequency of occurrence than when they have few meanings and low frequency of occurrence. Finally, Hauk and Pulvermüller (2004) found lower evoked-response potential amplitudes for high-frequency versus low-frequency words, indicating physio-

logical differences in the activation and processing of these different types of words.

Word frequency remains a factor at the sentence level. Shewan and Canter (1971) found that increasing vocabulary difficulty (reducing word frequency) reduced the accuracy and promptness of sentence comprehension in patients with aphasia. In addition, frequency of occurrence also applies to phrases and sentences when they occur as familiar units. For example, Van Lancker and Kempler (1987) have shown that patients with aphasia comprehend familiar phrases (idiomatic expressions, e.g., "While the cat's away, the mice will play.") more readily than novel sentences matched for word frequency, length, and structure.

Word frequency effects are also apparent in verbal output, reading, and writing. For example, Schuell and colleagues (1964), Gardner (1973), and Williams and Canter (1982) have reported negative correlations between errors on naming tests and frequency of occurrence. Siegel (1959) has found that less frequently occurring words were more difficult to read than frequently occurring words. Bricker, Schuell, and Jenkins (1964) reported that word frequency (and length) accounted for almost all aphasic spelling errors; and Santo Pietro and Rignodsky (1982) found that verbal perseveration on naming and reading tasks increased as word frequency decreases.

In contrast to the notion that word frequency is an important factor in verbal expression, Nickels and Howard (1995) found small effects of word frequency on naming performance. Their series of experiments involved two groups of individuals having aphasia. The first group consisted of six fluent and six nonfluent individuals, and the second was made up of three nonfluent, two nonfluent with apraxia of speech, two with primarily apraxia of speech, and eight with fluent aphasia. The authors investigated the effect of eight variables on naming: (1) word age-of-acquisition, (2) operativity (i.e., figurative vs. operative), (3) frequency, (4) familiarity (i.e., based on a rating of how often one might see, hear, or use the referent word), (5) imageability (i.e., ease of creating visual or auditory image of referent), (6) concreteness (i.e., how accessible to sensory experience the subjects rated the referent word), (7) length (i.e., number phonemes in the spoken word), and (8) visual complexity (i.e., complex vs. simple, based on number of elements in stimulus picture). Results indicated a far less marked effect of frequency on naming when the effects of the other variables had been accounted for (i.e., by means of simultaneous multiple regression or discriminate analysis procedures). Further, because of intercorrelations between variables and the wide range of variables that have been found to affect naming performance in individuals with aphasia, these findings must be interpreted cautiously. The authors concluded that previously, the effects of frequency on naming have been overstated because of the confounding effect of other variables, such as length and imageability. Finally, the two groups of individuals with

aphasia showed quite different patterns of predictor variables for naming performance, and the variables that affected an individual's performance was often different from those of the overall group, calling into question the applicability of conclusions drawn from group studies.

Although word frequency is certainly positively correlated among speakers of the language, we need to bear in mind that word frequency for individuals is determined by their unique experiences, needs, occupation, culture, and numerous other factors (e.g., the word "aphasia" is certainly more available to the speech-language pathologist than it is to the political scientist!). Although word lists such as that of Thorndike and Lorge (1944) are useful in selecting stimulus material, it is also important to identify verbal stimuli that are meaningful, relevant, and personally significant to the individual (Schuell, 1969; Schuell et al., 1955; Wepman, 1953).

The importance of this was demonstrated by Wallace and Canter (1985), who examined the responses of severely impaired patients with aphasia to personally relevant versus nonpersonal stimuli on verbal and reading comprehension tasks (e.g., "Is your birthday in ____" vs. "Is Christmas in February?"), repetition tasks (e.g., patient repeats their name vs. another name), and naming tasks (e.g., television vs. giraffe). Performance was better in response to personally relevant materials on all tasks, although the authors pointed out that personally relevant stimuli had a generally higher frequency of occurrence than nonpersonal material. Relatedly, Correia, Brookshire, and Nicholas (1989) asked if gender bias in pictures used to elicit narrative responses from male patients with aphasia affects what the patients say about them. After having subjects without aphasia identify picture stimuli as male or female biased (e.g., men working out in a gym vs. women in a beauty salon), these authors used the pictures to obtain narratives from aphasic and non-brain-damaged subjects. Subjects produced more words in response to male-biased stimuli, but no differences were found in measures of efficiency or amount of information conveyed. The authors concluded that gender bias in picture stimuli is not of great concern (at least for male subjects) unless the number of words in responses is important. Thus, some dimensions of personal relevance may or may not affect all dimensions of performance to the same, or to an important, degree.

The concept of meaningfulness is also tied to emotion and expectations. Reuterskiöld (1991) has demonstrated that patients with significant verbal comprehension deficits perform more adequately on single-word comprehension tasks when stimuli consist of objects and actions with emotional connotations (e.g., casket or kissing) than when they have no obvious emotional connotations (e.g., paper or typing). Graham, Holtzapple, and LaPointe (1987) examined the comprehension of patients with aphasia in response to contextually relevant commands (e.g., ring the bell), contextually neutral commands (e.g., touch the bell), and contextually

inappropriate commands (e.g., roll the bell). Contextually related tasks were easier than neutral or inappropriate ones, leading the authors to state that "if we pair objects with actions that are most expected both in terms of meaning and structure, we facilitate comprehension" (p. 183). Finally, Deloche and Seron (1981) as well as Kudo (1984) have established that comprehension is better when sentence meaning does not violate our knowledge of the world (e.g., "The policeman arrests the thief.") than when the meaning is implausible or unlikely (e.g., "The thief arrests the policeman.").

Abstractness

It has been suggested that individuals with aphasia have more difficulty with abstract than with concrete words (Goldstein, 1948) and that these individuals categorize words in a relatively concrete emotional manner when compared to individuals without aphasia (Zurif, Caramazza, Myerson, & Calvin, 1974).

Two problems present themselves when the concept of abstractness arises. First, abstractness is strongly tied to—and difficult to separate from—frequency of occurrence (concrete words occur more frequently than abstract words). Spreen (1968), however, has pointed out that, even when frequency of occurrence is controlled, words scaled as abstract are not perceived or recalled as readily as words scaled as concrete. Halpern (1965a), controlling for frequency of occurrence, found that patients with aphasia made more verbal errors in response to written words of high or medium abstractness than in response to words of low abstractness. Abstractness did not, however, play a role in repetition of verbally presented stimuli.

The second problem is more relevant to stimulus selection and is related to the fact that "abstractness" is a difficult concept to define. Words, however, are scalable on an abstractness dimension (Darley, Sherman, & Siegal, 1959), and Spreen (1968) has suggested that the degree of abstractness can be related tangibly to sense experience (e.g., "book" is more concrete than "hope," because it presumably generates more multimodality associations).

The performance of patients with aphasia suggests that we should be aware of the abstractness factor when selecting and ordering stimulus material. Problems related to isolating and defining abstractness, however, present practical clinical problems. Fortunately, we probably account for most of the effects of abstractness when we account for the more easily defined concepts of word frequency and intersensory redundancy or operativity.

Part of Speech and Semantic Word Category

When word retrieval and comprehension abilities are examined or treated at the single-word level, a marked tendency

exists for clinicians to focus on nouns, particularly object nouns. The evidence makes clear, however, that all parts of speech and word categories are typically affected in aphasia. This speaks against an object-noun orientation to treatment.

Kiran and Thompson (2003) investigated the role of semantic complexity in treating naming deficits in fluent individuals with aphasia. Subjects participated in a form of semantic feature treatment to improve naming of both typical and atypical exemplars within a semantic category. Training procedures were counterbalanced for whether typical versus atypical exemplars were trained first. Results revealed greater improvements in naming and generalization for those individuals who were trained on the atypical exemplars first versus the typical exemplars first.

Because different parts of speech (e.g., nouns vs. verbs) serve different linguistic functions, it seems possible that, for some patients or under some circumstances, they may present varying levels of difficulty. Consistent with this notion, recent research has demonstrated selective impairments in nouns versus verbs in some individuals with aphasia. For example, verb production has been noted to be more difficult than nouns for individuals with agrammatical aphasia, whereas nouns appear to be more problematic than verbs for some individuals with anomia (Marshall, Pring, & Chiat, 1988; Miceli, Silveri, Nocentini, & Caramazza, 1988; Miceli, Silveri, Villi, & Caramazza, 1984; Orpwood & Warrington, 1995; Saffran, Berndt, & Schwartz, 1989; Thompson, Shapiro, Li, & Schendel, 1994; Williams & Canter, 1987; Zingeser & Berndt, 1990). In addition, where a discrepancy exists between nouns and verbs on synonym-generating and sentence-generating tasks, the difference favors nouns over verbs (Kohn, Lorch, & Pearson, 1989). Finally, that the processing of nouns versus verbs can differ is also supported by the finding of Li and Canter (1991) that patients with aphasia responded better to phonemic than to semantic cues for noun naming, but that no difference existed between the cue types for verb naming. The authors felt that the greater concreteness, static nature, and imageability of nouns than verbs might explain some of the differences between them.

The observation that naming may be differentially impaired across semantic categories has led investigators to question whether verb production might also be differentially affected—that is, that certain types of verbs may be more difficult than others for some individuals. According to Thompson, Lange, Schneider, and Shapiro (1997), an important distinction among verbs pertains to their syntactic properties (i.e., the number and type of arguments or participant roles required by certain verbs). Like other classes of words, verbs are acquired and stored in memory on the basis of their phonologic form and lexical category. Verbs, however, are also represented in the lexicon by virtue of the sentence structures in which they occur. For example, the verb “wash” must always be followed by a noun phrase

and by a prepositional phrase. These rules of phrase structure are referred to as strict subcategorization and are related to, but separate from, argument structure. Argument structure pertains to meaning relations between the verb and constituents within a sentence (or the number of participant or thematic roles described by a verb). For example, the verb “wash” has two participant roles: an agent (someone doing the washing), and a theme (the thing being washed). The verb “put” has three roles: an agent (someone doing the putting), a theme (the thing that is put), and a location (the place where the thing is put). For certain verbs, all participant roles must be specified in sentence production for the sentence to be grammatical. Returning to the example of the verb “put,” it is obligatory that all three of its arguments be represented when it is used, whereas for other verbs, some arguments are optional and do not need to be specified in the syntax. This is the case for the verb “eat,” which can be produced with an agent only, as in “Tom ate,” or with both its arguments, as in “Tom ate the corn.” The critical issue is that the verb’s lexical representation includes information about its argument structure and that the grammaticality of sentences and syntax is determined by these argument structures and their representation in the sentence (Thompson et al., 1997).

To investigate the type of verb deficits that occur in those with aphasia, Thompson and colleagues (1997) examined verb and verb argument structure production in 10 individuals with agrammatical aphasia and in 10 individuals without brain damage. Production of six types of verbs—obligatory one-place (verbs with only one external argument [e.g., “The boy smiles.”]), obligatory two-place (verbs requiring both arguments [e.g., “The boy catches the ball.”]), obligatory three-place (verbs that require three arguments [e.g., “The girl gives the bone to the dog.”]), optional two-place (verbs that require one external argument and a second optional argument [e.g., “The woman eats.” and “The woman eats spaghetti.”]), optional three-place (verbs that require an agent and theme but for which a third argument is optional [e.g., “The woman throws the stick.” and “The woman throws the stick to the dog.”]), and complement verbs (verbs that require external and internal arguments [e.g., “The girl knows the answer.” and “The girl knows the cat is in the tree.”])—were examined in confrontation and elicited labeling conditions. Results indicated that individuals with aphasia produced the obligatory one-place verbs correctly significantly more often than they did the three-place verbs. In addition, a consistent hierarchy of verb difficulty was found in both the confrontation and elicited conditions. Data indicated that argument structure properties of verbs are important dimensions of lexical organization and influence verb retrieval.

Differences may also exist for other word categories and tasks. Halpern (1965a) found that patients with aphasia made more errors when repeating or reading adjectives and

verbs than they did with nouns. Siegel (1959) as well as Marshall and Newcombe (1966) reported similar findings for reading tasks. In contrast, Noll and Hoops (1967) did not find selective spelling difficulty among nouns, verbs, adjectives, and adverbs for a group of 25 patients, but they did find that pronouns, prepositions, and conjunctions were more difficult than other parts of speech. Finally, Goodglass and colleagues (1970) found different comprehension patterns among patients Broca's, Wernicke's, and anomic aphasia across measures of receptive vocabulary (nouns and verbs) and of comprehension of directional and grammatical prepositions.

It appears that the process of stimulus selection should consider possible differences among substantive word categories, such as nouns, verbs, and adjectives, with nouns likely to be easiest when word frequency is controlled. In general, the literature suggests that grammatical words, such as prepositions, conjunctions, and articles, are more difficult for patients with aphasia to comprehend than are substantive words (Lesser, 1978). The above findings suggest that both semantic categories and grammatical class are critical aspects of lexical organization. Such differences should be considered during stimulus selection.

The possibility that specific semantic word categories may be selectively impaired in aphasia is a matter of debate (Lesser, 1978, pp. 97–107), but some studies suggest that semantic word categories should be considered for some patients. For example, Goodglass, Klein, Carey, and Jones (1966) assessed the naming and comprehension of objects, actions, letters, numbers, and colors in patients with aphasia. Objects and actions were the easiest to comprehend and letters the most difficult, but objects were the most difficult to name and letters the easiest. This not only suggests differences among word categories but also implies that the difficulty of a particular category may vary between input and output tasks.

Although many investigators and clinicians argue convincingly against common or marked differences among semantic word categories, it does appear that stimuli restricted to a single semantic category (e.g., objects) occasionally may yield misleading diagnostic and treatment results. In addition, consideration of semantic category may lead to the identification of treatment stimuli with varying degrees of difficulty.

Grammar and Syntax

As noted earlier, Schuell hypothesized a hierarchically based reduction of available linguistic rules in aphasia. Her idea that such a hierarchy is based on the frequency of occurrence of grammatical structures in general language usage is untested and, perhaps, overly simplistic in light of current linguistic theory, but ample evidence suggests that grammatical complexity is an important factor in language activi-

ties. In other words, as for intact language users, a grammatical hierarchy of difficulty exists for patients with aphasia, with some grammatical structures being more difficult to comprehend and produce than others. Grammar and syntax therefore are important variables to consider when devising language stimuli. The following discussion is a sampling of the numerous studies that have examined the relationship between grammatical variations and performance in aphasia. (For more information on these factors, see Chapter 27 in this volume.)

The importance of grammar is illustrated by the fact that, even when lexical comprehension is quite good, sentence interpretation may be impaired because of grammatical processing deficits. Caramazza and Zurif (1976), for example, have shown that some patients have problems when sentence comprehension is dependent on syntax rather than on the logical relations expressed by individual semantic elements. To illustrate, the meaning of the semantically constrained sentence "The apple that the boy is eating is red" can be derived from an understanding of the meaning of its critical elements and the limited logical relationships among them. That is, our knowledge of the world tells us it must be the boy, not the apple, who is eating and it must be the apple that is red. On the other hand, consider the requirements for accurate comprehension of the reversible sentence "The girl that the boy is hitting is tall." Here, either the boy or the girl logically can do the hitting, and either can be tall. Correct interpretation requires the appropriate pairing of "boy" with "hitting" and of "girl" with "tall"—an interpretation arrived at only through adequate syntactic processing. Several studies have found that some patients have considerably more difficulty comprehending reversible sentences than semantically constrained ones, implying the presence of significant deficits in grammatical processing (Caramazza & Zurif, 1976; Kolk & Friederici, 1985; Sherman & Schweikert, 1989; Wulfeck, 1988).

Ample additional evidence indicates that sentences requiring structural-syntactic analysis are generally difficult for patients with aphasia (usually regardless of aphasia type) and that sentence comprehension is probably maximized when interpretation can be based on world knowledge and the understanding of critical individual elements (e.g., see Ansell & Flowers, 1982a, 1982b; Blumstein, Goodglass, Statlender, & Biber, 1983; Caplan & Evans, 1990; Curtiss et al., 1986; Friederici, 1983; Gallaher, 1981; Gallaher & Canter, 1982; Mack, 1982; Parisi & Pizzamiglio, 1970; Peach, Canter, & Gallaher, 1988). Constructing sentence stimuli with this in mind is of practical import for another reason. Gallaher and Canter (1982) suggest that the syntactic impact on comprehension in *real life* may be minimal, because much of what is said in everyday communication can be interpreted on the basis of real-world knowledge and comprehension of lexical items, with grammar and syntax providing largely redundant information.

Demands for processing of grammar and syntax should not—and cannot—be avoided entirely. A number of studies provide very useful information about the relative ease or difficulty of processing a variety of grammatical and syntactic devices for patients with aphasia. The following represent a sampling of these findings:

1. Present tense sentences are easier than past- or future tense sentences (Naeser et al., 1987; Parisi and Pizzamiglio, 1970; Pierce, 1981). When the tense changes, the use of an additional tense marker tends to facilitate tense comprehension (e.g., “The man has caught the ball” should be easier than “The man caught the ball”; “The man has already combed his hair” should be easier than “The man has combed his hair.”). Words like “yesterday” and “tomorrow” also help to mark tense (Ansell and Flowers, 1982b; Pierce, 1981, 1982, 1983).
The distinction discussed in the preceding paragraph is one example of what seems to be a fairly consistent hierarchy of syntactic difficulty that can affect comprehension. For example, gender, negative/affirmative, and singular/plural distinctions tend to be easier than past/present, subject/object, and past/future/present distinctions. Within distinctions, the marked features tend to be more difficult; for example, negative is more difficult than affirmative, plural more difficult than singular, and future and past tenses more difficult than present tense (Lesser, 1974; Naeser et al., 1987; Parisi and Pizzamiglio, 1970).
2. Other morphologic distinctions can also affect comprehension. For example, Goodglass and Hunt (1958) examined the ability of patients with aphasia to comprehend and express noun plurals and possessives that are represented by identical phonologic forms (e.g., “horses-horse’s”). Expressively, patients made many more errors on possessive endings than on plurals. Receptively, the same pattern was noted, with the additional observation that third person singular verbs also generated more errors than plurals. Goodglass and Berko (1960) have reported similar error patterns, and Goodglass (1968) indicated that such patterns of deficit are independent of the form of aphasia (nonfluent vs. fluent) and, therefore, are not just specific to patients who are labeled “agrammatical.” At the same time, it is important to keep in mind that syntactic deficits in aphasia are not an all-or-nothing phenomenon. In addition, the source of agrammatical production errors appears to be independent of comprehension errors (Goodglass, Christiansen, & Gallagher, 1993). The deficits typically encountered are relative, not absolute, and patients with aphasia (even “agrammatical” patients) are often able to process a good deal of syntactic information (Baum, 1989).
3. Patients with aphasia tend to use an active subject-verb-object (SVO) strategy for processing sentences and find active sentences easier to comprehend than other forms. In general, this means that sentences in which the order of mention reflects the agent-action-object relationship (“The mother kissed the baby.”) are easier than sentences in which the word order does not reflect that relationship (“The policeman was punched by the robber.”) (Ansell & Flowers, 1982b; Brookshire & Nicholas, 1980, 1981; Friederici & Graetz, 1987; Grossman & Haberman, 1982; Hickok & Avrutin, 1995; Hickok, Zurif, & Canseco-Gonzalez, 1993; Laskey et al., 1976; Pierce, 1983; Shewan & Canter, 1971). As mentioned above, SVO sentences that are nonreversible are easier to comprehend than reversible sentences.
4. Patients with aphasia tend to have more difficulty processing grammatically encoded (compact) sentences (e.g., “The man greeted by his wife was smoking a pipe” or “The woman was taller than the man.”) than sentences that are simplified syntactically by expansion into a series of propositions (e.g., “The man was greeted by his wife and he was smoking a pipe” or “The woman was tall and the man was short.”) (Goodglass et al., 1970; Nicholas and Brookshire, 1983). Similarly, individuals with aphasia have more difficulty processing object-gap relative clauses (e.g., “It was the farmer that the robber chased.”) than subject-gap relative clauses (e.g., “It was the farmer that chased the robber.”) (Hickok & Avrutin, 1995). These findings demonstrate that sentence comprehension is not simply a function of the amount of information and length, because compact and expanded sentences can contain the same amount of information and easier-to-comprehend sentences can be longer than compact ones. Results like these also highlight the complexity of the interactions among stimulus factors and show that maximizing the facilitatory effect of one factor may increase the difficulty imposed by another; for example, the generally desirable strategy of reducing sentence length may necessitate a generally undesirable increase in syntactic complexity. In addition, it has become evident that factors influencing sentence comprehension do not have the same effects on discourse comprehension and that performance on sentence-level material does not always predict discourse comprehension (Brookshire & Nicholas, 1984) (for further discussion, see the section on context).
5. Syntactic context, or the form in which sentence-level tasks are expressed, can influence response appropriateness, if not accuracy. For example, Green and Boller (1974) evaluated auditory comprehension in severe aphasia by testing differences in response to commands, yes/no questions, and information questions when such tasks were directly worded (e.g., “Point to the ceiling.”), indirectly worded (e.g., “I would like you to point to the

- ceiling.”), or directly worded but preceded by an introductory sentence (e.g., “Here’s something. Point to the ceiling.”). Commands constituted the easiest task, followed by yes/no questions and information questions. The various syntactic contexts did not affect response accuracy, but directly worded items were associated with a greater number of appropriate (i.e., relevant but incorrect) responses than were indirectly worded items. Directly worded items preceded by an introductory sentence were easier than indirectly worded items.
6. As discussed in the previous section, verb argument structure properties are important influences of lexical organization for verb retrieval; however, these structures are also important factors in sentence production by individuals with agrammatical aphasia. Previous research has indicated that subjects with agrammatical aphasia do not produce all argument structures required by the verb in their sentence productions (Caplan & Hanna, 1996; Thompson et al., 1994; 1995). Thompson and colleagues (1997) have also investigated the effects of these structures on sentence production in those with agrammatical aphasia during narrative tasks. The subjects with aphasia were noted to produce fewer verbs than the normal subjects. In addition, the individuals with aphasia showed a preference for producing simple one- and two-place verbs (i.e., verbs with the fewest participant roles) and rarely produced three-place or complement verbs (i.e., the most complex verbs). When complex verbs were produced by the subjects with aphasia, they were produced in their simplest argument structure forms. These results indicated that sentence production was also influenced by the number of arguments or participant roles as well as by the type of arguments required by the verb. The complexity of the verb (i.e., the number of possible argument structure configurations) influenced sentence production, with simple verbs being produced correctly with their arguments more often than complex ones. Finally, obligatory arguments were produced correctly more often than optional ones, even when the production of optional arguments was requested.

Clearly, a number of syntactic and grammatical factors may influence comprehension, repetition, and verbal formulation performance. It also appears that the hierarchy of difficulty for a number of syntactic and grammatical tasks may be differentially influenced by the nature of the aphasia.

Recently, Thompson, Shapiro, and colleagues (Jacobs & Thompson, 2000; Mitchum, Greenwald, & Berndt, 2000; Rochon, Laird, Bose, & Scofield, 2005; Thompson & Shapiro, 2005; Thompson, Shapiro, Kiran, & Sobecks, 2003) have investigated the effectiveness of training more complex grammatical forms through a series of treatment studies. In each study, complexity of sentence structure was

counterbalanced for each subject; that is, some were trained first on simpler sentence structures (who questions [e.g., “Who did the thief chase?”]) and others on more complex structures (object-relative clausal embedded sentences [e.g., “The man saw the artist who the thief chased.”]). Across all studies, results revealed greater generalization to untrained structures when the more complex structures were trained first. Similar findings have also been reported for individuals with Fluent-aphasia profiles (Murray, Ballard, & Karcher, 2004). The authors have proposed a Complexity Account of Treatment Efficacy based on their results. This theory states that greater generalization of treatment effects may be realized by training more complex sentence structures first, because these sentences contain all the information necessary for linguistically related, simpler sentence structures plus additional information that may enhance learning.

A number of syntactic and grammatical factors clearly may influence comprehension, repetition, and verbal formulation performance. It also appears that the hierarchy of difficulty for a number of syntactic and grammatical tasks must be carefully considered in treatment planning. For example, Thompson, Shapiro, and colleagues have presented convincing data that support the notion of beginning treatment of grammatical structures with complex rather than, as previously believed, simple forms.

Context

In recent years, interest has surged in the discourse comprehension and expression, the factors that influence discourse comprehension and expression, and the relationship of discourse to word- and sentence-level abilities of patients with aphasia. Findings indicate that word and sentence comprehension do not predict the comprehension of discourse (Brookshire & Nicholas, 1984; Hough, 1990; Hough, Pierce, & Cannito, 1989; Pashek & Brookshire, 1982; Stachowiak, Huber, Poeck, & Kerschensteiner, 1977; Waller & Darley, 1978) very well and that discourse comprehension is often better than single sentence comprehension. Brookshire (1992) points out that, because communication in daily life usually occurs more in the form of connected speech than single sentences, it may be that measures of sentence comprehension underestimate daily life comprehension competence.

It appears that context, redundancy, predictability, and extralinguistic cues within discourse and conversation facilitate communication for patients with aphasia. The following summary represents a sampling of findings from studies regarding comprehension and expression of language in discourse or natural communicative contexts by patients with aphasia. These studies provide clues for the design of intervention tasks that, for some patients, may be easier than shorter and, apparently, simpler word- and single-sentence-level activities:

1. Comprehension of syntactically complex sentences (e.g., reversible passive sentences) is facilitated when these sentences are preceded or followed by contextually relevant sentences containing semantic or syntactic information that predicts the relationship expressed in the target sentence (Boyle & Canter, 1986; Cannito, Vogel, & Pierce, 1989; Pierce, 1988; Waller & Darley, 1978; Wright & Newhoff, 2004). (An example of a previous facilitative context task is "The girl is on the ground. The girl was tripped by the boy. Who was tripped?" An example of a subsequent facilitative context task is "The woman went to the library. She returned a book. Where did the woman go?" [Pierce, 1988]). Some studies also show that the context that precedes or follows a target sentence may not have to predict specific information as long as it facilitates processing of the target information by, for example, identifying the topic, setting, or theme (Cannito, Jarecki, & Pierce, 1986; Hough, Pierce, & Cannito, 1989). Nonpredictive context, however, has also been noted not to facilitate comprehension of target sentences (Cannito et al., 1989; Cannito, Hough, Vogel, & Pierce, 1996). Contextual facilitation for both types of paragraphs has been reported to increase as a positive function of stage of recovery from aphasia (Cannito et al., 1996). Individuals with aphasia who are in the early stage of recovery (<1 month) demonstrated no advantage for predictive or nonpredictive narratives, those in the intermediate stage (1–6 months) demonstrated an advantage only for predictive narratives, and those with chronic aphasia (>6 months) exhibited facilitative effects of both predictive and nonpredictive narrative contexts. Finally, extralinguistic context, in the form of a picture depicting target sentence information, also facilitates comprehension (Pierce & Beekman, 1985), although Waller and Darley (1978) found that the facilitatory effect of a contextual picture was less powerful than verbal context.
Pierce (1991) has pointed out that these facilitatory effects are most apparent for patients with relatively poor comprehension. The benefits of this kind of contextual cue seem to derive from redundancy or the fact that certain events or relationships are made more plausible than others.
2. Predictability provided by discourse may explain why discourse is comprehended better than sentences. Armus, Brookshire, and Nicholas (1989) found that the knowledge of scripts by patients with mild to moderate aphasia is not significantly compromised (scripts are used to organize common situations [e.g., after repeatedly eating in restaurants, we "know" the events that usually occur]). Thus, if a patient has an internalized script for a discourse event, it may allow that person to predict what will happen next, infer what is not stated, and organize it for recall. The authors suggest that scripts may be used in treatment to facilitate comprehension, with fading of the degree to which discourse follows a script when comprehension improves.
3. Patients with aphasia comprehend implied meanings quite well, especially in situations aided by extralinguistic context. In fact, Foldi (1987) reported that those with aphasia, like those without brain injury, tend to prefer the pragmatic interpretation of indirect requests over the literal interpretation. Wilcox, Davis, and Leonard (1978) presented videotaped "natural" situations to patients in which the correct interpretation of an utterance was the meaning conveyed by the request in a particular context. For example, the literal interpretation of "Can you move the table?" simply requires a yes/no response, but the indirect, conveyed/contextual meaning is a request that the table be moved. Patients with aphasia generally performed similarly to normal control subjects in their ability to use extralinguistic cues to comprehend the intent conveyed in many indirect requests. These results suggest that the use of natural communicative contexts in treatment may raise communicative performance over and above that derived from more traditional, relatively pure linguistic tasks that often intentionally minimize extralinguistic cues.
It also appears that linguistic information may help some patients to appreciate the meaning of extralinguistic information. For example, Tompkins (1991) found that increased semantic redundancy facilitated the interpretation of emotions that were conveyed linguistically or prosodically to patients with aphasia.
4. Patients with aphasia have been shown to comprehend the main ideas expressed in discourse—that is, the most salient information—better than the details, and information that is expressed directly better than information that must be inferred (Katsuki-Nakamura, Brookshire, & Nicholas, 1988; Nicholas & Brookshire, 1986a). Of interest, increasing directness and salience (through repetition or elaboration) seems to be a more reliable way than decreasing speech rate to improve discourse comprehension. Nicholas and Brookshire (1986b) have also shown that the advantage of directly expressed information over that requiring inference is maintained in multiple-sentence reading tests.
5. Context can facilitate performance in certain word retrieval tasks. This same effect has been demonstrated (Bendt et al., 2002; Hough & Pierce, 1989; Hough, 1989) for tasks requiring generation of words in ad hoc categories (categories that are constructed for use in specialized contexts [e.g., things not to eat on a diet]). Significantly, more items were generated when contextual vignettes preceded ad hoc category tasks (e.g., before listing things to take on a picnic, the patient heard "Sam wanted to spend time outdoors. It was a beautiful day so he packed up some items and went to a

nearby park.”) than when they did not. The facilitative effect of context was not found for common categories (e.g., foods). Hough and Pierce suggest that ad hoc category tasks may be useful for patients with aphasia because they are more divergent in nature and allow reliance on experience and world knowledge to a greater extent than common category tasks.

6. Methods used to elicit narrative discourse from patients with aphasia have variable effects. For example, picture sequences representing stories generally lead to a greater number of words in narratives compared with single-pictured scenes, but the two types of stimuli generally do not affect other measures of production differently (Bottenberg, Lemme, & Hedberg, 1987). Gender bias of pictures (e.g., men in a gym vs. women in a beauty salon) may result in differences in the number of words and information but does not affect wpm or efficiency, at least in males (Correia, Brookshire, & Nicholas, 1990).
7. Main ideas are expressed to a proportionately greater degree than details when stories are retold (Ernest-Baron, Brookshire, & Nicholas, 1987). This may explain why patients get along reasonably well in daily life; it is usually main ideas that must be recalled rather than details.
8. Situational context may affect the manner in which patients with aphasia respond. Glosser, Wiener, and Kaplan (1988) reported that, despite their linguistic deficits, patients with aphasia showed appropriate and predictable changes in response to nonlinguistic social contextual variables (e.g., face-to-face conversation vs. telephone vs. conversation over video monitors). In contrast, Brenneise-Sarshad, Nicholas, and Brookshire (1991) found few meaningful differences in the verbal output of patients with aphasia when they narrated a sequenced picture story for a listener known to them who looked at the pictures as the story was being told versus a newly introduced person who could not see the picture stimuli. The authors felt that it may not be important to create treatment situations in which the patient believes the listener is naive to the information to obtain valid measures of communicative effectiveness.

In summary, the contextual information provided within discourse and natural communicative contexts can exert significant facilitative effects on language and communication for patients with aphasia. These effects occur not only for the processing of the main ideas and intents expressed in discourse but also extend “backward” to the comprehension and expression of semantic and syntactic relationships expressed within the context of discourse. Discourse tasks, particularly comprehension tasks, clearly need not await recovery of word and sentence comprehension ability to become a focus of treatment. In fact, in some instances, it appears that dis-

course should precede word- and sentence-level tasks in the treatment hierarchy.

Stress

Despite some evidence that patients with aphasia may be deficient in their ability to derive meaning from information provided by vocal stress (Baum, Daniloff, Daniloff, & Lewis, 1982) or that stress representation may be selectively impaired after brain damage (Cappa, Nespor, Ielasi, & Mozzo, 1997), it appears that stress can influence response adequacy in a positive way. For example, Swinney, Zurif, and Cutler (1980) have shown that patients with aphasia respond more rapidly to stressed than to unstressed words. More important, Pashek and Brookshire (1982) as well as Kimelman and McNeil (1987) found improved paragraph comprehension when exaggerated stress on critical words was employed. Pashek and Brookshire (1982) observed that improved comprehension in response to exaggerated stress was independent of improvement induced by a slowed rate, suggesting that slowed rate and exaggerated stress may be additive facilitators of auditory comprehension. More recently, Kimelman and McNeil (1989) showed the comprehension of normally stressed target words in paragraphs by patients with aphasia is better when preceded by a stressed as opposed to a normally stressed context. The magnitude of the facilitatory effect was greater for the patients with more severe impairment (those individuals most likely to need extralinguistic cues for comprehension). Kimelman (1991) has presented data that suggest the facilitative effect of stressing target words may actually derive from changes in duration and fundamental frequency in the context preceding the target word. Finally, emphasizing rhythm may facilitate phrase repetition abilities of individuals with nonfluent aphasia (Boucher, Garcia, Fleurant, & Paradis, 2001). Thus, it may be contextual stress modifications that alert the listener to the salience of the target word.

Eliminating consideration of information strongly associated with Melodic Intonation Therapy (see Chapter 31), most representative study on stress and speech output in aphasia has been conducted by Goodglass, Fodor, and Schuloff (1967). They found that fluent and nonfluent patients omitted initial unstressed function words much more frequently than initial stressed words in a sentence repetition task. The omission of unstressed words occurred more frequently for nonfluent patients. They also found that the stress pattern “/-/” was easier to repeat than any other three-word pattern tested when a function word was in the first or second position. Moreover, the facilitating effect of this stress pattern seemed to override grammatical complexity. For example, the negative interrogative “Can’t you swim?” (/-/) was easier to repeat than the grammatically simpler “Can you swim?” (-/). The authors felt that nonfluent (and, therefore, usually apraxic) patients, in particular, may depend on stress features to initiate and maintain a flow of speech. Goodglass (1968)

interpreted these and similar findings as supporting the importance of “saliency” in the initiation of speech. That is, many patients need a salient word to initiate speech, with saliency being characterized by stress and phonologic prominence, as well as other factors already discussed, such as informational and personal significance.

The clinical implications of these findings are obvious. The selection of sentence and paragraph material for comprehension and repetition tasks should consider stress-saliency as a variable capable of affecting the verbal comprehension and verbal production of patients with aphasia.

Order of Difficulty

Within a given treatment task, stimuli probably should be ordered so that more difficult items are presented last. This recommendation is based on evidence suggesting that success tends to breed success—and failure to breed failure—for patients with aphasia.

Brookshire (1972) studied the effects of task difficulty on naming behavior in nine patients. A group of easy-to-name and a group of hard-to-name pictures were derived from baseline measures for each patient and then subsequently presented in different orders. When easy pictures preceded hard pictures, responses to hard pictures were better than predicted on the basis of baseline measures. When easy pictures followed hard pictures, performance on easy pictures was poorer than expected on the basis of baseline measures. Brookshire speculated that when a patient experiences a high proportion of failures, emotional responses may be generated that disrupt subsequent responses. Although such negative effects tended to decay over time, he suggested that treatment should keep error rates low and that easy items should precede difficult ones. Brookshire (1976b) subsequently demonstrated very similar task difficulty effects for a sentence comprehension task in a group of 22 patients. The results differed from the study on naming only in that easy items facilitated comprehension on subsequent hard items for only a small number of patients.

Support for an order effect can be found in several other studies. Gardner and Brookshire (1972) found that naming performance under unisensory conditions is often facilitated when preceded by a generally easier auditory-visual stimulus condition and that responses to auditory-visual stimuli are reduced when preceded by a generally more difficult visual stimulus condition. Similarly, Brookshire (1971b) found that forcing subjects to respond at rapid rates depresses performance on subsequent items in which they are given more time to respond. Finally, Brookshire and Lommel (1974) reported the disruptive effects of failure on the performance of patients with aphasia and subjects without on a nonverbal sequencing task.

Dumond, Hardy, and Van Demark (1978) questioned (or qualified) the significance of the order effect. They readministered the PICA to 20 patients in split-half form, with the

18 subtests rearranged in two orders of difficulty, one ascending and one descending. No performance differences were found between the two orders of difficulty. In contrast to their results with those of Brookshire (1972), who examined a single task containing items of varying difficulty, Dumond and colleagues (1978) examined differences across tasks containing items of equal difficulty. They also indicated that “the changes in difficulty level between subtests were apparently less extensive than the changes in difficulty level within Brookshire’s experiment” (p. 358) and that this may have reduced subjects’ perception of their performance adequacy. They concluded that presenting PICA-like tasks in order of increasing difficulty is not likely to adversely affect performance on nonevaluative tasks for which difficulty levels do not vary extensively.

The available data appear to warrant the following generalizations regarding order of presentation during treatment:

1. Error rates should be kept low.
2. Stimulus presentation should generally proceed from easiest to hardest (with the possible exception of grammatical structures; see previous discussion in the grammar and syntax section), particularly within a given task and on tasks in which the patient is likely to be most sensitive to performance inadequacies).
3. If error rates are kept low, potential across-task order effects should be minimized.

In line with these generalizations, Crosky and Adams (1969) present some practical procedures for selecting and ordering vocabulary stimulus materials for individual patients. It is also reasonable to follow the suggestion of Brookshire (2000) that sessions begin with familiar and easy tasks, proceed to less familiar and more difficult ones, and end with tasks that result in a great deal of success.

Psychological and Physical Factors

In addition to stimuli that are directly intended to stimulate language, factors that affect the psychological and physical “set” of patients can influence response adequacy.

Skelly’s (1975) interviews with patients who have aphasia indicate that even relatively subtle signs of disinterest or impatience on the part of the clinician “bothers” patients. Stoicheff (1960) found that the overt attitudes expressed during instructions to patients can significantly affect responses. Using three groups of patients with aphasia, she examined the effects of encouraging, discouraging, and neutral instructions and comments during performance on naming, reading, and self-evaluation tasks. After 3 days of exposure to one of the conditions, the self-evaluation, naming, and reading performance of the group receiving the discouraging instructions was lower than the performance of the groups receiving neutral or encouraging instructions. No differences were found between the encouraging and neutral conditions. Obviously, the performance differences

were attributed to the negative effects of discouraging instructions. Finally, the previously discussed findings of Brookshire and colleagues on the effects of order of stimulus difficulty suggest that failure—or stress induced by failure—may produce emotional responses that disrupt subsequent responses. It seems, therefore, that disruptive psychological effects may result from negative attitudes expressed by the clinician during instructions and performance or from the failures that patient may experience during the course of a treatment session.

The effects of physical fatigue on language performance have been examined by Marshall and King (1973). Subjects were given the PICA following a period of isokinetic exercise and, on another day, following rest. The PICA scores were significantly lower following exercise than following rest for verbal, graphic, and overall PICA measures. Fatigue had its most pronounced effect on speaking and writing tasks. The authors suggested that language therapy be scheduled before physical exertion, such as physical or occupational therapy. In another study that probably reflects the cumulative effects of fatigue over the course of a day, Marshall, Tompkins, and Phillips (1980) found that patients with aphasia did better on assessment measures administered in the morning compared with measures administered in the afternoon.

It seems that psychological and physical factors facilitate performance best when treatment is conducted in a positive, encouraging, success-producing milieu and at a time when the patient's physical status during the treatment day is optimal.

Pattern of Auditory Deficit

Auditory impairments are not uniform and may reflect a number of different underlying problems. As a result, to ignore differences in the auditory deficits of patients with aphasia is to ignore a factor that may bear on the way in which we structure auditory stimulation during treatment. Consideration of such differences may help to identify stimulus factors that are especially important for a given patient and, in some cases, may serve to qualify or alter the generalizations and recommendations that have been made about those factors thus far.

Brookshire (1974) summarized and discussed five kinds of auditory deficits, supported by a variety of subsequent studies (e.g., LaPointe, Horner, Lieberman, 1977; DiSimoni, Keith, Holt, & Darley, 1975; McNeil, Hageman, & Matthews, 2005), the characteristics of which may have an important bearing on treatment planning. These characteristics reflect the need to avoid considering auditory deficits in aphasia as a unitary problem. These deficits and implications for stimulus selection are:

Slow Rise Time

Patients whose auditory systems are characterized by a slow rise time tend to miss the initial portion of incoming mes-

sages. They may be able to repeat or comprehend only the last part of sentences, may miss short messages entirely, or may do better on the final items of a subtest or treatment activity than on the initial items. Brookshire (2000) suggests that the use of warning signals before presenting auditory stimuli may facilitate processing for these patients, and Loverso and Prescott (1981) provide some indirect support for this. They found response times of subjects with aphasia on a same/different visual judgment task to be reduced when the visual stimuli were preceded by a half-second warning tone; maximum benefit was derived when the tone preceded the stimulus by 1.5 seconds. Presenting items with gradually increasing intervals between successive items may also help the patient to keep his or her "processor" active over longer intervals or help to activate the processor more quickly.

Patients with a slow rise time illustrate the fact that generalizations about a number of stimulus factors do not always hold. For example, contrary to "average" performance, the patient with a slow rise time may respond better to redundant sentences than to single words or may respond more appropriately to directly worded input preceded by an introductory sentence than to a directly worded sentence alone.

Noise Buildup

Patients with noise buildup tend to respond more accurately to the initial portion of auditory messages than to the following portions. More complex material tends to produce noise more rapidly than less complex material. Such patients may not be able to repeat or comprehend the final portion of sentences, may make more errors on complex than on simple materials, and may deteriorate progressively across items on a particular task. Brookshire (2000) suggests that they may benefit from a program with messages of gradually increasing length and complexity, with gradually decreasing intervals of silence between successive items.

Retention Deficit

Patients with retention deficits also deteriorate as length increases, but they are not as susceptible to complexity factors as are those with noise buildup. Performance breakdown tends to occur at the same point in all messages regardless of complexity. The important treatment consideration here is to gradually increase message length.

Information Capacity Deficit

Patients with information capacity deficit do not seem able to receive and process information at the same time (see Wepman (1972) for a discussion of the "shutter principle"). In such cases, performance may be alternately good or poor within a message, good for information that is received and

can be acted on and poor for information directed at the system while processing of previous stimuli is taking place. Such patients may, for example, be able to repeat the beginning and end, but not the middle elements, of a sequence of words. Brookshire (2000) suggests that these patients may benefit from the insertion of pauses within messages. Such pauses may initially be frequent and of relatively long duration, with fading of their frequency and duration as processing ability improves.

Intermittent Auditory Imperception

Patients with this problem constitute a separate category in Schuell's system of classification. Their auditory processing ability appears to fade in and out randomly, leading to sporadic and unpredictable performance. Because we do not understand the controlling factors in such a problem, Brookshire recommends that treatment be directed to other areas of deficit.

Brookshire points out that the above categories may be simplistic and incomplete, although the existence of several of them appears to have been verified by other investigators (McNeil & Hageman, 1979; Porch, 1967; Schuell et al., 1964). It is quite probable, however, that they exist in varying combinations within many patients, and are seen atypically in pure form. Regardless, the ability to recognize them when they occur has direct implications for the selection of potent stimulus factors when planning treatment.

Response Considerations

Although the emphasis of the stimulation approach is on input to the patient, the effectiveness of such stimulation can be assessed only if responses are elicited. Regardless of the form of response, three of the general principles of remediation stated earlier are relevant to response considerations:

1. There should be a response to each stimulus.
2. Responses should not be forced.
3. A maximum number of responses should be elicited.

To those, we can add one additional principle—response demands generally should proceed from short to long. Just as length is a potent stimulus factor, it is also a potent response factor for most patients, with short responses nearly always easier than long ones. In addition to these principles, certain other response considerations must be addressed when planning treatment.

Response Mode

Decisions regarding the mode of response are based on specific goals and baseline data. For example, if we wish to improve auditory comprehension or retention, we should place minimal demands on output and let baseline data aid us in selecting the most intact mode of response. If the goal

is to improve spoken language ability, the response mode has already been determined by the chosen goal.

Response adequacy in a particular modality can sometimes be facilitated by a simultaneous response in another modality. For example, Hanlon, Brown, and Gerstman (1990) found that patients with anterior lesions, hemiparesis, and Broca's aphasia named pictures more adequately when they simultaneously attempted to point to the picture with their hemiparetic right arm. (Note that this may represent facilitation of problems more related to apraxia of speech than to language per se.)

Output modes usually include pointing, nodding, object or picture manipulation, pantomime, other gestures, speech, and writing. Point-to tasks are frequently used when treatment focuses on auditory processes, because the motor control of simple pointing responses is usually unimpaired. However, Brookshire (1992) observes that such tasks can be relatively difficult for some patients. Such observations reinforce the need for letting the individual patient's abilities determine the mode of response.

Temporal Relationship

The temporal relationship between stimulus and response should be considered. Responses may be elicited in unison with a stimulus, immediately following a stimulus, or after a delay. Patients also may be asked to repeat a response consecutively.

Unison responses may be especially appropriate for severely impaired patients, because they give simultaneous auditory and visual feedback and are a step down the response hierarchy from repetition (Schuell et al., 1955; Wertz, 1978). Although immediate responses represent the most frequent and desirable temporal relationship, they may impose unreasonable demands on some patients; for some patients, requiring rapid responses may depress the adequacy of performance. In such cases, allowing a delay for processing may be very useful. Marshall (1976), for example, found that delay was the most effective response "strategy" employed by patients with aphasia for word retrieval.

How much delay? Schuell and colleagues (1964) suggested 60 seconds for some tasks. Brookshire (1971b) found that 30 seconds were better than 0, 5, or 10 seconds on an object naming task but also noted that, when patients were able to name objects, they usually did so within 10 seconds. Thus, it seems that delays allowed for processing to occur should rarely have to exceed 30 seconds, and probably should not, considering the principle that treatment should elicit a large number of responses.

On comprehension tasks, the effect of imposing delays between stimulus and response may not be predictable. Schulte (1986) examined the comprehension of 10 patients with aphasia on a Token Test type of task in which 0-, 5-, 10-, and 20-second delays were imposed before patients were

allowed to look at response choices and respond. No consistent effects on comprehension were found among the delay conditions for the group as a whole. Performance within subjects varied by nearly 20% between some conditions, however, and a few of the more severely impaired patients benefited from brief delays in some conditions. Schulte suggested that, for some patients, an imposed delay may facilitate full processing before a response but may be detrimental for others because of poor rehearsal mechanisms or reduced retention capacity. It therefore appears that imposing a delay between stimulus presentation and response has no generally predictable influence on sentence comprehension accuracy but that it may be a useful response parameter if its effects are predictable for individual patients.

In addition to using delay as an aid to comprehension or formulation, imposing delays before allowing the patient to respond may be a useful strategy for improving retention span. Imposing a delay between a patient's response and the next stimulus may also be an effective strategy for reducing perseveration in some patients. Santo Pietro and Rigrodsky (1982) found that the frequency of perseveration on sentence completion, naming, and reading tasks decreased as the time between a response and subsequent stimulus increased from 1 to 10 seconds.

Delay sometimes can be used actively by patients to improve response adequacy (this point could also be considered under the section dealing with consequences/feedback). Bernstein-Ellis, Wertz, and Shubitowski (1987) instructed a mildly impaired patient with aphasia and reduced conversational fluency (because of hesitation, revisions, and paraphasias) in the use of a pacing board (Helm, 1979) to slow the rate of speech. This reduced syntactic and paraphasic errors and permitted the same or more information to be conveyed with fewer verbalizations. Whitney and Goldstein (1989) used a different technique and achieved the same result for three patients with mild aphasia whose discourse was dysfluent because of revisions, repetitions, and audible pauses. After learning to recognize and identify their dysfluencies from audiorecorded samples of their speech, the patients were trained to monitor/identify their dysfluencies during picture description tasks. This resulted in reduced speech rate, a dramatic reduction of dysfluencies, and increased efficiency in the form of increased length of uninterrupted utterances.

Finally, some subtle uses of temporal relationships in stimulus presentation may influence processing demands and response adequacy. Brookshire and Nicholas (1980) have shown that patients with aphasia tend to use a find-and-compare strategy on sentence verification tasks in which the truth value of a sentence is based on a comparison with a simultaneously presented picture stimulus; in other words, instead of processing the full meaning of the sentence, they may simply match key words to elements in the picture. To force the patient to deal with the fuller meaning of the sen-

tence, those authors suggest that the spoken sentence and the picture stimulus presentations be staggered (e.g., present the sentence and then the picture) rather than simultaneous. It is quite possible that this more challenging approach to stimulus presentation in a verification task would also apply to point-to comprehension tasks (i.e., present sentence and then present picture choices).

Response Characteristics

Although accuracy is certainly the most commonly expected response characteristic, it is not the only relevant one. Green and Boller (1974) found that severely impaired patients (i.e., unable to respond very accurately to auditory tasks) often are able to respond appropriately; that is, they show signs of rudimentary comprehension by, for example, looking around the room when asked to point to the door or nodding when asked yes/no questions. In such cases, appropriateness of response may be the most appropriate expectation for an initial response. At the other end of the continuum, when a patient can respond with a relatively high degree of accuracy, it may be appropriate to expect a reduction of self-corrections and of incomplete, delayed, or distorted responses. (Such response characteristics are reflected in Porch's multidimensional scoring scale and are discussed in Chapter 28.) The important point is that response expectations need not be geared solely toward accuracy. For some patients, a high degree of accuracy may not be possible, and expectations may have to be lowered. For others, a high proportion of accurate responses may still leave considerable room for response refinement along a number of other response dimensions.

Consequences (Feedback)

The stimulation approach presumes that the stimulus (i.e., the antecedent event) is that part of the treatment sequence which facilitates, or is largely responsible for, the ability of the patient to respond adequately. This is in contrast to operant approaches, in which increased adequacy of responses is attributed primarily to the controlling influence of consequences on subsequent behavior. Because antecedents are, theoretically, the crucial modifier of language processing in the stimulation approach, however, does not mean that we should not respond to patient behavior.

It has already been stated that feedback about response accuracy and appropriateness should be given when necessary. Boone (1967) suggests that any specific response-contingent feedback may be trivial or unnecessary when patients are motivated (as is usually the case), know the target response, and can assess their response in relation to the target. Support for this type of feedback comes from research on the concept of "errorless learning," in which treatment is structured to decrease the likelihood of a

patient producing an inaccurate response. The notion behind this approach is that the brain is prevented from incorrect or inefficient processing to maximize accuracy of new learning (Fillingham, Hodgson, Sage, & Lambon Ralph, 2003). Additional support comes from the finding that mild to moderately impaired patients with aphasia modify their picture descriptions in response to failure in a referential communication task in the same way that speakers without aphasia do. In the relatively rare case when a patient is not motivated, response-contingent rewards or punishment may be necessary; but in general, reinforcement or punishment have little effect on speech and language performance in aphasia (Brookshire, 1977). When patients are motivated but give deficient responses, it may be most appropriate to confirm response adequacy or to give information about the closeness of a response to the target. Whether feedback is in the form of reward, punishment, confirmation, or information, Brookshire's (1971a) finding that patients with marked to severe impairment were sensitive to the effects of short delays between responses and their consequences on a nonlanguage learning task implies that feedback, when appropriate, should be immediate.

What information should be given to patients when their responses are inadequate? First, in most instances, such information should not be negative. The findings of Stoicheff (1960) suggest that discouraging comments during performance, such as "that's wrong," at least when combined with discouraging instructions, have a detrimental effect on performance. Second, Schuell and colleagues (1964) felt that one of the most common errors made by clinicians was overcorrection or overexplanation of errors and that the proper contingency for an inadequate response is usually more stimulation. In support of this, Holland and Sonderrman (1974), in their evaluation of an auditory comprehension program, felt that explaining errors to patients confused, rather than aided, subsequent performance. The analysis by Brookshire and Nicholas (1978) of clinical interactions in treatment of aphasia indicated that patients tend to make errors following corrective explanations of previous errors. It seems that confirmation of adequate performance may be helpful and encouraging and, generally, represents good clinical practice. Explanation and correction, on the other hand, should be carefully controlled and concise, bearing in mind that such feedback may be of little value, waste time, and be counterproductive.

In addition to considering response-dependent feedback, general encouragement and reassurance during a treatment session is always desirable. Brookshire (1997) supports the value of showing patients their progress over time, with graphs often being an effective format for doing so. Such feedback—aside from being information the patient has a right to know about—has motivational and reinforcement functions, and it provides a framework for discussing and/or

supporting the continuation, alteration, or termination of certain treatment activities.

Sequencing Steps in the Treatment Program

Where to Start

Schuell and colleagues (1964) indicated that treatment should begin at the level where language breaks down and should proceed through gradually increasing levels of difficulty. Bollinger and Stout (1976), arguing for the critical importance of stimulation in treatment, suggested that treatment should progress from highly clinician-cued antecedent events to low-cued events in which the patient carries most of the processing load. Brookshire (1997) offers some more specific suggestions regarding starting points, which can be summarized as follows.

1. Treatment should begin at levels where slight deficiencies exist and never where performance is completely inadequate. This assures that patients are not pushed beyond their capacity but, instead, forces them to work near capacity.
2. Tasks for which 60% to 80% of responses are correct and immediate represent good starting points. That is, not more than 20% to 40% of responses should be self-corrected or delayed.
3. Tasks should not be too easy. Difficulty should be increased when 90% or more of responses are completely adequate in the dimensions that are the focus of treatment.

The selection of appropriate starting points should be based on adequate baseline data, because without such information, treatment begins without knowing if tasks or stimuli are appropriate. Baseline data may be established through standardized tests, systematic sampling of patients' responses to their environment (this is critical for the establishment of relevant, practical tasks and stimuli) or selected stimuli, or probing of variations in stimuli to see how changes influence speech and language behavior (Hendrick, Christman, & Augustine, 1973). For example, standardized testing may indicate that the ability to identify objects named from among 10 choices is very adequate (e.g., 90% immediate, accurate responses) but also that identifying object-by-function from among 10 choices is below the level at which treatment would be appropriate (e.g., 50% inaccurate responses). Subsequent assessment of responses to functional items might confirm standardized results, but probing might establish that identifying those same objects-by-function from among only four choices generates response characteristics at a level appropriate for treatment (e.g., 80% accurate, with 20% delayed or self-corrected responses). Such baseline data identify a starting point for stimulating auditory abilities, specify the stimulus conditions and

response expectations to be employed during treatment, and give direction about the organization of succeeding steps. No less important is the fact that baseline data provide a pre-treatment measure of ability against which the results of treatment can be compared.

Criteria for Determining Success

Once tasks and stimuli have been established and target behaviors or response characteristics identified, we must determine the criterion for acceptable performance. When this criterion is reached, it is assumed that the specific task is no longer necessary and that the patient is ready to move on to tasks with greater demands. Experienced clinicians agree that a target behavior criterion of 90% is generally appropriate (Brookshire, 1992; LaPointe, 1977). LaPointe also suggests that the criterion be maintained for three consecutive sessions before terminating the task to ensure that the behavior is stable. When a patient's performance plateaus at a level below the criterion for a number of sessions, he suggests that the task be terminated or modified to make it slightly easier.

Compatibility of the Stimulation Approach and Programming

The discussion regarding the design of intervention has included information about stimulus and response considerations, contingencies, selection of starting points, and progression of activities. The acquisition of baseline data and the setting of criterion levels also have been highlighted. All these considerations can be strongly associated with programmed approaches to treatment. This may be somewhat surprising, because the appearance of information about the stimulation approach and the programmed approach to treatment in the same discussion has typically been in the form of contrast (e.g., see Darley (1975) and Sarno (1974)). Although operant-programmed approaches are dissimilar to the stimulation approach because of their emphasis on consequences as the primary modifiers of behavior, it is inappropriate to consider the stimulation approach and the application of general programming principles as being mutually exclusive treatment strategies (LaPointe, 1978b). A careful reading of Schuell's work shows that her principles and suggestions regarding treatment are compatible with the rigor and systematic nature of programming. Her admonitions to choose realistic goals, know where performance breaks down, elicit large numbers of responses, work systematically, and discard ineffective techniques are things with which a systematic, behavioral approach program is highly capable of assisting. It seems to be most appropriate, in this context, to consider programming as a tool for systematically implementing the stimulation approach. Programming is particularly desirable because of its commitment to accountability and its capacity for making treatment both replicable and

accessible to analysis (Holland, 1975; LaPointe, 1983). LaPointe's (1977) "Base-10 Programmed Stimulation" as well as Bollinger and Stout's (1976) "Response-Contingent Small-Step Treatment" are excellent, clinically applicable examples of the compatibility of the stimulation approach and structured behavioral methods.

EXAMPLES OF THERAPY TASKS

The preceding discussion regarding the design of intervention included numerous implied suggestions about tasks and techniques that may be appropriate for therapy. In this section, a number of specific tasks will be listed. They are offered as examples of activities that are considered to be appropriate for patients with aphasia and have enjoyed varying or undefined degrees of success. They are not offered as prescriptions or even as recommendations, because given our current state of knowledge, we have no way of predicting reliably which tasks and techniques work best with individual patients.

The focus of the examples here will be on tasks that emphasize auditory processes, because this is consistent with the stimulation approach. A number of examples of tasks requiring verbal output, many of which also involve auditory input, will be given as well. It should be understood that nearly all auditory and verbal tasks are readily adaptable to the reading and writing modes, but a few examples of tasks unique to reading and writing will be given.

The examples offered here cover a range of difficulty so as to include suggestions that are appropriate for patients with mild to severe impairment. The tasks are ordered from the anticipated easiest to hardest, but the reader is cautioned that the order provided is not empirically derived—and, probably, cannot be—because of patient variability. It is also important to note that difficulty level can be altered not only by switching tasks but also merely by altering certain stimulus factors or stimulus-response relationships associated with a given task. For example, increasing the number of response choices in a point-to auditory comprehension task may significantly increase task difficulty.

Many of the examples given below have been derived from suggestions offered in the following sources: Schuell and colleagues (1955, 1964); Schuell (1953a); Brookshire (1997); Kearns and Hubbard (1977); LaPointe (1978a); Darley (1982); and Rosenbek, LaPointe, and Wertz (1989). Many other examples are of such universal, long-standing use that they either defy or make accurate referencing trivial.

Tasks Emphasizing Auditory Abilities

Point-To Tasks

These activities involve the presentation of information auditorily and require a simple identification-by-pointing

response. The ease of the motor response allows patients to focus primarily on the reception, processing, and retention of the auditory message. Difficulty level on these and many other auditory tasks can be altered by variations of many of the stimulus factors discussed earlier in the chapter (e.g., rate, pause, stress, similarity and number of response choices, visual cues, syntactic complexity). Many of these tasks can be employed as speech activities by requiring verbal instead of gestural responses. Some examples include:

1. Point to an item (picture or object) named.
2. Point to an item described by function ("Point to the one used for writing.").
3. Point to an item to complete a sentence ("Please pass the bread and ____.").
4. Point to an item in response to questions ("What do you find in the kitchen?"—points to a stove). A more complex but analogous task might involve responses to questions based on the preceding sentence or paragraph material.
5. Point to two (or more) items named ("Point to the book and point to the pen," or "Point to book-comb.").
6. Point to two (or more) items described by function.
7. Point to an item best described by a sentence ("Those people are very busy"—represented by people building a house).
8. Point to an item whose name is spelled.
9. Point to an item described by a varying number of descriptors ("Point to the large white circle," or "Point to the one that is long, silver, and sharp"—points to a knife).
2. Questions requiring phonemic discrimination ("Do people wear shoes and blocks on their feet?").
3. Questions requiring semantic discrimination ("Do you start a car with a tire?").
4. Questions about picture material ("Is the boy wailing?"—picture of boy running).
5. Questions involving verbal retention ("Are cows, horses, dogs, trees, and lions all animals?").
6. Questions about preceding sentences or paragraph material ("I like to swim, play tennis, and go to the ball-park. Did I say I like to play football?").
7. The above question examples may be converted to sentence or paragraph verifications tasks, in which the patient is asked to verify the truth of various statements ("Kennedy was President in 1861," or "Cows, horses, dogs, trees, and lions are all animals.").

Following Directions

These tasks allow greater flexibility and complexity in the auditory demands placed on the patient. For example:

1. Follow one-verb instructions ("Pick up the pen.").
2. Follow two-object location instructions ("Put the pencil in front of the cup.").
3. Follow two-verb instructions ("Point to the cup. Pick up the eraser.").
4. Follow two-verb instructions with time constraint ("Before touching the penny, pick up the spoon.").

Yes/No Questions and Sentence Verification

These formats also increase flexibility, can reduce the possible effects of visual deficits on performance, and often allow the extension of stimulus material beyond the immediate environment. Only a simple verbal or nonverbal response is required. For example:

1. Questions dealing with general information ("Was Kennedy President in 1861?").

Response Switching

These tasks require the patient to switch responses from item to item and, therefore, require close attention to the nature of the task on each trial. Such activities may simply combine the auditory tasks previously discussed or also may include items requiring speech, reading, or writing abilities. For example, a response switching activity might include the following successive items:

1. Point to the door.
2. Give me the cup.
3. Is the floor lower than the ceiling?
4. Spell your name.
5. How are you feeling today?
6. Have I asked you to give me the cup?
7. Read this, and do what it says to do.

Tasks Emphasizing Verbal and Auditory Abilities

Repetition Tasks

These require reception and retention of auditory information and the ability to repeat the information verbally. Auditory comprehension is not necessary, although it may facilitate performance. Minimal demands are placed on word retrieval. For example:

1. Repeat spoken words.
2. Repeat phrases ("in the house"; "on the beach"; "to the store"; "black and white"; "shoes and socks").
3. Repeat series of items ("book-table"; "penny-key-knife"; "long-under-baby-pencil").
4. Repeat stereotyped or functional phrases ("Where are you going?"; "What time is it?"; "Please pass the salt"; "How are you?").
5. Repeat sentences with or without corresponding picture stimuli ("The girl is chasing the boy"; "The cat is up in the tree.").

Sentence or Phrase Completion

These tasks typically place more demand on auditory comprehension and word retrieval processes and less demand on auditory retention compared with repetition tasks. For most patients, they are more difficult than single-word repetition tasks but less difficult than single-word recall tasks without auditory input. For example:

1. Complete sentences with nouns with varying degrees of predictability ("Please pass the salt and ____"; "Throw me the ____"; "Read a ____"; "Buy me some ____").
2. Complete sentences with verbs ("I use a fork for ____"; "I use a paint brush for ____").
3. Complete paired-associates ("black and ____"; "hot and ____"; "salt and ____").

Verbal Association

These tasks require verbal comprehension but minimal retention. Verbal retrieval processes are taxed. For example:

1. Oral opposites ("hot-cold"; "night-day"; "early-late").
2. Rhyming—clinician says word and patient rhymes ("hot—pot").
3. Word fluency/rapid word retrieval—clinician provides a letter of the alphabet, a common category (e.g., clothes, sports) or a concept (e.g., things to do on vacation, things that can roll), and the patient generates as many words, categories, or concepts as possible.
4. Synonyms—"think of a word that means the same as 'car.'"

Answering "Wh-" Questions

These tasks always place some demand on auditory comprehension and may require significant retention as well. Word retrieval and sentence formulation may be taxed to varying degrees. For example:

1. Answering questions after imitative cues and a question prompt (clinician—"Answer the phone"—patient imitates; clinician—"What should I do?", and patient—"Answer the phone").
2. Answering questions after a model (clinician—"The boy went to the movies. What did the boy do?").
3. Answer familiar conversational questions ("How old are you?"; "How do you feel?").
4. Answer questions about the preceding sentence or paragraph material (e.g., "John was on the ground. John was tripped by Mary."—"Who was on the ground?").
5. Answer general questions ("What do you do when you're hungry?"; "Who is the President of the U.S.A.?"; "How did you get here today?"). High-level patients may be asked questions requiring lengthy responses ("How do you change a flat tire?"; "Exactly how do you get from here to ____?").

Connected Utterances in Response to Single Words

Minimal demands are placed on auditory input processes. Maximal demands are placed on word retrieval and sentence formulation. For example:

1. Use selected words of varying parts of speech, word class, tense, and so on in sentences (put-how; television; red; running; bigger; given in a sentence).
2. Define words.
3. Use sentences beginning (or ending) with selected words or phrases (I eat; when; if, she).

Although these tasks are not listed in a hierarchy of difficulty, Thompson and colleagues (Thompson et al., 2003) have suggested that initiating treatment with stimuli that require a more complex response, such as using intransitive verbs in sentence formulation, may increase the generalization of this skill to less complex responses, such as using transitive verbs in sentence formulation.

Retelling

These tasks can place relatively heavy demands on comprehension and retention and always tax word retrieval and sentence formulation. For example:

1. Listen to paragraph material, and then retell it.
2. Listen to radio or television broadcast, and then retell it.
3. Retell a familiar story.

"Self-Initiated" or Conversational Verbal Tasks

These tasks are not dependent on preselected auditory input to the patient, with the exception of directions about the general nature of the task. Other stimuli may be used to focus content and aid retrieval, but the primary demands are placed on the patient's verbal retrieval and formulation abilities and, often, on the ability to follow naturally occurring auditory and situational cues. For example:

1. Name pictures.
2. Describe the function of objects.
3. Describe activities in pictures.
4. Tell everything possible about pictured objects or activities (urge patient to describe all possible uses of objects, objects' physical properties, associated situations, people, etc.).
5. Describe activity of the clinician (clinician points to two pictures—patient describes; clinician touches an object, places another object near it, and then places an object on top of another—patient describes the activity when completed).
6. General conversation about a selected topic with one or more individuals.
7. Open-ended conversation on unrestricted topics with one or more individuals.

Tasks Involving Reading and Writing Abilities

Reading

Nearly all of the tasks previously described involving auditory input can be adapted easily for reading tasks simply by using written input. The following are some additional tasks that are associated more uniquely with reading:

1. Match written words, phrases, or sentences to pictures (gradually reducing the stimulus exposure time may be employed in an effort to increase the reading rate).
2. Identify letters named by the clinician among a number of written choices.
3. Name letters.
4. Read in unison with the clinician, with a gradual increase in rate and/or fading of the clinician's input.
5. Fill in missing words in sentences from among written choices ("They went to the movies last (day, night, show, fight)"; "John is (to, went, going, come) in a little while.").
6. Read sentences or paragraphs silently, followed by questions about content.
7. Read aloud a paragraph or story, and then retell.

Writing

Most of the examples offered under the sections dealing with auditory and verbal activities also can be adapted readily to the writing mode merely by requiring written instead of gestural or verbal responses. The following are some additional tasks that are associated more uniquely with writing modality activities:

1. Copy forms, letters, and words.
2. Write letters to dictation.
3. Write words dictated letter-by-letter.
4. Write overlearned materials (e.g., name, the alphabet, and the numbers 1–10).
5. Fill-in missing letters or words in written stimuli, with or without associated picture stimuli ("He is reading a book ____"; "He is reading a ____ b-ok.").
6. The clinician reads paragraph material, and the patient writes down the essential facts. Have the patient rewrite the paragraph based on those notes.

RESOURCE ALLOCATION MODEL FOR APHASIA

Resource allocation models provide a useful format in searching for the underlying causes of impaired performance. Recently, McNeil and colleagues (McNeil & Kimelman, 1986; McNeil, Odell, & Tseng, 1990) have proposed a resource allocation model for aphasia. Essentially, what resource allocation models suggest is that all humans have a limited amount of cognitive resources for conducting

mental or cognitive processes involved with perception, comprehension, memory, and response formulation. The mental energy, or fuel, required for carrying out these processes is referred to as "processing resources" and is contained in a central pool. With the activation of any process, resources must be transferred from the pool to the process. The number of cognitive processes that are called on simultaneously as well as the complexity of a given process determine how much fuel is drawn from the central resource pool. If the demands of the cognitive processes exceed the resources within the pool, the cognitive processes will not be provided with adequate resources, and performance will be negatively affected. If, on the other hand, the resource demands for a given process are low, the finite resources in the pool will not be exceeded, and performance will be normal. The issue of whether brain damage reduces the amount of resources within the central pool or hinders access to the pool is unclear. In either case, however, the allocation of suitable resources is insufficient for the task at hand; consequently, the performance of the individual with brain damage on a given task is at a level below that of the individual without brain damage. Performance will vary depending on the number and complexity of cognitive processes involved.

Resource allocation models have important implications for application of the stimulation approach to therapy for aphasia. If elements of treatment tasks are simplified, the demands on the resource pool will be decreased, thus improving the performance of the individual with aphasia performance. Brookshire (1997) provides an example that illustrates this notion. An individual with aphasia who has a visuoperceptual impairment is engaged in an auditory comprehension task involving pointing to black-and-white line drawings named by function ("Point to the one used for..."). After 10 trials, he has made eight errors. The patient comments that he cannot see what the pictures represent, so the clinician substitutes colored pictures for the line drawings. After 10 more trials, only three errors are noted. Although the targeted process was an aspect of auditory comprehension, this task required the individual to call on processes involved in visual perception that were impaired; consequently, the available resources were exceeded. By modifying the visual characteristics of the stimuli, the visuoperceptual demands of the task were decreased, freeing up cognitive resources, and performance on the auditory comprehension aspects of the task improved. As Brookshire notes, "[C]linicians can focus treatment on a targeted process by controlling the processing load associated with incidental task variables that are not related to the treatment objectives" (p. 217). The primary manner in which clinicians can manipulate the processing load is through manipulation of the task stimuli. Stimulus manipulations involve adjusting the factors that have been discussed throughout this chapter, such as visuoperceptual clarity, length and redundancy, frequency and meaningfulness, grammar and syntax, and so on, which get to the heart of the

stimulation approach—that is, the stimulus must be adequate. In other words, it must get into the brain.

EFFICACY OF THE STIMULATION APPROACH

It is impossible to make a single, empirically based statement about the efficacy of the stimulation approach. Nor would it be appropriate or particularly enlightening, within the context of this chapter, to review all of the group and single-subject studies that might bear on the issue of treatment efficacy (the reader is referred to Fucetola, Tucker, Blank, & Corbetta, 2005; Holland, Fromm, DeRuyter, & Stein, 1996; Robey and Schultz, 1998; Robey, Schultz Crawford, & Sinner, 1999; and Wertz and Irwin, 2001, for comprehensive reviews of such studies and issues related to assessing the effectiveness of treatment). A number of general statements about the effectiveness of treatment, however, and particularly about the stimulation approach, may help to put the current state of the art in perspective.

No single study can conclusively “prove” the efficacy of treatment (Holland, 1975), but reviews and observations by well-respected, active clinical aphasiologists and some neurologists generally have yielded cautious to confident conclusions that therapy helps patients with aphasia (see, e.g., Albert, 2003; Benson, 1979; Darley, 1977, 1979, 1982; Helm-Estabrooks, 1984; Wertz, 1983, 1991). In addition, since 2001, the Academy of Neurologic Communication Disorders and Sciences (ANCDS) has been engaged in an objective, far-reaching project involving the development and dissemination of evidence-based practice guidelines for several neurogenic disorders of communication, including aphasia. The ANCDS committee developing the evidence-based practice guidelines for aphasia has been charged with the following: (1) conducting systematic and comprehensive literature reviews, (2) evaluating the levels of evidence against objective criteria, (3) formulating guidelines based exclusively on the reviews and assessments of levels of scientific evidence, (4) disseminating this information to practicing clinicians, and (5) delineating those areas in which additional research is needed (Frattali et al., 2003). To date, the review process has identified aphasia treatment studies categorized into seven groups by primary outcome variable, including (1) overall language performance, (2) lexical retrieval, (3) syntax, (4) speech production/fluency, (5) reading, (6) writing, and (7) alternative communication. Each of the studies has been evaluated in terms of study design (e.g., case-study, single subject, within-group, or between-group designs), strength of evidence, and phase of treatment (i.e., ranging from pre-efficacy to efficacy). The current tables of evidence are available online (www.u.arizona.edu/~pelagie/ancds/index.html). Although the review of aphasia treatment studies is still underway and the evidence-based guidelines have yet to be summarized, the evidence accumulated from several group and single-subject treatment studies,

including at least one well-designed randomized, controlled clinical trial (Wertz et al., 1986a), justifies, at the least, a general conclusion that “there is ample evidence that what we do for some aphasic patients does some good” (Wertz, 1991, p. 318).

Do we know something about the effectiveness of the stimulation approach that we do not know about therapy for aphasia in general? We do know that Schuell and her colleagues believed in and reported observations of the effectiveness of the stimulation approach, excluding patients with an irreversible (severe) aphasic syndrome. Many other users of the approach also report measurable progress (for more recent, relatively unambiguous examples of studies supporting the efficacy of the stimulation approach, see Basso et al., 1979; Marshall et al., 1989; Poeck, Huber, & Willmes, 1989; Shewan & Kertesz, 1984; Wertz et al., 1981, 1986b). Because of its widespread use, the stimulation approach has probably been studied more extensively than any other approach to treatment (although the interpretation of most efficacy studies requires this conclusion to be inferred, because treatment approaches have rarely been well specified). A final point pertains to the timelessness of Schuell's approach to the treatment of aphasia. Although underlying language processing models may differ according to each clinician's bias, the manner in which treatment is administered by these same clinicians is consistent and strikingly similar to that which Schuell described nearly 50 years ago. These tenets of therapy continue to be introduced in graduate aphasia courses across the country.

Therefore, conclusions that therapy is generally effective are based on studies that have used—or probably have used—a stimulation approach. More pessimistically, we can say that much of our inconclusive evidence about treatment efficacy is derived from studies of the stimulation approach. It is very possible, however, that such inconclusiveness results more to the study of the treatment than to the treatment itself. Taken as a whole, treatment studies employing the stimulation approach are more conclusive than inconclusive, and the conclusion they generate is that it has a significant positive effect on the communication ability of many patients with aphasia.

FUTURE TRENDS

What does the future hold for the stimulation approach? Answering this question is risky business, subject to the predictor's biases and misconceptions, new fads and fashions, major advances in other therapeutic approaches, altered availability of funding for continued investigation, and so on. With these pitfalls in mind, we can address three questions about the future:

1. Will we increase our understanding of the efficacy and dynamics of the stimulation approach?

2. Is the approach likely to change?
3. How will we understand and use it in relation to other therapy approaches?

Will we increase our understanding about the efficacy of the stimulation approach and the dynamics that explain its success? A number of reasons exist to anticipate that this will happen. First, clinical aphasiologists have made a commitment to accountability—that is, a commitment to providing “proof” of the effectiveness, or lack thereof, of therapy for aphasia. The development of evidence-based practice guidelines for aphasia initiated by the ANCDs is an example of such a commitment. Second, we have identified many of the flaws in our previous attempts, as well as those variables that must be accounted for in any study of treatment efficacy. Third, our measuring instruments have become more sensitive and reliable (e.g., the PICA). Fourth, we have begun to specify and study the dynamics of treatment more precisely (especially in single-subject studies) so that we know better what is effective and under what circumstances. Fifth, although we have acquired a substantial body of data regarding stimulus factors that affect the performance of patients with aphasia in nontreatment conditions, we know very little about the specific effects of using such stimulus manipulation in ongoing treatment. That is, the simple observation of improved performance under a certain stimulus condition in a single-trial, nontreatment study does not constitute proof that use of that stimulus factor in treatment will be responsible for short- or long-term language gains within or beyond the specific language task. This gap in our knowledge is true for many of the stimulus factors reviewed in this chapter, and it is close to the heart of questions about whether stimulation in general and/or specific stimulation is important to inducing language gains with the stimulation approach. We are in a position to test the effects of many stimulus factors in treatment, and this will likely be pursued in the future. Finally, the effect of stimulus factors and other variables that affect communication in discourse, conversation, and natural communicative settings are receiving increased attention. These efforts should help to identify the components of stimulation likely to have the greatest impact on communication in daily life and, thus, stimulus factors that are most meaningful to the patients we treat (i.e., social validation of the stimulation approach).

Is the stimulation approach likely to change? Probably not in any fundamental way. Major change is unlikely because the stimulation approach is an old and established one, the major principles and techniques of which have been reasonably well articulated and, in principle, consistently employed. Any major departures from the basic approach will likely be considered to be new approaches, given new names, and studied and employed separately. Several chapters in this volume reflect this trend and demonstrate divergence from the stimulation approach along many different lines.

The change that can be expected for the stimulation approach is refinement of our understanding of stimulus factors that do—and that do not—influence performance and, as mentioned previously, an increase in our ability to selectively and effectively employ that knowledge in treatment. Hopefully, these changes will be rapid and numerous and significantly improve overall treatment efficacy. Probably, they will be slow and painstakingly acquired. Certainly, they will require the efforts of many investigators who are interested in the increased understanding of the essence of aphasia as well as its effective management.

Finally, how will we understand and use the stimulation approach in relation to other therapeutic approaches? We have no way to answer this, because so little has been done to compare the effects of different treatment approaches. This is at least partly a result of the enormous past efforts expended to establish that treatment, in general, is effective (Albert, 2003) and to develop new approaches and preliminary efficacy data for them. Another reason, one that is really not to be confronted until more comparative studies are attempted, has been perceived by Sarno (1981). She said, “It is probably appropriate that there have been few studies comparing treatment methods in view of the seemingly insurmountable methodologic problems associated with such research and our present state of knowledge” (p. 512). Despite these past priorities and ever present methodologic challenges, it can be argued that, unless comparative studies are done, we will not learn what works best and with whom, and we will either become complacent in our use of a single “old and familiar” approach or, out of boredom, frustration, or fadism, will move randomly from one approach to another. Numerous comparative questions should be addressed, including:

1. How do various treatment approaches differ in terms of ultimate level of recovery, time demands, cost-effectiveness, professional and family requirements, and so on?
2. What is the best approach to use for patients with particular severity levels and forms of aphasia?
3. Are some approaches more effective early post-onset or late post-onset?
4. Is there a best sequence of approaches to use over the course of treatment?
5. Is language recovery enhanced if certain approaches are used in combination?
6. Do some approaches have to be used in isolation for them to be effective?

Finally, although Schuell’s stimulation approach was developed for the treatment of aphasia, the utility of the approach for the treatment of cognitive deficits that often accompany aphasia is also worthy of study because of its sound clinical methodologies.

It is likely that some of the above questions will be addressed in the next 5 to 10 years. The number of approaches now in

use make this increasingly necessary for rational, data-based clinical decision making. In addition, because more appears to be known about the efficacy of the stimulation approach compared with almost any other, it likely will frequently be among the approaches compared. In fact, we might anticipate that it will be the standard against which the effectiveness of other approaches will be measured.

KEY POINTS

1. The bulk of Hildred Schuell's work in aphasiology spanned the 1960s and 1970s and included significant contributions in the areas of diagnostic testing, classification of patients with aphasia, and theory development regarding the underlying nature of aphasia. It was probably this sound foundation in theory, evaluation, and methods of observing and categorizing behavior that helped to develop the compelling rationale for the stimulation approach. Schuell's beliefs about the organization of language and the nature of language breakdown in aphasia can be summarized as follows:
 - a. Language cannot be thought of as a simple sensorimotor dichotomy or a three-system cortical relay involving reception, transmission, and execution.
 - b. Neurophysiologically, language is the result of the dynamic interaction of complex cerebral and subcortical activities.
 - c. The language mechanism contains a system of stored, learned elements and rules, the use and maintenance of which require discrimination, organization, storage, comparison, retrieval, transmission, and feedback control.
 - d. Schuell's unidimensional, multimodality concept of aphasia does not require that patients vary only along a severity continuum. In aphasia, the problems of most patients appear to be more related to performance factors than to competence factors.
 - e. Although the language mechanism can exist separately from input and output modalities, our primary language processes are acquired and organized through complex, interacting sensory systems and sensorimotor processes. Notably, auditory processes are at the apex of those interacting systems that aid in the acquisition, processing, and control of language.
2. Schuell's classification system for aphasia aimed at descriptive and predictive utility by classifying patients according to severity of language impairment, the presence or absence of related sensory or motor deficits, and prognosis. She identified seven categories: (a) simple aphasia, (b) aphasia with visual involvement, (c) aphasia with persisting dysfluency, (d) aphasia with scattered findings, (e) aphasia with sensorimotor involvement, (f) aphasia with intermittent auditory imperception, and (g) irreversible aphasia syndrome.
3. The stimulation approach can be defined as that approach to treatment that employs strong, controlled, and intensive auditory stimulation of the impaired symbol system as the primary tool to facilitate and maximize the patient's reorganization and recovery of language. Although numerous input modalities may be used, the auditory modality is at the foundation of the stimulation approach.
4. The design of intervention used in the stimulation approach is based on a number of general principles:
 - a. Intensive auditory stimulation should be used.
 - b. The stimulus must be adequate—that is, it must get into the brain. Therefore, it needs to be controlled, perhaps along a number of dimensions.
 - c. Repetitive sensory stimulation should be used.
 - d. Each stimulus should elicit a response.
 - e. Responses should be elicited, not forced or corrected. If a stimulus is adequate, a response will occur.
 - f. A maximum number of responses should be elicited.
 - g. Feedback about response accuracy should be provided when such feedback appears to be beneficial and should show patients their progress.
 - h. The clinician should work systematically and intensively.
 - i. Sessions should begin with relatively easy, familiar tasks.
 - j. Abundant and varied materials that are simple and relevant to the patient's deficits should be used.
 - k. New materials and procedures should be extensions of familiar materials and procedures.
5. The following variables have been found to be most relevant to the structuring of stimulation:
 - a. Auditory perceptual clarity.
 - b. Nonlinguistic visuoperceptual clarity.
 - c. Linguistic visuoperceptual clarity.
 - d. Method of delivery of auditory stimulation.
 - e. Discriminability.
 - f. Combining sensory modalities.
 - g. Stimulus repetition.
 - h. Rate and pause.
 - i. Length and redundancy.
 - j. Cues, prompts, and prestimulation.
 - k. Frequency and meaningfulness.
 - l. Abstractness.
 - m. Part of speech and semantic word category.

- n. Grammar and syntax.
 - o. Context.
 - p. Stress.
 - q. Order of difficulty.
 - r. Psychological and physical factors.
 - s. Pattern of auditory deficit.
6. With regard to implementing the stimulation approach to treatment:
 - a. Schuell indicated that treatment should begin at the level where language breaks down and should proceed through gradually increasing levels of difficulty.
 - b. Once tasks and stimuli have been established and target behaviors or response characteristics identified, we must determine criterion for acceptable performance.
 7. Conclusions that therapy for aphasia is generally effective are based on studies that have used—or probably have used—a stimulation approach. Treatment studies employing the stimulation approach are more conclusive than inconclusive, and the conclusion they generate is that it has a significant positive effect on the communication ability of many patients with aphasia.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. How is Schuell's definition of aphasia reflected in her aphasia classification system and the stimulation treatment approach?
2. Compare and contrast three treatment approaches for aphasia discussed in this text. How are they similar to and different than Schuell's approach?
3. Which of the stimulus variables described by Schuell would be most difficult to manipulate in the design of an individualized treatment task?
4. Design a treatment task for improving auditory comprehension of short sentences that could be used for an individual with severe aphasia. How could this task be modified for an individual with mild aphasia?
5. Design a treatment task for improving auditory comprehension of sentences by an individual with mild to moderate aphasia and significantly reduced visual acuity.
6. Design a 30-minute treatment session for an individual with moderate aphasia that targets naming of noun pictures.
7. Your client, a 60-year old man with mild to moderate aphasia, has just been authorized by his insurance company for 20 sessions of outpatient speech and language therapy. Design a treatment program that will maximize this treatment, and describe how you will demonstrate the effectiveness of your intervention.

Chapter 16

Thematic Language-Stimulation Therapy

Shirley Morganstein and Marilyn
Certner-Smith

OBJECTIVES

In this chapter, we provide a theoretic background for *Thematic Language Stimulation (TLS)*, an intervention technique for aphasia; explain the rationale for TLS and delineate its various components; provide suggestions for clinical and functional communication analysis as a precursor to the use of TLS; and provide a template for replication of TLS modules and directives for implementation in aphasia therapy.

In the previous chapter, the reader will find an excellent description and discussion of the work of Hildred Schuell. Despite evolving knowledge gained in neurologic substrates of speech and language function, Schuell's model of aphasia rehabilitation remains relevant. Schuell posited a neurobiologic change with controlled stimulation, and so do today's researchers in "the community of brain repair."¹ Jenkins and colleagues (1990) found expansion of distal digit representation in monkey brains after sensory training, suggesting that the brain can change with systematic motor stimulation. Similarly, Kilgard and Merzenich (1998) reported changes in the organization of monkey auditory cortex after exposure to a combination of sound and chemical neurotransmitters.

Thematic Language Stimulation is firmly rooted in Schuell's stimulation treatment model. Indeed, as a graduate student in the 1960s, the senior author was privileged to have studied with Schuell during her tenure at the University of Minnesota and the Minneapolis VA Hospital. Some approaches to management of aphasia are based on

abstract or theoretic models of language (Boyle & Coelho, 1995; Drew & Thompson, 1999) Schuell's approach was conceived as a result of focused clinical observation and data collection on large numbers of patients. This clinical approach enabled her to see and record relevant behaviors, postulate and evaluate the underlying mechanisms for that behavior, and find ways into the wounded brain. Since the 1960s, many aphasia therapists have found an intelligent and comfortable point of entry in Schuell's work. It was from that place of comfort that TLS was born.

Since the original formulation of TLS in 1982, a variety of different therapeutic approaches have developed in response to changes in the way that we, as a profession, perceive aphasia, the concept of disability, and the therapeutic milieu. Specifically, we are looking more closely at the *person with aphasia*, rather than the *disorder of aphasia*, as did Schuell. This is not to say that Schuell did not consider the interpersonal aspects of communication—quite the contrary. All of her investigations and interventions sought to alleviate the symptoms that interfered with normal communication. She did speak to the devastating effect of impaired communication on the person with aphasia:

Like anyone who, suddenly in the midst of the journey of his life has found himself alone in a dark wood where the straight way is lost, the aphasic patient knows despair. Surely anyone partially paralyzed and unable to communicate must feel himself in a dark wood, indeed, and surely the straight road he took for the natural way must seem lost to him." (Schuell, 1964, p. 321)

Schuell would have greatly appreciated the work of individuals currently involved in the social, environmental, and life participation approaches. Today, many speech-language pathologists may feel a pull away from traditional interventions and into the more person-centered ones. Without question, we are learning from people with aphasia what the form and content of our therapy can be. The disability empowerment movement is having a strong, positive effect on the work of the aphasia therapist, yet some new views about how we can intervene in the workings of the brain in the person with aphasia also have appeared. Constraint-induced therapy, for example (Maher et al., 2003; Pulvermuller et al., 2001), is based on the neurophysiological finding that "doing" actually changes structure within

¹Leslie Gonzalez-Rothi, *Speaking Out!* 2004, Tampa, Florida.

the brain. Other recent studies are revisiting the notion that some specific drugs may have an enhancing effect on brain function for communication (Greener, Enderby, & Whurr, 2001).

Perhaps more to the point is an examination not of *which* intervention is appropriate but, perhaps, *at what point in the therapeutic process, in what order, and for which persons with aphasia* different intervention approaches may be useful. As we noted in our chapter in the fourth edition of this text, a significant body of research that might help us to reliably identify specific candidates and the most beneficial timing for these specific techniques continues to be absent.

The current version of TLS continues to reflect its original stimulation roots. We also have found it to be helpful in the metalinguistic exploration of symptoms and strategy training and in the education of other speech-language pathologists and caregivers. We view TLS as one technique in a growing professional armamentarium. None of these techniques is mutually exclusive; indeed, some actually may be enhanced by the inclusion of others at another point in time.

DEFINITION

“Thematic language stimulation” is a systematic method of therapy for aphasia that employs thematically related vocabulary in multimodality stimulation, targeting changes in language processing for functional communication. Specifically, it begins with a select group of words related in meaning, places them in particular linguistic contexts, uses them in tasks that employ both input and output modes, and targets improvement of underlying language processes to impact on conversational success. The TLS hypothesis is that you are changing the way the brain is working by “working the brain.” It extends concepts originally presented by Schuell and colleagues (1964) and by Wepman (1953, 1972). In addition, the authors have been influenced by the work of Edith Kaplan (1989) and of Nancy Helm-Estabrooks and M. Albert (1991), who emphasize the process approach in evaluation and treatment—that is, understanding the *why* as well as the *what* about aphasia.

Like all stimulation approaches, TLS places the burden of success on therapists, because they provide a possible neurobiologic link between what the person with aphasia knows and what the person with aphasia can produce. Theoretically, restoration of language proficiency comes about by means of carefully controlled stimulation. Stimulation targets overall improved understanding, speaking, reading, and writing. Observation of the person’s behavior during stimulation reveals information about underlying processes. Awareness of these processes has value in the development of strategies for success in conversation.

TLS THEORY

Organizing Content and Delivery

The organization of the language used for stimulation is central to TLS. This is accomplished in two ways: first, in establishing a relevant, thematic “core vocabulary,” and second, in creating predictable, systematic linguistic stimuli for each presented task.

Thematic Content

Wepman (1972), in his *content-centered treatment approach*, believed that treatment should focus on ideas. He advocated stimulation of thought to enhance verbal production during conversation. In contrast, TLS requires more stringent control of content and its manipulation within the session. Content themes heighten the saliency of the therapy and provide a context for both the stimulation and the subsequent conversation. Meaningful content in natural contexts strengthens the therapeutic effect. Rather than creating new ones, the TLS structure capitalizes on the organizational systems already established within the brain.

Both Schuell (1964) and Wepman (1972) agreed that treatment content should be *personally relevant*. At the most basic level, people tend to have more to talk about when the subject is connected to them (Wallace & Canter, 1985). In addition, Marshall (1994) noted that, for those with fluent aphasia, personally relevant material is “comforting and helps to break the garbage in-garbage out cycle” (p. 444). Human beings are simply more at ease and better equipped to talk about topics that interest them most. Therefore, in choosing a TLS topic that is relevant for the person with aphasia, we establish a heightened “performance edge” for therapy as well as a shared referent for subsequent exchanges. In addition, choosing material of high personal relevance can reassure patients that we know more of who they are than they are able to tell us. In this way, we foster an atmosphere of respect that affirms the present value of the patient in a therapeutic partnership.

Thematic language stimulation themes may be fairly universal, such as “cooking” or “sports.” Often, however, the authors create units based on the unique backgrounds and interests of the individuals with whom we work. For example, we once used a family interview and a few trade magazines to construct a TLS unit on the garbage industry for a particular client, and it proved to be a great success. In this way, we have learned a good deal about the world in which our clients live and work. It is frequently most interesting in and of itself, but it also has practical value, in that we can sometimes use this information again in TLS sessions with others.

A TLS unit usually consists of 8 to 10 vocabulary words, primarily nouns and verbs, that are highly related to a topic. From this pool of core vocabulary items, we develop, for

language practice, a variety of activities, all linked to the theme. (See Appendix 16-1 for an example of one such unit.) Simultaneously, the functional communication segment uses extensions and elaborations on this theme. The reader will note that, with some exceptions, the exercises employed are highly familiar: repetition tasks, fill-ins, multiple-choice selection, and more. What is different about TLS is the way they are created, selected, ordered, delivered, extended, and enhanced.

Stimulation Delivery in TLS

Chapter 15 (Duffy and Coelho) provided a comprehensive discussion about the principles of Schuell's stimulation therapy. Several of these are very important in the development and execution of TLS and warrant further elaboration here:

1. **Stimulus Adequacy** The adequate stimulus, by definition, is one that has an intended result. Such stimuli must be sufficiently intense, focused, and redundant to create a neurobiologic effect—that is, a change in brain-mediated language performance. In TLS, stimuli can be made adequate in several ways. First, the high degree of relevant content ensures saliency. Second, redundancy, in the form of repeated semantic and syntactic elements, and the use of multiple input and output channels are programmed into stimulus/response tasks that literally bombard the patient with linguistic stimuli. Third, the hierarchical development of task sequences builds and extends stimuli in familiar but varied contexts.
2. **Maximal Patient Response** TLS supports this principle by providing many opportunities for the client to respond in all modalities. That is, between 10 and 15 different multimodality exercises are presented for each vocabulary item over the course of five to seven sessions. In addition, therapists are encouraged to repeat activities with minor adaptations from session to session. Task repetition, reordering, adaptation, and extension in meaningful context enable maximal response. Using a variety of tasks that can be rearranged and adapted for use over a period of several sessions, therapists can broaden the stimulation base without shifting out of the theme. In addition, language can be extended further by using environmental materials and objects, such as a real restaurant menu for a unit on dining out or a trade magazine on a specific chosen topic.
3. **Systematic and Intense Presentation** TLS activities are composed and delivered systematically to obtain the greatest number of accurate responses. The progression is from introductory topical conversational material to identification of theme vocabulary to manipulation of language in carefully adapted and sequenced multimodality tasks and a return to conversational format—all within one session. Within that structure, the order of presentation also is from those likely to result in the

greatest degree of success to the more difficult. Here, “more difficult” is relative; the TLS philosophy employs an 80% to 90% success level for activities. Less success than that simply affirms failure to both the client and the therapist—that is, failure to achieve an adequate stimulus. Greater than 90% success suggests the activity is not truly stimulating the brain but, instead, is riding the wave of current capabilities—rather enjoyable at times but, perhaps, not therapeutic. The degree to which clients achieve high numbers of “correct” responses in therapy is dependent on the therapist's understanding of performance variables and how to influence them, the intensity of language stimulation delivered and for which there is a response, and the moment-to-moment adjustments made during sessions. This is probably more about what is frequently called “the art of aphasia therapy,” for which we believe there is a definite learning process.

Functional Communication

The stimulation of language in clinical exercises is not the only benefit of TLS; it also can be of value in the transition from language used in structured activities to conversational exchanges in a shared topical context. The desire for *functional change* is a powerful one and is shared by the clinician, client, family members, and more recently, the sources of therapeutic funding.

Intervention in the functional domain has become central in several models of therapy for aphasia. These social and ecological models propose that the effectiveness of intervention be measured by functional communication success in natural environments and that therapeutic interventions employ analysis and problem solving in that milieu (Boles, 1998).

In many therapeutic models, treatment includes a problem-solving component, in which the clinician tries various combinations of cues and strategies to facilitate improved language function (Chapey, 1994a; Holland, 1998; Kaplan, 1989; Wepman, 1972). This process draws on the very essence of our practice as speech-language pathologists: the ability to observe symptoms and behavior and apply interventions that help. In TLS, because we are keeping the treatment structure consistent, the process itself becomes more of a focus. Freed of the necessity of constantly learning new directions and rules of therapy for new tasks, clients engage more easily in problem-solving activity and can concentrate more on their own performance issues. This consistent structure helps both the clinician and the client to develop insights that assist in facilitating functional communication behaviors.

We believe that TLS may provide a link from clinical to functional language stimulation by manipulation of the theme. The daily segue from clinical task to relevant, theme-based

conversation moves the clinician and the person with aphasia back and forth between both environments. Capitalizing on what may be improved access primed in the stimulation mode, the therapist skillfully shifts the environment of practice to functional conversation. Once there, both clinician and client continue the problem-solving process, exploring successful strategies, heightening awareness, and developing insights.

Metalinguistic Dialogue

Metalinguistic dialogue is used in conjunction with TLS to strengthen the clinical to functional link. A metalinguistic act requires that an observation be made about the use of language. The observation could be about one's own language or about another's use of his or her language. Engaging in metalinguistic dialogue requires skill, but the speech-language pathologist has the ability to describe and codify the speech, language, and communication behaviors that affect conversation. From the personal and experiential perspective, the person with aphasia has valid observations to contribute, and both perspectives are complementary. Conversation strategies that are personalized and congruent with the individual's ideas of what works or fits that individual's life, however, are more likely to be the strategies that are actually used. Nina Simmons-Mackie (2001), in her description of "enhanced compensatory strategy training," notes that "the person with aphasia is considered a partner in identifying and elaborating a strategy repertoire" (p. 254).

The metalinguistic dialogue can happen at any point in the therapy session. We have found that it usually occurs quite naturally toward the end of the session, after the client and therapist have experienced the activities and the follow-up functional conversation. The typical flow is from baseline conversation to TLS activities to functional conversation and, then, to metalinguistic dialogue.

This metalinguistic dialogue often begins with the speech-language pathologist sharing examples of positive performance that are tied specifically to language and communication. Such observations or questions may assist those with aphasia to explore and reflect on their own performance. Beyond its usefulness to develop strategies, the exchange may serve to increase the patients' understanding about the nature of aphasia and how it operates with their present brain function. Once such dialogues are integrated into the session and the patients are "on board" with this component of treatment, the therapist offers more detailed observations about performance and asks the clients for their discoveries. The dyadic exchange could include comments about performance during transaction, interaction, and eventually, to domains beyond language (e.g., metacognition). Commenting and problem solving about the style of various conversation partners in the social network that either supports or exists as a barrier to conversational success may lead to productive solutions.

Metalinguistic dialogue reinforces the collaborative relationship in problem-solving treatment outcomes. Because it encourages the person with aphasia to take on more responsibility and independence in symptom and communication management, it is a helpful tool for discovering those strategies that are most likely to actually be used with confidence both inside and outside the treatment session. An example of a metalinguistic dialogue is as follows:

Therapist I noticed that when you had trouble saying some of the words just now, you seemed to pause and think about it more in your head. What did you notice?

Patient Yes, I try to see the word.

Therapist So you see the word written in your mind, and then you can say it easier?

Patient Yes, that's right

Therapist Is that easier than trying to write it?

Patient Yes, and it's faster.

ASSESSMENT FOR TLS

Regardless of the theoretic basis for provision of language treatment, clinicians need specific information about language function to develop a program. Schuell (cited in Byng, Kay, Edmundson, & Scott, 1990) proposed that treatment planning requires knowledge of which cerebral processes are impaired, the level at which performance breaks down in each modality, and the reason why performance breaks down when it does. For the present authors, this is a prescription for a process-oriented examination of both functional performance and behaviors more typically elicited in a formal test milieu. Whereas formal aphasia tests can provide some information, clinicians would do well to heed the warning inherent in Edith Kaplan's (1991) comment that "batteries are for cars, not for people".

Assessing aphasia is one of the most complex requirements of speech-language pathologists. Competent evaluation requires astute observation of language behavior combined with a thorough knowledge concerning the range of possible symptoms and how they influence communication. The speech-language pathologist also must have the knowledge and skill to manipulate the environment and explore all possible avenues of success. Thus, proper aphasia assessment bridges both domains of science and art. When the therapist has a thorough understanding of the patient's clinical and functional picture, the therapist can create an appropriate therapy program; specifically, the therapist can choose a particular approach or environment suited to the information provided by the evaluation. Moreover, endpoint recommendations then are more individualized and helpful for communicative partners.

Establishing Baseline Functional Conversation

At the onset of treatment, a baseline of functional communication is obtained. Although we have used some formal

instruments to measure functional communication in research or for other purposes (Taylor, 1969; Yorkston & Beukelman, 1980), our approach for TLS usually is more informal. That is, we believe that the experienced clinician usually can answer questions about functional communication after a relatively short period of interaction with the client.

How Well Do Patients Initiate and Sustain Conversation?

Assessment of the client's overall level of participation in a conversational exchange establishes a baseline for measuring progress and helps the clinician to develop initial ideas about intervention. Therefore, the relative burden of information exchange as well as the degree to which information must be inferred need to be determined.

How Well Do Patients Express Themselves Verbally and Nonverbally?

Assessment focuses on content. Observations address the patient's relative use of alternatives to speech when they appear in the natural course of an exchange. This information about preferred modes, and relative ease of success in any mode, will assist in decisions about TLS activity selection and order. It also will guide the way in which we introduce options for enhanced communication and how we train the communicative partner.

How Well Do Patients Follow Conversation and Directions? How Complex Can Auditory Demands Be Before Performance Breaks Down?

Information regarding comprehension informs decisions about task selection and presentation and about adjustments that need to be made in the therapist's verbal behavior when introducing tasks, counseling the client, and engaging in conversation. Skilled clinicians can derive a good deal of information during conversational exchange about the intermittency of auditory processing, regardless of whether patients are aware of a loss in understanding and how well they comprehend subtleties, humor, and/or sublinguistic information.

Assessing Clinical Performance on Tasks

Thematic language stimulation is strongly dependent on a process approach. Therefore, we continually ask "Why?" when symptoms are revealed. It is only by understanding the "why" that we can determine "what" can be done about it in treatment. Standard aphasia tests tell some of the "what" but none of the "why." In comparing the various standard aphasia instruments, a core group of subtests occur repeatedly: repetition, naming, answering yes/no to questions, and so

on. The value of these subtests is that they assist the clinician in the differential diagnosis of aphasia. They do not, however, explain what to do once aphasia is confirmed. Therefore, the clinician must engage in further analysis, adding probes to explore cognition, behavior, and therapeutic style to determine both "what to do" and "where to begin" in therapy.

Formal Testing

1. **Repetition** Some people with aphasia can repeat well, and some cannot. Because TLS relies completely on the objective of "language in, language out," therapists must know whether repetition will be a primary stimulation task, one to avoid completely, or one that will need to be adapted but can still be used successfully. Any formal test of repetition can provide the level of breakdown with respect to length and complexity of units, but further observations are required to assist in therapeutic decision making. For example, if repetition is better than spontaneous speech, the clinician has discovered a key aural-oral connection to modify speech output; if it is worse, the clinician must look elsewhere, most likely to the visual modality, for primary input. In addition, for many individuals with aphasia, repetition is not a "can do/can't do" phenomenon. Many patients "can do" once some structural stimulation requirements are met, such as slowing the rate of presentation or providing face-to-face delivery (particularly for the patient with apraxia). Such observations are critical to TLS planning, and success that can be achieved using this approach.
2. **Sentence Construction** Most formal aphasia batteries assess the ability of the patient to create sentences given a one-, two- or three-word stimulus. Creation or expansion of verbal utterances that are substantive and grammatically correct is an objective of many treatment approaches. Clinicians learn more about how best to facilitate this for a particular patient when they know (a) the required length and grammatical composition of stimuli, (b) the effect of vocabulary complexity, and (c) how much and what type of verbal or visual cues are needed to facilitate performance.
3. **Automatic Language** For some people, automatic language is far more preserved than propositional language, and automatic language should be facilitated first if it will create a base of success. Knowing the ease with which automatic language can be facilitated will help with therapeutic task selection and sequencing. For example, fill-in tasks with multiple-choice response requirements are high in predictability and might be considered to be a natural extension of automatic language material.
4. **Picture Description** A pictorial cue can be powerful for some clients in eliciting a flow of ideas. When aural-oral

presentation and response is tenuous, a pictorial cue also can provide a starting point for therapy. In addition, the contrast between narrative and spontaneous expression can be explored with respect to the complexity of ideas and vocabulary generated as well as the degree of clinician-initiated cueing that is necessary for a response.

5. **Following Instructions** Although it is desirable to minimize task instructions to the patient at each session, it is important to determine each particular patient's need for such repetition of procedures. When we apply process parameters to listening, the logical questions to be asked are (a) how complex and lengthy can directions be, (b) will a visual cue be needed to support the verbal request, (c) how does the rate of presentation affect comprehension, and (d) is the auditory mode a strong or weak one for the individual?
6. **Yes/No Reliability** For the client with more severe aphasia, ability to respond readily and consistently in a yes/no question format is an essential skill. Indeed, it is a valuable task for auditory, verbal, and visual stimulation of all clients. In addition, before construction of a TLS unit, the parameters of length, complexity, ease, and facilitation requirements should be noted via descriptive comments.
7. **Reading Comprehension** For many individuals with aphasia, reading comprehension is a valid alternative to auditory comprehension. In this instance, treatment first emphasizes presentation of information via the visual modality rather than the more traditional auditory mode. The comparison of results on subtests that tap auditory processing of directions and commands with those that examine silent reading of sentences and paragraphs allows the clinician to decide on a preferred input mode. It also is important to compare scores obtained during testing as well as the overall ease of performance in both modalities, because this information sometimes provides a clue about a client's "hardwiring" for processing language. For example, if visuographic expression is more preserved and preferred to the aural-oral system, that will be the road that we follow. In addition, for some individuals, silent reading before verbal performance has a priming effect; only when a detailed process approach is applied to tasks are such important pieces of information learned. This information then can be applied not only to task and cue selection but also can be shared with those who have aphasia and with their communicative partners. Thus, treatment decisions are made based on a balancing of the patient's strengths and weaknesses (Holland, 1998).
8. **Oral Reading** Oral reading is another avenue that provides an opportunity to get language "in and out." Therefore, the clinician needs to know if oral reading is more preserved than speaking and whether the patient

can correct errors that occur in this format. For some clients, visual stimuli are more salient. In addition, when the patient and clinician share a visual reference in the same context, this may reveal specific symptoms and procedures for modification.

9. **Graphic Expression** Writing adds to the sources of linguistic bombardment necessary to reach a threshold for response. Integrated into the therapeutic program, it comes to be thought of as a welcome addition, adding to the patient's repertoire of success. For the person with milder aphasia, one needs to know how much and what kind of assistance is needed for the production of words, phrases, sentences, or narratives and whether a self-initiated written cue aids verbal performance. Therefore, clinical and functional graphic abilities are explored fully. The therapist investigates writing and drawing not only as an augmentative communication tool but also as a source of stimulation itself. By integrating writing at an early stage of treatment, the clinician stimulates the patient's language system in yet another way. Many individuals with global aphasia can copy neatly and accurately. In addition, after several such trials are combined with repetition, they may even produce the target word verbally without struggle.

These formal test probes, combined with observation of performance, comprise our "minimal data set" for evaluative exploration in both clinical and functional domains.

Cognitive and Behavioral Considerations

Several non-language behaviors have an impact on the treatment planning process. Additional knowledge about the person's cognitive and behavioral strengths and weaknesses will influence the treatment model or approach that is chosen. In the case of TLS, such an analysis is necessary to customize both the content and delivery of therapeutic materials. As in the language analysis, certain behaviors are observed, described, and noted for future reference.

Patient Involvement

For some, the purpose of therapy is obvious, and they "get with the program" immediately, respond well to the treatment materials, and provide clinicians with evidence that they are on the right track. For others, however, lack of insight is as much an obstacle to recovery as their symptoms. Naturally, TLS works best with insightful, motivated clients who "get it." Therefore, very early in the period of evaluation and during the initial phases of therapy, we note the patient's ability to connect with the disorder, comment on the patient's own internal processes or performance for such behavior on task, and consider other types of metalinguistic analyses. Because of the way TLS is structured, however, it also is a treatment approach that can facilitate improved insight and

understanding about the therapeutic process. Even at the lowest level of function for this type of reflection, we offer many opportunities and indicate to the person that such concerns are not only worthwhile but also essential to recovery. We share our observations with the patient, and we encourage the patient to do the same. This process is important, because recovery does not happen via neurobiologic stimulation alone but, rather, via the insights that people with aphasia derive from their own process. Therefore, we continually ask “why” of our clients, and sometimes, they can give us an answer.

Specific Symptom Awareness

Clients are asked to modify their symptoms as part of the therapeutic process. Some modifications result from the clinician’s direct intervention; others result from the person’s own insight regarding a specific symptom and the patient’s resultant, focused response to it. To us, clients with specific symptom awareness seem to achieve greater progress and do better overall. Indeed, such awareness has a significant impact on how we structure material in tasks and how we cue or strategize for success. We all have memories of such moments in our therapy sessions. For example, one author recalls a person with conduction aphasia who taught her clinician the value of graphomotor association by producing a dictionary of words beginning with target sounds and then using that list to aid pronunciation of words in general.

Task Orientation and Retention

When clients have good task orientation and retention of treatment set, directions need not be repeated from day to day. Subsequently, a natural flow occurs from one task to the next and from one day to the next. In addition, because of its organization, TLS can assist even the person with severe aphasia to prepare himself cognitively for the tasks at hand. In turn, this sometimes engenders feelings of competence in the “knowing” of what to do. Therefore, keeping structure constant and changing the items within it, rather than the constant shifting of exercises that sometimes is seen in more traditional language therapy, is valuable.

Perseveration

For some people with aphasia, perseveration is a highly problematic and unwelcome intrusion for communication. In our experience, the semantic relatedness of TLS can make perseveration even worse for these clients. Typically, this tendency is discovered once treatment is underway and the clinician observes that the client’s responses, rather than demonstrating the advances in vocabulary retrieval and sentence use, contain recycled errors in word choice that are not evolving into something better. For such an individual, TLS is not an appropriate treatment approach.

Visual Perception

Because TLS relies heavily on multimodality stimulation, any visual problems that affect task presentation, such as the presence of hemianopsia or the need for altered print size, should be known in advance. For some, it may simply be a matter of modifying the aural-oral elements and adapting visual materials. For others with severe accompanying visual impairments, TLS may not be effective.

TREATMENT DELIVERY

After completing an assessment of conversational proficiency, language, and cognitive/behavioral status, the clinician is ready to incorporate this information into an organized treatment delivery plan. Before therapy can begin, however, one more set of questions needs to be answered:

1. **Is this person a good candidate for TLS?** Candidacy for TLS is best determined in one or two sessions of trial therapy; however, certain rules of thumb seem to be of help in deciding which clients have the potential for success. Good candidates generally are those with no marked perseveration or semantic confusion in task performance and with good ability to understand the purpose of therapy, stable emotional status, and some amount of visual language preservation. Level of severity may vary, but patients with moderate to severe difficulties appear to profit most. Although preliminary research findings suggest otherwise, we feel the technique is of value to people with either fluent or nonfluent aphasia.
2. **How should tasks be chosen and sequenced?** Our analysis during assessment has told us very specifically which modalities and tasks are the strongest and which are the weakest. Therefore, to adhere to the principle of stimulus adequacy, we begin there. In addition, because it will prime the session for all subsequent task presentations and adaptations, the first task should be one that provides a high probability of success. If it is known, for example, that the patient does not repeat well but that he can read words and phrases both silently and orally with good success, then the TLS exercises chosen first should require this patient to do just that. Because treatment is multimodal, the next task might begin to include aural-oral requirements, such as answering questions using the material just practiced visually. This might be followed by a writing task at a level compatible with demonstrated skills in this modality; for example, the client might be able to copy or write the target words as the clinician dictates them.
3. **What cues are most beneficial to achieve maximal success in treatment?** Because successful language stimulation should neither involve too much struggle nor be so “easy” that it does not provide a neurobiologic effect, an 80% to 90% success rate is targeted in TLS therapy. To achieve this level of success, considerable experimentation regarding facilitatory cueing takes

place; however, our assessment analysis has provided clues about the likelihood that they will or will not succeed. Therefore, the clinician answers questions such as the following: (a) Are visual cues more powerful than auditory ones? (b) How much spontaneous writing is possible with and without input from dictation? (c) When can I fade out a verbal, auditory, or visual cue and still maintain an accurate response?

When we determine cueing that works at baseline, we also determine the beginning of a cueing hierarchy. These hierarchies are individualized and will change over time as the client progresses and needs to be challenged further. Maintaining a high level of success throughout treatment, however, should be a constant goal.

4. **How do I select theme and vocabulary?** As mentioned earlier, theme selection is based on each client's interests; personal relevance generates ideas and themes that provide a shared reference point for all subsequent interaction. The inclusion of material based on client input reflects respect for the client's personal contribution to the decision about treatment needs. Themes that are more concrete—or even able to be pictured—are easier to conceptualize. It is entirely possible, however, to select complex themes and create vocabulary and tasks that can be modified to levels consistent with normal language complexity. A minimum of 6 and maximum of 10 words are recommended.

A closed set of core vocabulary permits manipulations that fulfill some of the content and delivery principles described earlier: redundancy, multimodality presentation, and predictable task inventory. The majority of words are nouns; however, an occasional verb or adjective also is desirable. For example, if the theme is “restaurant,” appropriate vocabulary words might be *waitress*, *tip*, *table*, *menu*, *appetizer*, *water*, *check*, *chef*, and *order*.

The actual tasks that we have employed in our TLS work are familiar to any experienced aphasia clinician. What is different is the constancy of theme that connects them all and the systematic way in which they are employed. A complete TLS unit (“Books”) is provided for your use in Appendix 16-1.

PRELIMINARY RESEARCH WITH TLS

According to Darley in 1972 (as cited in Howard, 1986, p. 89), “If speech pathologists are to have a role in the management of aphasic patients, it must depend not on wishful thinking, but on unequivocal demonstration of effectiveness in significantly altering, in a favorable way, the course of recovery.” In the 1980s, this was referred to as “evaluating efficacy.” In 2005, American Speech-Language-Hearing Association adopted the term “evidence-based practice” and created a position statement reinforcing the need for evidentiary support for clinical interventions. Although in the typical speech therapy clinical

milieu, single-subject design studies are accomplished more easily than group studies, therapists, according to Siegel (1987) as well as Siegel and Spradlin (1985), often find it difficult to integrate them into a typical service delivery model. In 1993, we completed one such clinically based, single-subject study with TLS.

Defining Success

In the early stages of our clinical work with TLS, we were relatively comfortable with clinical evidence that the approach was making language more available during the execution of tasks. As sessions progressed, performance seemed to improve during each session and from session to session. If TLS or, for that matter, any restorative technique is to be judged efficacious, however, it must be held to the ultimate standard—that is, improvement in conversational speech. We found immediate difficulties in selecting functional conversation as the improvement measure, because few quantifiable options from which to choose were available and those that were available seemed to be insensitive to discriminating what would undoubtedly be very small changes. For that reason, we declined to use the CADL (Communication Activities of Daily Living) (Holland, 1980), the CETI (Communicative Effectiveness Index) (Lomas et al., 1989), and the FCP (Functional Communication Profile) (Taylor, 1969). We found support, however, in our frustration:

Clinicians and investigators who wish to quantify changes in the informativeness of the connected speech of adults with aphasia in response to manipulation of experimental variables have been hampered by the scarcity of standard measures for characterizing this aspect of connected speech. (Nicholas & Brookshire, 1993, p. 338).

At the time we embarked on our study, the only published system for measuring small improvements in discourse appeared to be that proposed by Yorkston and Beukelman in 1980. In their system, the individual's response to the cookie theft picture from the *Boston Diagnostic Aphasia Examination* (Goodglass & Kaplan, 1983) is analyzed for the number of *content units* produced and for a measure of communicative efficiency, which is determined by the ratio of content units per minute of discourse. Content units, or groupings of information expressed by normal speakers in response to the cookie theft picture, are finite and offer a clear index of relative performance in response to this specific picture stimulus. Concerns regarding the differences between connected speech elicited in this manner and that elicited in a conversational exchange remained, but a content unit analysis seemed to be our best method of defining success—that is, communication of information in discourse.

Design Choice

In general, single-subject studies investigating the efficacy of a particular approach to aphasia intervention employ either

a reversal/withdrawal or multiple-baseline design (Pring, 1986). Our desire was to determine whether TLS was more effective than a “traditional” approach, and we therefore chose a reversal design in which TLS and non-TLS modules would alternate with each other for 3 weeks after a baseline determination of communicative efficiency. Modules 1 and 2 (i.e., TLS and non-TLS, respectively) were ordered such that subjects would receive either one first for a 3-week period. This served to control for the number of times that each was received. The same content unit analysis obtained at baseline was performed between each of the modules.

The decision regarding the content of the non-TLS module was of great concern, because many differing approaches to therapy for aphasia are available. Our personal journey involved exploration of many of these approaches, and we would—and will—employ many of them therapeutically when we felt it to be an appropriate choice for a specific individual. Our choice of non-TLS therapy for Module 2, however, was derived from what seemed to be “the norm” for many speech-language pathologists—that is, a “general language stimulation” approach employing a variety of exercises for word retrieval, comprehension, reading, and writing but *without* controlled content and delivery around thematic structure and Schuellian principles.

Therefore, Module 2 employed activities from the many easily accessible aphasia workbooks frequently used by clinicians. These activities were administered by us subsequent to completion of the same evaluative procedures described above. In other words, we attempted to treat the patient with traditional speech and language tasks selected for the individual’s level of performance in each modality but without regard to semantic uniformity across modalities. We did not hesitate to assist patients in achieving success on these tasks within the session, and we provided whatever degree of stimulation and support was required for specific activities. Even

so, we avoided any linking of materials with conversational topics. It may be argued that we did not provide the best possible non-TLS modules because of our bias; however, we are accustomed to delivering other kinds of therapy to those for whom TLS is not appropriate and attempted to do that for this study. Our hope is that, in future studies, we will be able to employ other therapists so as to eliminate any possible bias in this regard.

Subject Selection

The individuals who participated in the study completed a 3-week course of treatment while at an inpatient acute rehabilitation facility, and they were selected without regard to age, type of aphasia, etiology, duration of symptoms, or any other particular characteristic. All were screened for adequate vision and hearing, and all received traditional aphasia testing before inclusion in the study.

Procedures

Before beginning the first module, in between modules, and again at the end of the last module, the responses of each patient to the cookie theft picture were audiotaped and videotaped. Written transcripts of these descriptions were obtained and analyzed according to the procedure of Yorkston and Beukelman (1980). Each therapy session was videotaped as well. All subjects received 30-minute sessions of therapy 5 days per week for each of the three consecutive weeks.

Results

Pring (1986) offers some encouragement for the analysis of data in a visual rather than a statistical manner when changes are likely to be small. Thus, as can be seen in Figure 16-1, two

Figure 16-1. Treatment effects of thematic language stimulation. JS, RE, and LS refer to individual patients.

of the three subjects (both people with fluent aphasia) demonstrated treatment effects with TLS. That is, the communicative efficiency score (number of content units divided by rate) increased after TLS modules, and decreased after non-TLS modules, relative to baseline. No treatment effect was observed for patient JS; in fact, her scores appear to be poorer with both treatment approaches relative to baseline.

Discussion

Because of the very small number of subjects in our study, little about the efficacy of TLS can be confirmed. Certainly, we would need to test many more individuals before drawing any conclusions. What seems safe to assume, however, is that the use of a content unit analysis as a measure of discourse for revealing small, quantifiable changes in performance is a good idea. We found it interesting, however, that our best results were obtained when treating individuals with fluent, rather than nonfluent, aphasia given our clinical impression that people with nonfluent aphasia respond quite well. Even so, we observed that patient JS, the subject with nonfluent aphasia, lacked a sense of treatment purpose despite a good degree of cooperativeness regarding therapy. Our impression is that this person would have had difficulty with any intervention because of her inability to interact with the concept of treatment in general. Further exploration of TLS intervention is warranted with a greater number of subjects, individuals of varying aphasic syndromes, and consideration of the timing of implementation during the recovery phase.

FUTURE TRENDS

The World Health Organization's model for classification of functioning and disability differentiates deficit, activity, and participation as points of reference in the individual's health perspective. To treat individuals for their deficit or brain impairment in isolation is to ignore other critical features of their recovery. Improved language function that stays in the therapy room without application to functional activities and participation goals also reflects inadequate therapy. With a driving force to make life better for people with aphasia and those who matter most to them, our therapy needs to be authentic, flexible, and congruent at each of the various points in recovery. To meet these criteria, the speech-language pathologist needs to direct less, listen more, and support the direction described by patients and their chosen partners to assist in achieving a satisfactory recovery.

Our role as educators and trainers will continue to expand. If people are to be successful outside of the therapy room, they must be knowledgeable and empowered to problem solve and make choices. Similarly, families and others in the social network of those with aphasia need to be knowl-

edgeable and comfortable with partnership to be supportive and effective.

Training aimed at understanding aphasia and how to be of help needs to be addressed early and frequently throughout the course of treatment. Although communicative partners generally cannot provide TLS therapy, they learn, by observing sessions and talking with us, about how those with aphasia organize their language, employ appropriate strategies, and requires in the way of priming input or providing support to do their best. These lessons can be learned from many different approaches; because of its strong dependence on structure, TLS may simply be a more organized observational environment for shared insights and opportunities regarding problem solving.

Thematic Language Stimulation is an intervention that bridges treating the language deficit and facilitating function via the conversation focus. In recent years, addition of the metalinguistic component to complement the TLS format has reinforced the role of problem solving by the patient, family, and other supporters. Success in conversation often is a prerequisite to success in chosen activities and participation goals. Being skilled to problem solve and advocate for life's goals beyond the duration of the speech therapy intervention is of great value for the ultimate outcome.

Lastly, our training needs to involve the community. For the person with aphasia to participate successfully in chosen activities, we must assist the community with learning to recognize aphasia and to respond effectively. After all, the ultimate goal is for people with aphasia to succeed.

KEY POINTS

1. Thematic language stimulation is a neurobiologic approach to speech and language therapy, based on the theory of aphasia treatment first postulated by Hildred Schuell in the mid-twentieth century.
2. Success in implementation of TLS may depend on several factors, including the ability of the therapist to provide adequate stimulation and the abilities of the client to understand and respond to the aphasic symptoms.
3. Therapists who employ TLS must use the client's interests and talents to tap into the best possible subject matter for a successful outcome.
4. Thematic language stimulation extends out of the basic Stimulus-Response formats into the natural flow of speaking and listening in a conversation.
5. The ability of both therapist and client to examine language and cognitive abilities and make decisions about how to integrate treatment is key to the use of TLS.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Create your own “mini” TLS unit by following these steps:
 - a. Select four vocabulary items on a topic of choice. Include nouns and verbs.
 - b. Using the examples given in Appendix 16-1, place each vocabulary item:
 - i. In a word-phrase-sentence format.
 - ii. In an open-ended sentence for a fill-in.
 - iii. In a multiple choice reading format.
 - iv. In a question designed to elicit discussion.
 - c. What other exercises NOT in Appendix 16-1 might be used with the same four vocabulary items?
2. Create a “cueing hierarchy” for someone who might not be able to succeed with item b.iii above. How would you adapt and change the presentation or task requirements to enable success?

APPENDIX 16.1

Thematic Language Stimulation (TLS) Unit on Books with Instructions for Creating TLS Units.

How to Create a TLS Unit

Select between 8 and 10 words that have a close association to your chosen theme. These words will become your *core vocabulary*, which will be used in each exercise. Use nouns primarily, but verbs and adjectives are fine as well.

Twelve Exercises

Exercise 1: Repetition

This is controlled repetition practice, in which the stimuli gradually increase in length and complexity. Use each core vocabulary item, and create a phrase and sentence sequence for them in which the target word is in the final position, whenever reasonable.

Exercise 2: Speech Stimulation/Production

This is a grouping of three statements and one question, which evolves for each core vocabulary item from repetition to open-ended fill-ins to generation of novel utterances. Begin with a statement for the client to repeat in which the core vocabulary item is the last word. Create the next statement using the exact language of the first, but with the last word as a fill-in. Create a question requiring the target word as an answer. End with a question relevant to the content just practiced, but designed to elicit a novel response.

Exercise 3: Copying

Provide opportunity for the client to copy each target item at least three times, and attempt to write from memory.

Exercise 4: Categorization

This task is for identification of the core vocabulary in a list of words that vary in their semantic closeness to the target items.

First, randomize core vocabulary items in a list of roughly twice its size. Use foils (i.e., other words) that are varied in the degree to which they may be related, visually or semantically, to the targets. The semantic closeness of the foils will determine the difficulty of the task.

Exercise 5: Sentence Fill-Ins, Multiple Choice

These are fill-in sentences for which the target word is one of the choices. For each fill-in sentence, three choices are offered. Semantic closeness of the foils determines the complexity of the task.

Exercise 6: Yes/No Questions

Questions are formulated with target vocabulary, and the task is to provide a yes/no response.

Exercise 7: Answering Questions, Multiple Choice

Questions are developed for which correct answers are randomly ordered in a vocabulary grouping of four or five items. Place these choices above four or five questions. The client must choose and write the correct word.

Exercise 8: Sentence Arrangement

The client is provided with a scrambled sentence for each core vocabulary item. Create out-of-order sentences of varied complexity, but within the mild to moderate range for each vocabulary item.

Exercise 9: Sentence Construction

Pairs of words are provided with which to create sentences. Create two columns. On the left, list the core vocabulary first, followed by a verb. In the next column, list a noun phrase.

Exercise 10: Sentence Correction

The client is provided with sentences containing two errors of either word choice, grammar, or spelling, which the client must identify and correct.

Exercise 11: Paragraph Reading, Multiple Choice Questions

A paragraph is created in which all (or most) of the vocabulary has been used. The client must then answer some multiple-choice questions about the paragraph. When possible, use humor or idiomatic expressions to improve processing. Create three or four questions with multiple-choice answers for practice in processing factual and implied information.

Exercise 12: Conversational Questions

This is A list of questions on the topic designed to elicit conversation.

Vocabulary Unit: Books*Exercise 1: Repetition/Oral Reading*

Directions: Repeat or read aloud these words, phrases, and sentence.

fiction	read
enjoy fiction	read my book
I always enjoy fiction.	Tonight I will read my book.
print	library
large print	at the library
The book comes in large print.	See you at the library.
glasses	characters
reading glasses	many characters
I've lost my reading glasses.	The novel has many characters.
writer	mystery
great writer	solve the mystery
She is a great writer.	Did you solve the mystery?

Exercise 2: Speech Stimulation/Production

Directions: Listen, fill in, and answer the questions.

- | | |
|---|--|
| <p>1. I prefer to read fiction.
I prefer to read _____.
What do I prefer to read? _____
What do you prefer to read?</p> | <p>3. She is a famous writer.
She is a famous _____.
What is she? _____
Name a famous writer.</p> |
| <p>2. The story is a mystery.
The story is a _____.
What is the story? _____
Why are mysteries fun to read?</p> | <p>4. The book comes in large print.
The book comes in large _____.
How is the book printed? _____
How is large print helpful?</p> |

5. I wear reading glasses

I wear reading _____.

What do I wear? _____

Where do you buy reading glasses?

6. I borrow books from the library.

I borrow books from the _____.

Where do I borrow books? _____

How long can you borrow books?

7. The book has three main characters.

The book has three main _____.

What were there three of _____?

How many characters are too many?

8. I've always liked to read.

I've always liked to _____.

What have I liked to do? _____.

What kind of books do you read?

Exercise 3: Copying

Directions: Write each word three times. Then, cover it up, and try to write it from memory:

Name: _____

Date: _____

read

library

writer

fiction

print

glasses

mystery

characters

Exercise 4: Categorization

Directions: Circle the words that belong in the category “Books.” If you prefer, you can cut these out, mix them up with another set of words from this book, and sort them into two categories.

fiction	butter
print	read
banana	salami
pill	rain
library	writer
spoil	weather
glasses	splash
inkling	characters
mystery	insult

Exercise 5: Sentence Fill-ins, Multiple Choice

Directions: Read the sentence, circle the correct word, and then write it.

night

print

perfect

1. The book is no longer in _____.

mystery

show

petal

2. A “whodunnit” is a _____.

ocean

travel

library

3. Borrow the books from the _____.

puppet

muffler

writer

4. Stephen King is a popular _____.

glasses

ears

advice

5. To read better, I need my _____.

filling

fiction

syrup

6. That type of book is _____.

wash

read

order

7. My cousin likes to _____.

characters

tumbles

services

8. The book has too many _____.

Exercise 6: Yes/No Questions

Directions: Read the question, and circle “yes” or “no.”

- | | | |
|---|-----|----|
| 1. Do you read only paperbacks? | Yes | No |
| 2. Is fiction about real events? | Yes | No |
| 3. Are all writers good? | Yes | No |
| 4. Are most libraries quiet? | Yes | No |
| 5. Are characters a key part of a book? | Yes | No |
| 6. Do you wear glasses on your nose? | Yes | No |
| 7. Does large print help some people? | Yes | No |
| 8. Does a mystery keep you guessing? | Yes | No |

Exercise 7: Answering Questions, Multiple Choice

Directions: Use each word to answer the questions that follow:

fiction	print	characters	writer
---------	-------	------------	--------

1. Who are the people in a novel? _____
2. What are the words on a page? _____
3. What is a story not based in fact? _____
4. Who creates a story? _____

read	library	glasses	mystery
------	---------	---------	---------

5. Where can you borrow books? _____
6. What do you do with a book? _____
7. What do you wear to help you read? _____
8. What is a book about a crime? _____

Exercise 8: Sentence Arrangement

Directions: Rearrange these words to make a correct sentence. Write that sentence on the line.

1. I asked if the book: in came print large
- _____
2. Our library: new has a wing
- _____
3. My book: characters many has too
- _____
4. I bought a new: reading pair glasses of
- _____

5. Stephen King: writer is a popular

6. The ending of the mystery: was total surprise a

7. I like: book to read reviews

8. Her brother: fiction will only read

Exercise 9: Sentence Construction

Directions: Create sentences with these word pairs.

- | | |
|----------------------|-------------------|
| 1. fiction-prefer | fiction shelf |
| 2. print-see | large print |
| 3. library-borrow | new library |
| 4. characters-admire | twelve characters |
| 5. glasses-broke | reading glasses |
| 6. writer-produced | well-known writer |
| 7. mystery-confusing | clever mystery |
| 8. read biography | never read |

Exercise 10: Sentence Correction

Directions: There are two errors in each sentence below. Find the errors, circle them, and rewrite the sentence.

1. The print is two small for me to feed.

2. Someone found my library cargo in them bathroom.

3. She is famous for solvent the mystery before she funishes the book.

4. Eye need a strongest prescription for my glasses.

5. Do yous prefer function or nonfiction?

6. I like to read the newspaper ever mourning.

7. I cold easily identification with the lead character.

8. The writer has writen nearly thirty books in his careen.

Exercise 11: Paragraph Reading, Multiple-Choice Questions

Directions: Read the paragraph, and then answer the questions.

Once a month, Ellen goes to the public library to attend a book club. This month's selection was a mystery by Agatha Christie. Ellen asked her friend Laurie to read the book and try the club. At the meeting, Laurie was particularly annoying and negative. She had forgotten her glasses and could not read the print. She disliked the writer's style; said there were too many characters to keep straight, and she guessed the ending. When it was time to go, Laurie announced she would like to join the group, but insisted the next selection be contemporary fiction. Ellen reacted quickly and suggested another Agatha Christie book and that the group read only mysteries for the rest of the season.

1. The writer of book was:
 - a. Stephen King
 - b. Agatha Christie
 - c. Ernest Hemmingway
 - d. Angela Lansbury
2. Laurie didn't like the book because:
 - a. too many characters
 - b. too many pages
 - c. it wasn't funny
 - d. the print was in color
3. What did Laurie suggest that the club read next time?
 - a. contemporary fiction
 - b. another mystery
 - c. a biography
 - d. poetry
4. Ellen suggested they read more Agatha Christy because:
 - a. she likes repetition
 - b. she wants Laurie to drop out
 - c. she wants Laurie to try harder
 - d. she is a mystery buff

Exercise 12: Conversational Questions

Directions: Answer these conversational questions on the topic.

1. Why are books easier to read in large print for some people?
2. How has your library changed in the way you can borrow books?
3. Do you prefer fiction or nonfiction? Why?
4. What do you like or dislike about mysteries?
5. Why do drug stores now stock reading glasses?
6. Besides books, what else do you like to read?
7. What makes a character in a book memorable?
8. Why are the benefits of a writer holding a book signing?

Chapter 17

Cognitive Stimulation: Stimulation of Recognition/Comprehension, Memory, and Convergent, Divergent, and Evaluative Thinking

Roberta Chapey

OBJECTIVES

The objectives of this chapter are to define communication as a problem-solving, decision-making task; review the stimulation approaches to aphasia intervention; discuss the Guilford SOI model; define cognition, intelligence, language, problem solving, decision making, learning, information processing, and composite abilities within the context of the Guilford model; discuss assessment within a cognitive stimulation approach to aphasia management; explain the general and specific objectives of cognitive stimulation therapy and suggest possible tasks and materials for such therapy; and discuss the relationship between cognitive stimulation therapy and Wepman's Thought Process Therapy, Kearns' Response Elaboration Training, and the Life Participation Approach to Aphasia.

I served as a speech pathologist for a 6-week summer program in the NYC Board of Education that included a group of 5-year-old, nonverbal, language-impaired children. Each day, I used subsequent activities and lessons from the *Peabody Language Development Kit* (1965), based on the Guilford Structure-of-Intellect model—specifically, on divergent thinking, convergent thinking, and associative thinking. The results amazed me: The children gained a large amount of language in a very short time—so much so that they were not recommended for therapy that September. I became fascinated with the results, the kit, and the Guilford model, and the application of part of the model to adults with aphasia was the subject of my doctoral dissertation (“Divergent Semantic Behavior In Adult Aphasia”). The kit has subsequently been expanded to include multiple levels and is still used throughout the world.

COMMUNICATION: A PROBLEM-SOLVING/DECISION-MAKING TASK

Communication is a problem-solving/decision-making task. One possible model of problem solving and decision making may be the Guilford Structure-of-Intellect (SOI) model (Fig. 17-1). There are four reasons why this model may be appealing. First, it appears to have ecological and communicative validity. That is, communication usually involves deciding who can say what, to whom, in what way, where, and when (Prutting, 1979). It is a constant attempt to decide what is the message of best fit for this partner in this situation. It is the back and forth—the give and take—of ideas for a specific purpose or problem. During such communication, when we comprehend a literal or implied message (e.g., “What time is it?” perhaps meaning “You are late.”) or that a problem exists, we use the mental operation of recognition/comprehension. When we comprehend a joke or double meaning of a word (e.g., “If the #2 pencil is the most popular, why is it still #2?” or “Why is the time of day with the slowest traffic called rush hour?”), we use recognition/comprehension of systems. When we remember what was said, we use memory; when we ask ourselves “What are all the possible reasons that I can use to explain the fact that I’m late?” we use divergent thinking. (Divergent thinking also is called brainstorming or creativity.) When we think of relevant contingent and/or adjacent utterances, we often use divergent thinking. When we decide between “My car broke down,” “I overslept,” and “The dog turned off my alarm clock,” we use the mental operation of judgment.

When individuals have a communicative (or other) problem to solve or a decision to make, they make use of whatever *content* (figural, symbolic, semantic, and/or behavioral), *mental operation* (recognition/understanding, memory, convergent thinking, divergent thinking, and/or evaluative thinking), and/or *product* or *association* (units, classes, relations, systems, and transformations)—or some combination of these—is called for by the specific communication (or other) problem or decision at hand.

Figure 17-1. Guilford's Structure-of-Intellect model.

STIMULATION APPROACHES TO LANGUAGE INTERVENTION IN APHASIA

The stimulation approaches to therapy form the cornerstone of language intervention strategies used with adult patients who have aphasia (Chapey, 1981a). None of these approaches attempts to teach naming or other specific responses to particular stimuli. Rather, each emphasizes the reorganization of language through stimulation or increased cortical activity through problem solving (Duffy & Coelho, 2001). The stimulation approach first articulated and later developed and refined by Schuell and colleagues (1955, 1964) places its primary emphasis on the stimulation presented to the individual with aphasia. The stimulation approach is grounded in the observation that the patient has not lost linguistic elements or rules but, rather, that the language system is working with reduced efficiency. This approach, therefore, employs strong, controlled, and intensive auditory stimuli as the primary tool to facilitate and maximize the patient's reorganization and recovery of language. It emphasizes the action elicited within the patient by the stimuli presented, because "sensory stimulation is the only method we have for making complex events happen in the brain" (Schuell et al., 1964, p. 338). Some proponents of the stimulation approach encourage us to stimulate patient ability to solve problems (Jennings & Lubinski, 1981; Zachman et al., 1982), to predict outcomes and determine causes of events (Zachman et al., 1982), and to think (Chapey, 1977a, 1981b; Chapey & Lubinski, 1979; Chapey, Rigrinsky, & Morrison, 1976, 1977).

In light of the current emphasis on cognition, one might ask what types of cortical activity are increased through problem solving, predicting outcomes, and/or determining causes of events? What complex events happen in the brain when one stimulates a patient? What are cognition, intelligence, and information processing, and how do they relate to these complex events in the brain? Are problem solving and decision making unitary or composite abilities? What is the difference between cognitive processes and products? What language-based cognitive abilities elicit action within the patient and make complex events happen in the brain to stimulate the comprehension and production of language? Answers to these questions and operational definitions of these abilities are crucial if we are to develop a coherent and generative rationale for intervention, as opposed to the listing of tasks that should be presented to patients. We need a better understanding and specification of the processes we are stimulating in the brain as well as an operational definition of the action elicited within the patient and the complex events that happen in the brain. We need to concretize the cognitive processes and the processes involved in problem solving and decision making. Specification of the underlying targets of our stimulation therapy may increase the effectiveness of our intervention efforts.

The following discussion represents one possible way to answer the above questions.

DEFINITIONS OF COGNITION IN THE PSYCHOLOGY LITERATURE

The study of cognition represents the work of numerous psychologists with a variety of related approaches. Thus, no single comprehensive theory of cognition exists. Rather, cognitive psychologists are viewed as "information-processing" theorists who seek to determine what "functional mental events transpire while a person actually behaves" (Rosenthal & Zimmerman, 1978). Their focus is not on observable behavior but, rather, on examining the characteristics of internal, central brain processing or mental events, such as perception, recognition, reasoning, thinking, evaluation, concept formation, abstraction, generalization, decision making, and problem solving.

"Cognition," then, is a generic term for any process whereby an organism becomes aware of or obtains knowledge of an object (English & English, 1958). It "refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used" (Neisser, 1967, p. 4). It is a group of processes by which we achieve knowledge and command of our world—that is, a method of processing information. It is "the activity of knowing; the acquisition, organization, and use of knowledge" (Neisser, 1967, p. 1)—knowledge that will, in turn, influence or instigate and guide subsequent and more overt behavior (Rosenthal & Zimmerman, 1978). It should be noted that

cognitive psychologists do not interpret the above mental processes as occurring in stages or in isolation; rather, they are seen as dynamic and interacting variables.

HOW THE MIND WORKS

In his book *How the Mind Works*, Steven Pinker (1997) presents a computational theory of the mind and suggests that the mind is not the brain but, rather, is what the brain does. The brain's special status comes from what the brain does—information processing or computation. Thus, “beliefs and desires are *information*, incarnated as configurations of symbols” (p. 25). Computation “allows meaning to cause and be caused” (p. 25) by allowing patterns of connections and patterns of activity among the neurons (p. 25). The “content of brain activity lies in the patterns of connections and patterns of activity among the neurons” (p. 25). Also, “[o]nly when the program is run does the coherence become evident” (p. 25). Rather, it is the arrangement of neurons that matters. Programs are assemblies of simple information-processing units, which are functionally specialized and which must assemble themselves. “A program is an intricate recipe of logical and statistical operations directed by comparisons, tests, branches, loops, and subroutines embedded in subroutines” (p. 27).

According to Pinker, evolution equipped us with a neural computer that often supplies missing information and makes good guesses. It contains modules that are “defined by the special things they do with the information available to them, not necessarily by the kinds of information they have available” (p. 31). Pinker suggests we need ideas “that capture the ways a complex device can tune itself to unpredictable aspects of the world and take in the kinds of data it needs to function” (p. 33). Intelligence, Pinker says, “is the ability to attain goals in the face of obstacles by means of decisions based on rational (truth-obeying) rules” (p. 62).

INTELLIGENCE AS DEFINED IN THE PSYCHOLOGY LITERATURE

The most widely accepted definition of intelligence is that “intelligence is what the intelligence tests test.” Another definition is the SOI model (Fig. 17-1), which was developed by J.P. Guilford (1967) during his 20 years as the director of the Aptitudes Research Project at the University of Southern California from 1949 to 1969. His project, funded by the Personnel and Training Branch of the Psychological Sciences Division of the U.S. Office of Naval Research, was designed to define various intellectual abilities to match the native skills of U.S. Navy personnel to specific job requirements. For example, Guilford sought to determine which subjects were best suited for officer status, for pilot training, and so on.

In an attempt to define the numerous intellectual abilities available to individuals and, thereby, achieve a taxonomy of

intellectual functioning, Guilford (1967) as well as Guilford and Hoepfner (1971) developed numerous tests, each of which was thought to tap a specific intellectual ability. The validity of each test and ability was then assessed by performing numerous-factor analytic studies of responses to the tests and determining which of these tests loaded on specific statistical factors. Results of this research suggest that 120 factors exist in humans (Fig. 17-1). These 120 factors are divided into three parameters: (1) mental operations, (2) contents, and (3) products.

THE GUILFORD MODEL

The Guilford model has five mental operations, four content areas, and six products ($5 \times 4 \times 6 = 120$). An ability is a combination of one kind of operation, one kind of content, and one kind of product (e.g., convergent symbolic units or divergent semantic classes). Each operation is a computation.

Mental Operations

The five mental operations are cognition, memory, convergent thinking, divergent thinking, and evaluative thinking or judgment.

Cognition

The mental operation of cognition is basic to all other operations; hence, it is first. “If no cognition, no memory; if no memory, no production, for the things produced come largely from memory storage. If neither cognition nor production, then no evaluation” (Guilford, 1967, p. 63).

Cognition involves knowing, awareness, attention, immediate discovery (or rediscovery), and recognition of information in various forms (comprehension or understanding). Recognition involves acknowledgment that something has been seen or perceived previously. For example, cognition of semantic material might be tested by using a multiple-choice vocabulary test in which the correct alternative is a synonym of the word to be defined and the other alternatives are not. Tests of cognition determine how much the examinee knows or can readily discover on the basis of what is known. (The term “cognition” has been used to refer to all mental activity or operations by most cognitive psychologists; however, Guilford used the term to refer to one specific mental operation—recognition/comprehension—which can be confusing).

Memory

Memory is the power, act, or process of fixing newly gained information in storage. It involves the ability to insert new information into memory and to retain that new information. According to Guilford (1967), good memory tests require that subjects essentially have a full comprehension of

the studied information. Therefore, test material is not difficult. Otherwise, tests may load on cognition, convergent thinking, and/or divergent thinking. The operation of memory, then, is the fixation and retention of new information.

Convergent Thinking

Convergent thinking is the generation of logical conclusions from given information, in which the emphasis is on achieving conventionally best outcomes. Usually, the information given fully determines the outcome, as in mathematics and logic. In accordance with the information given to them, examinees must converge on the one right answer (Guilford, 1967; Guilford & Hoepfner, 1971).

Convergent production is in the area of logical deductions or compelling inferences, and it involves the generation of logical necessities. An example of a convergent semantic test would be verbal analogies completion, in which subjects must supply their own answers, or picture group naming, in which subjects write a class name for each group of five pictured objects.

Divergent Thinking

Divergent production involves the generation of logical alternatives from given information, in which the emphasis is on variety, quantity, and relevance of output from the same source. It is concerned with the generation of logical possibilities, with the ready flow of ideas, and with the readiness to change the direction of one's responses (Guilford, 1967). It involves providing ideas in situations where a proliferation of ideas on a specific topic is required. Such behavior necessitates the use of a broad search of memory storage and the production of multiple possible solutions to a problem. It is the ability to extend previous experience and knowledge or to widen existing concepts (Cromptley, 1967). Divergent behavior is directed toward new responses—new in the sense that the thinker was not aware of the response before beginning the particular line of thought (Gowan, Demos, & Torrance, 1967).

Divergent questions are open-ended and do not have a single correct answer. For example, the individual might be asked to list numerous things that are soft and fluffy, to think of problems that anyone might have when eating lunch, or to list what might happen if people no longer needed or wanted sleep. Responses can be grouped according to the number of ideas produced (fluency) and the variety of ideas suggested (flexibility). If an individual is asked to list objects that can roll and responds with “a baseball, a football, a basketball, a nickel, a dime, a quarter, a car, and a truck,” this person would receive a fluency score of eight and a flexibility score of three (balls, money, and transportation). Guilford also uses originality and elaboration scores to measure divergent ability. “Originality” relates to the unusualness of the response, and “elaboration” is the ability

to specify numerous critical details in planning an event or making a decision. Responses also are evaluated for relevance. Answers that are not relevant to the specific questions are not scored. Thus, if the above individual had responded, “Isn't that an interesting question?” or “I like to eat lunch,” these responses would not be scored, because they do not answer the question.

Evaluative Thinking or Judgment

According to Guilford (1967), judgment involves the ability of the individual to use knowledge to make appraisals or comparisons or to formulate evaluations in terms of known specifications or criteria, such as correctness, completeness, identity, relevance, adequacy, utility, safety, consistency, logical feasibility, practical feasibility, or social custom. Although judgment behavior is based on the individual's previous experience and knowledge of the subject involved, it is always an extension of what is known. It is an appraisal or evaluation based on knowledge.

Guilford (1967) developed a number of tests to study judgment or evaluation skills. These tests require that the individual keep specific criteria in mind and select one best answer or solution from among several alternatives. In one test, for example, the individual chooses the best word for the sentence “A sandwich always has (a) bread, (b) butter, (c) lettuce, (d) meat. Which one must it have in order to be a sandwich?” In another, the subject must judge whether a sentence expresses a complete thought—for example, “Is ‘Milk comes from’ a sentence?” In yet another test, the individual is given specific classifications and is asked to determine if new information can be assigned to the previously established class—for example, “Should the word ‘chair’ be put with the words ‘cow’ and ‘horse’ or with the words ‘table’ and ‘lamp’?” Each judgment task has a predetermined best response or solution (Chapey & Lubinski, 1979).

Content

The human organism discriminates four broad, substantive, basic kinds (or areas) of information, material, or content: figural, symbolic, semantic, and behavioral.

Figural

Figural content pertains to “information in concrete form, as perceived or as recalled in the form of images.” The term “figural” minimally implies figure-ground perceptual organization (Guilford & Hoepfner, 1971).

Symbolic

Symbolic content pertains to “information in the form of denotative signs having no significance in and of themselves, such as letters, numbers, musical notations [and] codes” (Guilford & Hoepfner, 1971).

Semantic

Semantic content pertains to “information in the form of conceptions or mental constructs to which words are often applied. Therefore, it involves thinking and verbal communication. However, it need not necessarily be dependent on words. For example, meaningful pictures also convey semantic information” (Guilford & Hoepfner, 1971).

Behavioral

Behavioral content pertains to psychological information—that is, to essentially nonfigural and nonverbal aspects of human interactions, in which the attitudes, needs, desires, moods, intentions, perceptions, and thoughts of others and ourselves are involved. Some of the cues that the human organism obtains about the attention, perception, thinking, feeling, emotions, and intentions of others come indirectly through nonverbal means, such as “body language.” For example, this might involve matching two faces that are similar in terms of the mental state conveyed. Such ability enables us to remain aware of what behavior is going on and also to interpret it. It is important for coping with other individuals in face-to-face encounters, in solving interpersonal problems, in detecting and analyzing problems, and in generating information that is needed to derive solutions. This type of content sometimes is called social intelligence (Guilford & Hoepfner, 1971).

Products

The six types of products are units, classes, relations, systems, transformations, and implications. They represent the way that things are associated in the mind such that each level enters into the next level, producing a larger and larger number of associations between and among items of information. Thus, units enter into classes, classes into relations, relations into systems, and so on. Therefore, products represent a possible continuum from simple (units) to complex (implications) (Chapey, 1994).

Units

Units are things to which nouns often are applied. They are relatively segregated or circumscribed items or “chunks” of information having “thing” character (Guilford & Hoepfner, 1971) and often referring to one item, such as a cup or a chair. Units may be synonymous with the idea of “figure-on-ground” in Gestalt psychology. An example of a semantic units test might be a multiple-choice vocabulary test in which the correct alternative is a synonym of the word to be defined and the other alternatives are not. Semantic units are meanings, ideas, or thoughts in the form of a particular whole. Of the products, units are regarded as basic; hence, they appear at the top (Guilford, 1967).

Classes

Units enter into classes or “conceptions underlying sets of items of information grouped by virtue of their common properties” (Guilford & Hoepfner, 1971). They involve common properties within sets, such as dishes or furniture. Such semantic classes involve class ideas or concepts or choosing the class name that best describes a given set of words or objects.

Relations

Relations are meaningful connections between items of information based on variables or points of contact that apply to them (Guilford & Hoepfner, 1971). For example, a test of semantic relations can be the logical relations of a syllogism in which two premises and four alternative conclusions are presented, only one of which is correct. It also might involve an analogy task, in which case the individual must grasp the relations between the initial pair of words and apply it to the second (e.g., “soup is hot; ice cream is _____.”).

Systems

Relations enter into systems or organized patterns or items of information; they are complexes of interrelated or interacting parts (Guilford & Hoepfner, 1971). For example, a semantic system can be a “sentence—a complex of relationships among ideas, an organized thought—a sequence of events, or a common situation” (Guilford & Hoepfner, 1971). It might involve double meanings, puns, homonyms, and redefinitions or shifts in meaning.

Transformations

Systems enter into transformations or changes of various kinds, such as redefinitions, shifts, transitions, or modifications in existing information.

Implications

Transformations enter into implications or circumstantial connections between items of information, such as connections by virtue of contiguity, or any condition that promotes “belongingness” (Guilford & Hoepfner, 1971). Implications involve information expected, anticipated, suggested, or predicted by other information. For example, a semantic implication can be sensitivity to problems such as stating two things seen wrong with a common appliance or those that might arise in the use of a given specific object.

Composite Abilities

According to Guilford and Hoepfner (1971):

It must not be supposed that, although the abilities are separate and distinct logically and they can be segregated by factor

analysis, they function in isolation in mental activities of the individual. Two or more of the abilities are ordinarily involved in solving the same problem. The fact that they habitually operate together in various mixtures in ordinary mental functioning has been the reason for the difficulty of recognizing them by direct observation or even by ordinary laboratory procedures. (pp. 19–20)

Indeed, it was largely through the construction of special tests, each one aimed at a specific ability, and the sensitive and searching procedures of factor analysis that Guilford and colleagues clearly demonstrated the separateness of the various mental operations, contents, and products.

The following sections will explore the composite or unified notions of problem solving, decision making, and information processing.

PROBLEM SOLVING

According to Guilford and Hoepfner (1971), problem solving is a complex composite ability. A problem is presented whenever a situation calls for the individual doing anything novel to cope with something that is different from past behavior. Problem solving involves the use of all five mental operations, all types of content or information, and any kind of product, depending on the problem presented, the context in which the problem arises, and the kinds of products required to reach a solution.

Initially, the individual must become aware that a problem exists. This is a matter of cognition, often involving implications. Next, the problem must be analyzed or structured, which usually involves cognition of systems. After the problem is structured:

[The] individual generates a variety of alternative solutions, which is divergent production. If sufficient basis for a solution is cognized and then produced, there is convergent production. (Guilford & Hoepfner, 1971, p. 31)

At each stage in the problem-solving process, there is evaluation

in the form of accepting or rejecting cognitions of the problem and generated solutions. At any step what happens may become fixated and retained for possible later use, so that memory is involved. When evaluation leads to rejections, there may be new starts, with revised cognitions and productions. (Guilford & Hoepfner, 1971, p. 31)

Thus, problem solving can be said to have five steps: (1) preparation (recognition of a problem, cognition), (2) analysis (cognition), (3) production (divergent and convergent), (4) verification (evaluation), and (5) reapplication.

The problem-solving factors found by Guilford and his colleagues using factor analyses are as follows:

Cognition	CMU	}	Inductive	Therefore, 8 factors are involved in reasoning (5 cognition, 3 convergent)
	CMC			
	CMR			
	CMS			
	CMI ^a			
Divergent	DMU	}		
	DMR			
	DMT			
Convergent	NMC	}	Deductive	
	NMR			
	MNI			
Evaluation	EMI	}		

^aSensitivity to problems = CMI, EMI.

DECISION MAKING

Decision making and planning ability both belong in the category of problem solving and usually entail all of the steps described above. Guilford (1967) notes that the more a problem, decision, or plan involves the generation of numerous responses or novelty, or the more creative the solution, then the more it involves divergent production abilities—especially divergent transformation abilities—or, possibly, all transformation abilities.

INFORMATION PROCESSING

The present writer suggests that Guilford’s (1967) SOI model also can be viewed as an information-processing model (Fig. 17-2). Within this information-processing model, incoming sensory information is figural, symbolic, semantic, and/or behavioral. An attention mechanism selects a small portion of sensory information to be held for several seconds for further processing. This further processing takes place in the central processing unit. The processes of this central processing unit are cognition, memory, convergent thinking, divergent thinking, and evaluative thinking or judgment. It is suggested that these are the functional mental events that transpire while a person actually behaves. The mental events or processes by which sensory information is transformed, reduced, elaborated, stored, recovered, and used. This is the group of mental processes that are used to acquire, organize, store, and use knowledge—the processes whereby an organism becomes aware of or obtains knowledge of an object, event, or relationship.

Within this information-processing model, then, incoming figural, symbolic, semantic, and/or behavioral sensory information is attended to and processed in the central processing unit by one or more of the five SOI mental operations. If the information is immediately recognized, known, comprehended, or understood, the mental operation of cognition has occurred. When situations call for the individual to generate logical conclusions from given information, in which emphasis is on achieving conventionally best outcomes, then

Figure 17-2. Human information processing model based on the Guilford Structure-of-Intellect model. (From Chapey, 1994; with permission.)

convergent thinking occurs. When a novel response is required, the divergent operation is generated. Inserting newly gained information into storage involves memory. Judging the appropriateness, acceptability, relevance, and/or correctness of information requires evaluation.

When the mental operations are used and new information or knowledge is produced, these new discriminations come about in the form of new products: units, classes, relations, systems, transformations, and implications. Products are the basic forms that figural, symbolic, semantic, and behavioral information take as a result of being processed by one or all of the organism's mental operations. These new associations usually are produced as responses and/or may be processed by the mental operation of memory and inserted into memory storage.

Memory

It is important to differentiate between memory as an operation, or short-term memory, and long-term memory, or memory storage. The operation of memory (or short-term memory) is the act or process of fixing newly gained information in storage. In contrast, long-term memory is a storage area that contains everything that is retained for more than a few minutes, such as all learned experience, including language and the rules of language. It retains the products generated by the various mental operations as they process or act on experience. Thus, each individual has his or her own summary of past experiences, or a memory structure of the

world in long-term memory. It has been shown that the capacity of this storage is not static or fixed; rather, it is dynamic. Indeed, "the more you know, the more you can know, the more you remember, the more you can remember" (Muma, 1978). This "theory of the world in our heads serves as the foundation for learning." Indeed, what we know makes our experience meaningful.

One of the characteristics of long-term memory is that what is recalled often is not simply what was seen or heard but, rather, is a modification of the original learning. That is, external stimuli cannot enter the organism. Instead, organisms do not react directly to representations of the world but, rather, to information that they themselves construct (Guilford, 1967). An individual's representation of reality as internal symbols and the interrelations among these symbols are what is called "information." When the amount of memory we need to process is large, the operation of memory is capable of collapsing (or "chunking") the data it receives in more efficient ways and treating it in groups, such as classes. Through chunking, we can deal successfully with larger amounts of information with only minimal difficulty in storage and retrieval. Chunking provides a way of representing information so that it conforms to one's conceptual organization (Muma, 1978)—that is, to one's previously stored associations or products.

When the individual is faced with a meaningful problem and uses all of the cognitive processes to solve a problem, the results of this information processing frequently are inserted into long-term memory. Rote memory, on the other hand,

uses only one mental operation: memory. The use of more numerous operations during problem solving and the establishment of numerous associations, or products, during the process may be one reason why meaningful memory is longer lasting.

All of the mental operations depend on memory storage, because all operations retrieve information from this store (Fig. 17-2). That is, all of the mental operations search long-term memory to recall information that has been stored. Thus, there is cognitive retrieval, memory retrieval, convergent retrieval, divergent retrieval, and evaluative retrieval.

Perception/Attention

Where, one may ask, is perception in all this? In the literature, perception is defined as knowing and comprehending the nature of the stimulus (Muma, 1978). To perceive is to know. Attention is part of this process. Therefore, within this model, both perception and attention are viewed as part of cognition.

LEARNING

According to cognitive psychologists, learning is an active process of problem solving (Lazerson, 1975). A learning situation arises whenever our present cognitive structures prove to be inadequate for making sense of the world when something in our experience is unfamiliar or unpredictable (Smith, 1975). Thus, “learning” is an interaction between the world around us and the theory of the world in our heads. In this view, the learner is seen as a scientist who constructs theories or forms hypotheses about the world and then conducts experiments to test these hypotheses.

A distinguishing feature of the “cognitive” approach to learning is the assumption that what is learned are concepts or schema and conceptual associations about the relationships between and among objects, events, and relationships. This process of concept formation involves identifying common features and grouping together all things that have a common feature (i.e., forming classes). Concept learning involves the acquisition of a common response to dissimilar stimuli (Saltz, 1971). It is regarded as the process of making differentiations and discriminations, a process of recognizing similarities and differences or reorganizing material into new patterns or products. It involves the generation of lists of specific characteristics to differentiate membership into particular categories.

Concept formation enables us to transform the world of infinite appearances into finite essences (Saltz, 1971) and to organize past learning in such a way that it no longer is bound to the specific situation in which the learning occurred. Thus, instead of having to react to each object as something unique, we learn to make generalized responses to classes of objects. The generalized responses function as

principles or laws. When we learn something in this type of generic manner, we are able to benefit from analogy when we deal with a new problem. When this occurs, one of the major objectives of learning has been accomplished. We are able to adapt to our environment in more satisfactory ways, and we are saved from subsequent learning (Bruner, 1968).

According to Bruner (1968), all of a human being’s interactions with the world involve classifying input in relation to classes or categories that he or she has already established. Bruner’s contention is that to perceive is to categorize, to conceptualize is to categorize, to learn is to categorize, and to make decisions is to categorize.

In SOI theory, learning is “the acquisition of information which comes about in the form of new discriminations in terms of new products” (Guilford & Hoepfner, 1971, p. 30). Learning and concept formation employ the five operations of the SOI theory. According to Guilford and Hoepfner (1971):

[No] item of information has been learned until it has been cognized. That which is learned cannot have any future effects unless it is fixated and retained (memory). Items of information produced (divergent and convergent) in response to new cues may also be fixated and remembered. In attempting to learn, the individual makes errors and he must discriminate between errors and correct information. This involves evaluation. Evaluation is conceived as playing an important role in reinforcement. (p. 30)

Concept formations, the largest product of cognitive processing, are products of SOI operations and are called units, classes, relations, systems, transformations, and implications. Thus, the SOI model also is a model of learning.

Results of factor analyses led Guilford (1967) as well as Guilford and Hoepfner (1971) to redefine some of the terminology traditionally used in reference to learning. For example:

Serial learning is essentially dealing with systems, because learned order is a system.

Reasoning, redefined as relational thinking, involves mostly cognition and convergent production—but especially cognition of semantic systems.

Induction is thought to be in the area of cognition because of its discovery properties.

Deduction is primarily in the area of convergent production, because it has to do with drawing firm conclusions.

Classifying objects involves cognition of semantic classes.

Sensitivity to problems is primarily cognition of meaningful implications.

Analysis and synthesis are not coherent SOI factors.

Abstraction, generalization, and transfer

Abstraction occurs when the person selectively picks “abstract dimensions of the object” and reacts to those dimensions and no others. With transfer, “he is obviously adding some personal component to his original learning

experience. Thus, more than the literal, external properties of stimuli guide the individual's behavior" (Rosenthal & Zimmerman, 1978). Abstraction is apparent during concept development: "Concepts are developed by abstracting the common stimulus elements in a series of stimulus objects" (Staats, 1968). After having experience with the common stimulus elements of the concept, the individual will be able to pick this common component from a new set containing the same element.

Abstraction and transfer are apparent during rule learning:

By a rule, we mean that two or more objects or events are related to one another in a systematic way. For example, we learn that a flashing red light signifies stopping before crossing an intersection. Later, we exhibit transfer of this rule by stopping when we unexpectedly see a flashing red light beside a stalled car on the highway. (Rosenthal & Zimmerman, 1978)

Abstraction and transfer are involved in a judgment of class inclusion. For example, a baby concludes that certain objects are movable. Understanding the "abstract dimension" of movability, the child transfers this by adding some personal component to his or her original learning experience: The child knows that one way of moving something is to pull it, another way is to kick it, and yet another is to get a parent to pull it (Boden, 1980). This is analogous to the child who knows that the class of beads includes the subclass of green beads (Boden, 1980).

The transfer of learning to new stimuli means that the individual will add quite dissimilar response elements that were not directly related to his or her original learning (Rosenthal & Zimmerman, 1978). Transfer is an additional concept used in problem solving; it is when an individual uses something he or she learned previously and transfers it to a new situation. Positive transfer is when what was learned for one situation helps to solve a problem in a new situation. Negative transfer is when what was learned for one situation makes it harder to solve a problem in a new situation. When an individual is continuously exposed to similar sorts of problems, he or she learns strategies for solving them. A skill that can be transferred to solve problems in new situations is termed a strategy. Harry Harlow (1949) calls this "learning to learn."

Strategies can be transferred from one situation to another. A strategy also can be divided into its components, and then the components can be recombined in new ways (transformations). A transfer in which the components are recombined to "suddenly" solve a problem is called an insight; it is when a problem is solved with the "Aha! Reaction" (Lazerson, 1975).

The intellectual ability to generalize is a significant component in the definition of "cognition." To incorporate specific knowledge and generalize it into everyday experiences is cognition that is well defined and developed (Scott, Osgood, & Peterson, 1979).

Why We Solve Problems or Learn

According to cognitive psychologists, the mind possesses an innate order-generating capacity—that is, a built-in drive to learn. We carry out that drive by acting on our environment. Thus, the individual must act on and interact with the physical, emotional, social, language, and thinking world for cognitive processing to occur. When something is unfamiliar or unpredictable, or when we do not understand, we are motivated to learn (Smith, 1975). According to Smith (1975):

We learn because we do not understand, cannot relate, cannot predict. Everything we know, then, is a consequence of all our previous attempts to make sense of the world. Our present knowledge arises out of a history of problem solving or of predicting the consequences of potential actions. (p. 161)

We learn by relating new information to previous information and by seeing relationships among various bits of information.

For cognitive psychologists, learning is an active process that is significantly influenced by motivation, especially intrinsic motivation (Bruner, 1968), and by curiosity (Yardley, 1974). Bruner (1968) explains this intrinsic motivation in terms of curiosity drive, a drive to achieve competence, and a need to work cooperatively with others, which he termed "reciprocity."

Leon Festinger (Lefrancois, 1982) conceived of cognitive dissonance—that is, the motivating effect of possessing simultaneously compatible items of information. "It is assumed that dissonance leads to behavior designed to reduce conflict" (Lefrancois, 1982, p. 71). An individual remembers more distinctly and for longer periods of time material that is somewhat different from what is already known. According to Ausubel (Lefrancois, 1982), if this material is completely new and unrelated to anything in the individual's cognitive structure, rote learning, rather than meaningful learning, will occur. If the material is too similar, it is rapidly forgotten.

Other variables that intervene between the stimuli and the response are the individual learner's purpose, aspirations, beliefs, and ideals (Marx, 1970). In addition, the learning potential of an individual includes the requisite intellectual capacities, the ideational context, and the existing store of knowledge as it is currently organized (Ausubel, 1965). On this basis, the potential meaningfulness of learning material varies with factors such as age, intelligence, occupation, and cultural membership.

Two people, therefore, are likely to respond differently to the very same stimuli because of what they have already learned, what they feel they are capable of achieving, differences in the ways their minds work, or other differences that distinguish one person from another (Dember & Jenkins, 1979). Smith (1975) observes two other crucial conditions for the individual to exercise a capacity to learn: the individual has the expectation that there is something to learn, and

the learner must have some reasonable expectation of a positive outcome.

COGNITION

Cognition, then, can be operationally defined as the use of the five mental operations: (1) cognition (recognition/understanding/comprehension), (2) memory, (3) convergent thinking, (4) divergent thinking, and (5) evaluative thinking or judgment. These are the mental events or processes by which we learn or obtain knowledge about our world and by which we organize, store, recover, and use that knowledge. Knowledge is a product of cognition and is associated or organized into units, classes, relations, systems, transformations, and implications.

LANGUAGE DEFINED

Psycholinguistics is the study of the mental processes underlying the acquisition and use of language (Slobin, 1971). Within the context of the Guilford model, incoming information or language experience is semantic and behavioral (Fig. 17-3). This information is then processed by one or more of the five cognitive operations: cognition, memory, convergent thinking, divergent thinking, and evaluative thinking. These are the mental processes underlying the acquisition and use of language.

Language is something we know (Slobin, 1971). It is a body of knowledge represented in the brains of speakers of a language, the content of which is inferred from overt behavior (Slobin, 1971). According to Bloom and Lahey (1978),

language can be defined as “a knowledge of a code for representing ideas about the world through a conventional system of arbitrary signals for communication” (p. 23). Specifically, there are three types of language knowledge: content, form, and use. Thus, “language consists of some aspect of content or meaning that is coded or represented by linguistic form for some purpose or use in a particular context” (p. 23). These three types of language knowledge come together in both understanding and saying messages, and indeed, linguistic competence can be defined as the interaction of content, form, and use (Bloom & Lahey, 1978; Lahey, 1988).

Content: Language Represents Ideas About the World

Psycholinguistic research suggests that our

code or means of representing information can operate only in relation to what [we] the speaker and hearer of the language know about objects and events in the world. Speakers of a language need to know about objects and actions in order to know the names for objects and actions. [O]ne cannot know about sentences and the relations between the parts of a sentence unless one also knows about relations between persons and objects in different kinds of events . . . It is the knowledge that individuals have about objects, events and relations in the world that is coded by language—ideas about events are coded, not events themselves. (Bloom & Lahey, 1978, p. 5)

It is this knowledge, these ideas, that are the meaning, topic, or subject matter involved in conversation. For example, an individual might comment about a specific object, such as a pipe; a particular action, such as eating lunch; or a specific relation, such as that between Harry and his pipe. Or, meaning could relate to a content category, such as possession, or having or owning an object, quality, or ability; recurrence, or the reappearance of an object or event; and rejection, or the opposition to an action or object.

An individual learns to understand and use language in relation to the ideas or mental concepts that have been formed through experience (Bloom & Lahey, 1978). The experience of many different objects—some of which are more alike than others—is “an active process whereby persons perceive patterns of structure and invariance in the environment” (Bloom & Lahey, 1978, p. 7), such as similarities among different chairs and the mobility of certain objects but not others. The ability to perceive the similarities in repeated encounters with physical and social events involves the ability to process and analyze experience using the five cognitive processes. Words and categories represent regularities that the individual notes in his or her environment. Individuals learn new words and categories gradually, by testing hypotheses of what a word means in different situations in which they think one or another word might fit (Bloom & Lahey, 1978; Lahey, 1988). This results in the organization or association of information—or the formation of schema into units (or chunks of information having “thing” character; things to

Figure 17-3. Model of language based on the Guilford model (From Chapey, 1994; with permission.)

which words often are applied; meaning, ideas, or thoughts in the form of particular wholes [e.g., a cookie]); classes (or conceptions underlying sets of items [e.g., cookies]); relations (or meaningful connections between items of information [e.g., all desserts]); systems (or complexes of interrelated or interacting relationships among objects, ideas, and events; double meanings, puns, homonyms, and redefinitions or shifts in meaning [e.g., “This is what I call cheesecake.”]); transformations (or various types of changes, such as redefinitions, shifts, transitions, or modifications in existing information [e.g., when baking a cake, if a recipe calls for two eggs and there is only one, a person might open one egg, put it into a measuring cup, and then double the volume by adding water or milk]); and implications (or the formation of hypotheses of what is expected, anticipated, suggested, or predicted by other information [e.g., “Desserts are sweet, fattening, and taste good; are sold in a bakery; are frequently chocolate; can often become stale or spoil,” and so forth]).

New experiences may cause the brain to place the experience into an existing unit or class; to create a new concept; to reprocess existing information and reformulate the structure of individual units or to group units together into classes, systems, and/or relations; to transform the information; and/or to see the implications of such information.

Language content is developed and used within the context of the speech act. Communication, which is a problem-solving task, usually is initiated and/or maintained to convey meaning about certain topics or ideas or to convey an intent. For example, during communication, an individual may become aware that it is necessary to describe something (an intent) that he or she knows (cognition). The individual may sort through all the possible ways to express this intent (divergent thinking) and may make a judgment, based on past experience, that certain content would be inappropriate (evaluation) for his or her purpose, intent, or listener. The individual therefore comes to a logical conclusion about the conventionally best content for his or her intent (convergent thinking) and then conveys the content to the listener.

Form: Language Is a System

The rules of language specify how to arrange symbols to express ideas (McCormick & Schiefelbusch, 1984). Specifically, a system of rules determines the “ways in which sounds combine to form words and words combine to form sentences for representing knowledge” (Bloom & Lahey, 1978, p. 7). For words, a limited number of rules specify which sounds can and cannot combine. For sentences, a limited number of rules specify how linguistic elements (words and morphemes) are combined to code meaning (Bloom & Lahey, 1978; Lahey, 1988). According to Slobin (1971), syntax is a device that relates sound and meaning. Thus, the form of language or system of rules “is the means for connecting sounds or signs with meaning” (Bloom & Lahey, 1978, p. 15).

Linguistic competence is a system of rules that relates semantic interpretations of a sentence to their acoustic phonetic representations (Slobin, 1971). It is a set or system of rules for processing utterances (Slobin, 1971).

Two rule systems in English are word order and markers. Word order tells us about the subject-object relationship. Markers can be divided into two types: function words (*the, a, with*) and suffixes (*-s, -ing*). The markers do such things as identify classes (e.g., *the* identifies a noun), specify relations (e.g., *with* relates *girl* to *eyes*), or signal meanings (e.g., *-ing* signals ongoing activity, and *-s* signals plurality), and so on (Slobin, 1971).

Chomsky (1957) postulated two basic sorts of rules or two levels of sentence interpretation. Phrase structure rules generate deep structures, which are directly related to the meaning of the sentence. The semantic component of grammar “relates deep structures to meanings” (Slobin, 1971, p. 19). Transformational rules convert deep structures into surface structures. The surface level of a sentence is directly related to the sentence as it is heard. The phonologic component of grammar “converts surface structures into sound patterns of spoken utterances” (Slobin, 1971, p. 19).

According to Chomsky (1972), the surface structure often is misleading and uninformative: “Our knowledge of language involves properties of a much more abstract nature, not directly in the surface structure” (p. 32). Because the meaning is not always directly expressed in the sounds we hear, we must have rich inner mental structures that make it possible to utter and comprehend sentences (Slobin, 1971). We cannot explain language learning on the basis of observable “stimuli” and “responses” alone, because all of the information for the processing of speech is not present in observable behavior” (Slobin, 1971, p. 19). Rather, the individual is biologically predisposed to learn a set or system of rules for processing utterances.

Grammar, then, is

a device for pairing phonetically represented signals [into a] system of abstract structures generated by the syntactic component. Thus, the syntactic component must provide for each sentence (actually for each interpretation of each sentence), a semantically interpretable deep structure and a phonetically interpretable surface structure, and in the event that these are distinct, a statement of the relation between these structures. (Chomsky, 1964, p. 52)

Abstract structural patterns underlie grammatical sentences. Understanding a sentence is based on knowledge of this structure. Indeed, “you can only make sense of the string of words you hear if you know . . . the grammar of your language” (Slobin, 1971). This syntactic knowledge or finite system of rules makes it possible for us to comprehend and generate an infinite number of sentences and connect sounds or signs with meaning.

These rules of language that allow us to process and/or generate utterances and connect sounds or signs with meaning

are learned by “listening to the language of the environment and abstracting from it the rules that are used to generate it” (Naremore, 1980). Individuals do not learn language form and then apply it to meaning. Rather, they focus on what they see and hear and then “use their conceptual capacity for linguistic inductions” (Bloom & Lahey, 1978, p. 72) to develop a knowledge of language content, form, and use to communicate meaning. Meaning is the essence of language (Goodman, 1971).

Developing a language system is a problem-solving task. It involves, among other things, hypothesis formation, abstraction, transfer, judgment of class inclusion, and generalization. As individuals process and use semantic and behavioral information, they become aware that the system of rules they now possess is not adequate for expressing meaning or what they would like to say. Becoming aware that a problem exists is a matter of cognition, often involving implications. Next, the problem in the rule system is analyzed or structured, which usually involves cognition of systems. After the problem is structured, the individual generates a variety of possible ways to code what he or she wishes, which is divergent production. If sufficient basis for a solution to the rule system is cognized and then produced, there is convergent production. At each stage in the process, there is evaluation or judgment in the form of accepting or rejecting cognitions of the problem and the generated solutions. At any step, what happens may become fixated and retained for possible later use, so memory is involved. When evaluation leads to rejections, there may be new starts, with revised cognitions and productions.

Thus, we learn new forms of language when our present system of rules proves to be inadequate for expressing meaning. The acquisition of new rules comes about in the form of new discriminations in terms of new products. Individuals learn rules gradually, by testing hypotheses of what a form can express in different situations where they think the rule might be appropriate for the expression of meaning.

Use: Language Is Used for Communication

Communication is an assertive act of coping—an active problem-solving task. It is a constant attempt to vary the content, form, and acceptability of a message; to switch or shift sets of reference as topics change (Muma, 1975); and to be sensitive to the influence of one’s communicative partner and the physical context in which communication occurs (Prutting & Kirchner, 1983) to achieve a message of best fit and, thus, effective and efficient communication (Muma, 1975).

Therefore, communicative competence implies knowledge of how to converse with different partners and in different contexts (Craig, 1983) as well as knowledge of the rights, obligations, and expectations underlying the maintenance of discourse (Ochs & Schieffelin, 1979). It is a knowledge of who can say what to whom, in what way, where, when, and by what means (Prutting, 1979).

Pragmatics involves the acquisition and use of such conversational knowledge and of the semantic rules necessary to communicate an intent to affect the hearer’s attitudes, beliefs, or behaviors (Lucas, 1980). Such semantic knowledge develops and is “used within the context of a speech act, a theoretical unit of communication between a speaker and a hearer” (Lucas, 1980). According to Searle (1969), the speech act includes “what the speaker means, what the sentence (or other linguistic elements) uttered means, what the speaker intends, what the hearer intends, what the hearer understands, and what the rules governing linguistic utterances are” (p. 12). Speech acts include making promises, statements, requests, assertions, and so on (Table 17-1). In Searle’s theory, the proposition is the words or sentences produced, and the elocutionary force of this proposition is the speaker’s intent in producing the utterance.

Thus, pragmatics involves the interactional aspects of communication, including sensitivity to various aspects of social contexts (Prutting & Kirchner, 1983). It is an analysis of the use of language for communication. The emphasis is not on sentence structure but on how meaning is communicated—that is, how units of language function in discourse (Prutting & Kirchner, 1983).

Pragmatics is inextricably related to cognition, and indeed, the conversational knowledge or discourse structures that are derived by an individual are the products of one or all of the five SOI cognitive processes or operations. The incoming semantic and/or behavioral information is processed by cognition, memory, convergent thinking,

divergent thinking, and/or evaluative thinking to generate pragmatic (semantic and/or behavioral) units, classes, relations, systems, transformations, and implications. Communication (and, therefore, pragmatics or language use) is an active process of problem solving. We learn new pragmatic rules when our present pragmatic knowledge proves to be inadequate for a situation or when something in our experience is unfamiliar or unpredictable. The acquisition of new pragmatic information comes about in the form of new discourse structures as a result of the use of one or all of the five mental operations of the SOI model.

Discourse Structures

A number of cognitive/pragmatic products or discourse structures are discussed in the literature. These relate to physical context variables, communicative partner variables, communication of intent, and turn-taking rules (including topic selections, maintenance and change, code switching, and referential skills) (Table 17-1).

Physical Context Variables

A pragmatic view of language assumes that language will vary with each context, that contexts are dynamic, and that any language sample therefore will be the interactive product of contextual variables and the individual's structural linguistic knowledge (Gallagher, 1983). Various conversational settings may affect the number and variety of utterances produced by a speaker (Gallagher, 1983). For example, one may have a rule that says, "Don't talk in church"; one that says, "Don't talk loudly in an elegant restaurant"; and yet another that says, "Cheer loudly for your team at a football game."

As individuals encounter various contexts or settings, they categorize or classify these contexts and either simultaneously or subsequently develop rules for interacting in specific types of contexts. The individual tries to determine if he or she knows or recognizes the context; may, perhaps, try to think of all of the other possible responses or behaviors that might be appropriate to this context; may make judgments about certain variables within the context; may try to hypothesize what is expected, anticipated, or suggested for this or for analogous situations; and so on.

Communicative Partner Variables

Specific communicative partners may affect the length, complexity, redundancy, fluency, and responsiveness (e.g., elaborations of comments), semantic relatedness of comments, and amount of eye contact during an utterance (Gallagher, 1983). Indeed, partner characteristics, such as age, sex, familiarity, and status, frequently affect communication. Again, the individual categorizes and classifies partners and develops rules for interacting with specific partners, types of partners, and groups of partners.

When people first encounter a potential communicative partner, they may determine if they know or recognize the partner or type of partner. They may sort through all the possible topics or intents that would be appropriate for this partner and, subsequently, judge or evaluate the form, reference, and acceptability of various possible communications and the implications of such communication.

Communication of Intent

Language is used to communicate a variety of intentions. For example, Dore (1974) specified the following intents: to label, to respond, to request, to greet, to protest, to repeat, to describe, and to call attention to something. The intents specified by Searle (1969) are to request, to assert, to question, to order, to argue, to advise, and to warn.

Language intent may be communicated and comprehended through semantic-syntactic utterances and/or by previous or subsequent utterances. In addition, intent may be expressed (and comprehended) through facial expression or accompanying actions, gestures, or tone of voice. What is not said also may communicate intent. In addition, one can say one thing but mean another. Individuals frequently use their knowledge regarding the physical context variables and the communication partner to help them decipher between what is said and what is meant. Thus, the communication of intent involves the use of semantic content (what is said) as well as behavioral content, or the nonfigural and nonverbal information that communicates the attitudes, needs, desires, moods, intentions, perceptions, and thoughts of others and ourselves. It may even involve the use of symbolic content when symbolic gestures are used.

Individual intents are semantic and/or behavioral units—that is, items or "chunks" of information. These units are developed when the brain processes semantic and behavioral experiences using the five cognitive operations. New experiences may cause the brain to place the experience into an existing unit or class; to create a new concept; to reprocess existing information and reformulate the structure of individual units or to group units together into classes, systems, and/or relations; and/or to see implications of such information. The way in which the individual chooses to communicate an intent at any particular point will reflect his or her knowledge of physical context variables and his or her communicative partners. Thus, the individual evaluates group membership, ability of the listener to interpret the various levels of complexity, receptiveness to various intents, and so on. Comprehension of the intent will be based on the units, classes, systems, relations, transformations, and implications that the listener has already established as well as on the information, associations, or products that he or she has constructed with respect to this specific partner or class of partner, this type of context, and this type of topic. According to Haviland and Clark (1974), comprehension of

an utterance in context also involves relating new information to assumed information. Thus, the individual makes a judgment based on past experience as to what is new information and what he or she can assume this particular partner knows.

Turn-Taking Rules

The reciprocal nature of communication involves a number of aspects, including the initiation of the speech act and the maintenance of communication. Initiation of the speech act (as speaker) includes topic selection and introduction and/or change of topic. Usually, the communicative act should contain new, relevant, and what is judged to be sincerely wanted information. It is important to evaluate the implicitly shared information aspect of the communication act. Thus, topical or referential identification involves searching one's long-term memory for information that is judged to be relevant to this partner, wanted by this partner, and perhaps, interesting.

Maintenance of communication involves a number of variables. First, role taking involves the establishment and variation of roles with respect to the speaker and the listener and the reciprocal roles of speaker-initiator and listener-respondent.

The listener's role is to comprehend the speaker's message, which involves cognition. The listener maintains this role with nonverbal (behavioral) responses that are "characterized by visual orientation rather than gaze avoidance" (Davis & Wilcox, 1981, p. 172), a nod of the head, or leaning forward. The listener also may respond with a short and, usually, affirmative verbal response, such as "Yes."

Feedback to the speaker is essential as well. This involves the listener's ability to monitor and evaluate the speaker's message and ability/willingness to indicate whether he or she believes it is effective and acceptable. Listener feedback will depend on the listener's previously established concepts of effectiveness and acceptability in general and his or her concepts that are relevant to this speaker and this context. Occasionally, the listener will assist the speaker in conveying the message, which involves cognition, judgment, and possibly, convergent and divergent thinking.

Role switching may occur as a result of the speaker's desire to relinquish the role. It can be communicated and/or comprehended semantically and/or behaviorally. In many instances, nonverbal (behavioral) cues are used by partners to signal a wish to maintain or change roles (Harrison, 1974; Rosenfeld, 1978). The speaker usually retains his or her role by gaze avoidance and a hand gesture that is not maintained or not returned to a resting state through a phonetic clause juncture (Rosenfeld, 1978). When a speaker wants a listener's reaction, he or she signals "with a pause between clauses" or "with a rising or falling pitch at the end of a phonemic clause" (Davis & Wilcox, 1981, p. 171). Thus, the listener needs to use knowledge of such cues as well as the

cues themselves to formulate a judgment concerning the speaker's willingness to switch roles. When role switching occurs in the absence of the speaker's readiness to switch, however, it may be accompanied by overloudness and a shift of the head away from the speaker (Davis & Wilcox, 1981), which would be behavioral content.

Maintenance of communication also may involve a response that sustains a topic (the listener becomes the speaker)—one that involves a specific response to the speech act. For example, contingent utterances are utterances that share the same topic as the preceding utterance and that add information to the previous communication act. A contingent utterance is an elaboration of the speaker's topic. Production of contingent utterances usually involves semantic and behavioral cognition to understand or comprehend an utterance and its intent; convergent production, or a logical and sequentially ordered response; and divergent thinking, or an elaboration of a topic and judgment as to the relevance, accuracy, and appropriateness of a response in this context to this communicative partner.

Maintenance of communication also involves a sequential organization of topics. Thus, adjacent utterances are used as well. These are utterances that occur immediately after a partner's utterance but that are not related to the speaker's topic. Such utterances are considered to be logical or possible elaborations of communication and, therefore, involve convergent and divergent semantic thinking.

Repair and revision also are part of discourse maintenance and regulation. This involves the speaker's sensitivity to cues provided by the listener, which involves semantic and behavioral cognition and judgment and the ability to respond to such cues by repeating and/or modifying the message when necessary. It involves the speaker's use of convergent production, divergent production, and judgment. Moves by the speaker and the listener to repair sequences and respond to such regulatory devices as requests for clarification are essential to the maintenance of communication (Fey & Leonard, 1983).

Code switching is the degree to which the individual can produce stylistic variations in the form or frequency of specific acts to meet situational requirements (Fey & Leonard, 1983), such as the ability to role play. Judgment is essential.

In 1975, John Muma addressed the issue of role/code switching. In his article, he differentiated between two different variations in one's method of communication. One he called "dump," and the other he called "play." Dumping pertains to the issuance of a coded message. Play involves ascertaining needed changes for appropriate recoding of a message and making necessary adjustments to achieve the message of best fit. According to Muma, role-taking attitudes involve the active resolution of communicative obstacles of form, reference, and acceptability in an effort to achieve the message of best fit for a particular situation and listener. It is the ability to issue a "message in the most

appropriate form for conveying intended meanings to a particular person for particular efforts” (p. 299). In role taking, “both speaker and listener are active participants in formulating, perceiving and revising messages until necessary adjustments are made in form, reference or psychological distance, and acceptability in order to convey intended meanings” (p. 299). The objective of true communication is aimed at ascertaining or judging which message is most suited to achieve effective and efficient communication.

Content, Form, and Use

Language learning and use, then, are problem-solving tasks. A problem is presented whenever a situation calls for the individual doing anything novel to cope with something that is different from his or her past behavior. A problem is a question or a proposition that necessitates consideration and a solution (Webster, 1977). Problem solving involves the use of all five mental operations, all types of content or information, and any kind of product, depending on the context in which the problem arises and the kinds of products that are required to reach a solution.

If the information is immediately recognized, known, comprehended, or understood, the mental operation of cognition has occurred. When situations call for the individual to generate logical conclusions from given information where emphasis is on achieving conventionally best outcomes, convergent thinking occurs. When a novel response is required, the divergent operation is generated. Inserting newly gained information into storage involves the operation of memory. Judging the appropriateness, acceptability, relevance, and/or correctness of information requires evaluation.

The three types of language knowledge that develop and are used (content, form, and use) are products of these five mental operations. Normal language functioning, then, requires the efficient action and interaction of all five cognitive processes for effective decoding (cognition and memory) and encoding (convergent thinking, divergent thinking, and evaluative thinking) to occur.

ASSESSMENT OF COGNITIVE OPERATIONS

Guilford and Hoepfner (1971) developed a number of tests to assess each of the five mental operations. A list of some of these tests follows.

Semantic Awareness/Recognition Tests

Verbal Comprehension Choose a word that means about the same as the given word.

Reading Comprehension Answer questions about a short passage.

Verbal Opposites Give a word that is opposite in meaning to the given word.

Sentence Synthesis Rearrange scrambled words to make a meaningful sentence.

Vocabulary Choose the alternative word that has the same meaning as a word that completes a sentence.

Semantic Memory Tests

Picture Memory Recall names of common objects pictured on a previously studied page.

Recalled Words Recall words presented on a study page.

Word Recognition Recognize whether given words were on a previously studied page.

Memory for Facts Answer questions regarding information previously given in two sentences.

Convergent Semantic Tests

Picture Group Naming Write a class name for each group of five pictured objects.

Associations Write a word that is associated with each of two given words.

Largest Class Form the largest class possible from a given list of words so that the remaining words also make a class.

Attribute Listing List attributes of objects needed to serve a specific function.

Divergent Semantic Tests

Common Situations List problems that are inherent in a common situation.

Brick Uses List many different uses for a common object.

Product Improvement Suggest ways to improve a particular object.

Consequences List the effect of a new and unusual event.

Object Naming List objects that belong to a broad class of objects.

Differences Suggest ways in which two objects are different.

Similarities Produce ways in which two objects are alike.

Word Fluency List words that contain a specified word or letter.

Planning Elaboration List many detailed steps needed to make a briefly outlined plan work.

Semantic Evaluation Tests

Word Checking Choose one of four words that fits a single criterion.

Double Descriptions Select the one object of four that best fits two given descriptions or adjectives.

Class Name Selection Select a class name that most precisely fits a group of four given words.

Commonsense Judgment Select the two best of five given reasons why a briefly described plan is faulty.

Behavioral Tests

Alternate Expressional Groups Group pictured expressions in different ways so that each group expresses a common thought, feeling, or intention.

Cartoon Predictions Choose one of three alternative cartoon frames that can be most reasonably predicted from the given frame.

Expression Grouping Choose one of four expressions that belongs with a given group by virtue of common psychological dispositions.

Expressions Choose one of four expressions that indicates the same psychological state as another given expression.

Other Assessment Techniques

Torrance (1966) adapted Guilford and Hoepfner's (1971) work on divergent thinking and developed the *Torrance Test of Creative Thinking* (Torrance, 1966). (Norms are available only for children.) Parts of this test, along with other tests from Guilford and Hoepfner (1971), have been used with patients who have aphasia, right brain damage, or closed-head injury as well as with elderly individuals (Braverman, 1990; Chapey, 1974, 1983; Chapey & Lubinski, 1979; Chapey et al., 1976, 1977; Diggs & Basili, 1987; Law & Newton, 1991; Schwartz-Crowley & Gruen, 1986) to assess abilities and impairments of specific mental operations in these groups. The *Test of Problem Solving* (Zachman et al., 1983), which was developed to measure reasoning abilities in children, also can be used with adults to assess specific cognitive semantic abilities, such as explaining inferences, determining causes, answering negative "wh-" questions, determining solutions, and avoiding problems.

Other techniques for assessing cognitive semantic abilities can be obtained through the Educational Testing Services' Test Collection Department, which has a number of unpublished research instruments measuring aptitude and cognition. Several of these measures target Guilford and Hoepfner's (1971) mental operations.

Clinicians who use the cognitive semantic approach to intervention also may evaluate the specific language assets and liabilities of each patient so that the therapeutic effort is individualized to fit the needs, interests, and abilities of each person who receives such therapy. For example, clinicians may want to explore the nature of each patient's language impairment, including performance on appropriate tasks, types(s) of errors made, and the manner in which each patient goes about tasks (Byng, Kay, Edmundson, & Scott, 1990).

In addition, clinicians may need to break tasks (e.g., comprehending sentences, reading aloud single words, gesturing, hailing a bus, filling in a check, and turn taking) down into their component processes and examine the functioning of each of those processes in detail (Byng et al., 1990) to derive hypotheses about the nature of the underlying processing

problems in the language deficits in specific patients. A more in-depth discussion of assessment techniques can be found in Chapter 4.

INTERVENTION

The present writer agrees with Martin (1979) that:

1. **Normal functioning** is the "efficient action and interaction of the cognitive processes which support language behavior within and by the organism". The disorder is a "reduction of the efficiency of action and interaction of the cognitive processes which support language behavior".
2. **Therapy** is "the attempt to manipulate and to excite the action and interaction of the cognitive processes which support language behavior within and by the organism so as to maximize their effective usage . . . Therapy [is] directed toward the subsystems which process language" (pp. 157–158).

Within the context of the present chapter, the cognitive processes or subsystems that process language are cognition, memory, convergent thinking, divergent thinking, and evaluation. Aphasia is a reduction in the efficient action and interaction of these processes, and therapy is an attempt to manipulate and excite the action and interaction of these processes. We employ strong, controlled, and intensive figural, symbolic, semantic, and behavioral stimuli—most frequently, semantic stimuli—to elicit the action of cognition, memory, convergent thinking, divergent thinking, and evaluation. These are the cognitive processes or the complex events that happen in the brain.

What is happening between the stimulus and the response is that the individual is using one or all of his or her mental operations. Task input is defined as figural, symbolic, semantic, and/or behavioral stimuli. Processing occurs through the use of cognition, memory, convergent thinking, divergent thinking, and evaluative thinking. Output is generated in units, classes (or categories), relations, transformations, systems, and implications. This holds true for problem-solving, decision-making, learning, and language tasks.

Rationale

A cognitive approach to therapy is based on the belief that propositional language (H. Jackson; cited in Head, 1915) or functional communication is an active problem-solving task that necessitates the use of all five cognitive processes. These operations are the intervening, mediating variables or constructs responsible for language comprehension and production. Thus, cognitive semantic therapy advocates the stimulation of all five mental operations, because this type of processing is required for the comprehension and production of spontaneous language. Indeed, most definitions of

language and communication have components that are highly suggestive of all five operations. For example, Hughy and Johnson (1975) state that language is used primarily for information getting and giving, problem solving, and persuasion. Another definition, that proposed by Muma (1975), notes that communication entails the ability to switch or shift sets of reference as topics change, to initiate such shifts, and to overcome obstacles to communication flow. Both definitions reflect the fact that language and communication require the use of all five cognitive processes.

The ability to produce functional communication or spontaneous speech also involves what Noam Chomsky (1957, 1964) refers to as deep structure and surface structure. Deep structure specifies the basic relationship being expressed—who did what to whom. It tells the meaning relationship. The surface structure is the actual sentences that are spoken and written. Meaning often is not audible or visible. Rather, the listener or reader must identify the relationships of the concepts to the events being communicated or described. Understanding a message depends on the memory structure of the people involved in the communication. The entire structure is not communicated if the receiver of the information can already be assumed to understand certain basic concepts. That is, some relations are assumed to be known or to be relatively easy to discover and, therefore, not necessary to mention.

According to Chomsky (1957, 1964), not everything we know about a sentence is revealed in the superficial string of words. That is, all information for processing speech is not present in observable behavior. Meaning is not directly expressed in the sounds we hear and the words we read. Our capacity to interpret sentences depends on our knowledge of deep structure. We do not learn a set of utterances (surface structures). Rather, we learn methods of processing utterances. We have rich cognitive structures that make it possible to utter and comprehend sentences.

In everyday communication, surface structure frequently is deficient, misleading, and uninformative. For example, there are extensive deletions, extensive use of pronouns, and ambiguous referents. Nevertheless, meaning structure may be communicated. Therefore, language is an aid to communication. Production of spontaneous, functional language, and therefore, deep and surface structure requires the use of all five mental operations. These are the methods for processing utterances, the rich cognitive structures that make it possible to comprehend and produce sentences. Cognitive therapy therefore targets all five mental operations for the production of meaningful ideas and the elaboration of those ideas.

A third rationale is based on the observation that patients with aphasia are unable to produce the highest-level central nervous system integrations (Wepman, 1951). Research by Bolwinick (1967) indicates that the highest-level cognitive integrations are thinking (e.g., convergent thinking, diver-

gent thinking, and evaluative thinking), problem solving (all five cognitive operations are viewed as essential components of problem solving), and creativity (divergent thinking is used as a synonym for creativity). Tasks using all five mental operations will focus on the essence of the aphasic impairment—that is, inability to produce the higher-level cognitive integrations.

Cognitive therapy also is rooted in the observation that aphasia is a problem in language retrieval (Schuell et al., 1964) or in the searching and scanning mechanism that selects among many possibilities. Schuell and colleagues (1964) noted that the search mechanism is controlled by instructions, directing it to go to a specific address and bring out information. They suggest that appropriate stimuli are required to activate or reactivate patterns. The information-processing model presented in this chapter hypothesizes that divergent production and evaluative production both involve the use of a broad search of memory storage, whereas cognition and convergent production involve a narrow search of long-term memory. Tasks that stimulate retrieval under a variety of cognitive operations appear to facilitate the patient's reorganization and retrieval of language. Specifically, the stimuli presented foster the action of a broad and narrow search of memory within the individual. The clinician attempts to manipulate the patient's retrieval strategy to aid the patient in making maximal responses.

Another appeal of the Guilford SOI model is that it is a model of learning (Chapey, 1994). Indeed, the acquisition and use of knowledge may involve the use of the five mental operations in the model: memory, recognition/comprehension, and convergent, divergent, and/or evaluative thinking (Chapey, 1994).

In addition, the Guilford SOI model has statistical validity. That is, the entire model has been proven to exist in "normal" individuals (Guilford, 1967; Guilford & Hoepfner, 1971), and the mental operations have been proven to exist in individuals with aphasia (Chapey, 1974, 1977a, 1983, 1988, 1992, 1994; Chapey & Lubinski, 1979).

The fourth appeal of the model is that some individuals may solve problems and make decisions more effectively and efficiently when they use a structured problem-solving, decision-making model.

Accountability

Despite the wide acceptance of the cognitive and pragmatic approaches to therapy in our literature, and the acceptance of the distinction between deep structure and surface structure, many intervention agencies and many government agencies mandate that each therapy session have an operationally written, behavioral goal. Many clinicians also use such goals. For example, the audience (American Speech-Language-Hearing Association–certified speech-language pathologists) at a workshop were asked to write short-term

goals for a moderately language-impaired patient. More than half wrote goals such as "By the end of this session, X will say the name of five common objects."

Behavioral, operationally written objectives, however, are counterproductive to the development of language. They are unacceptable within both a cognitive model and a pragmatic model of intervention. Behavioral objectives target surface structures. Cognitive and pragmatic intervention focus on meaning or deep structure. In cognitive-pragmatic intervention, we attempt to increase the patient's viability as a communicative partner (Lubinski, 1986).

Behavioral, operationally written objectives are inappropriate, because they ignore the fact that meaning is the essence of language and that meaning is not an observable behavior. They ignore the fact that a conversation is like a game. It involves a series of moves by participants. Every conversation is altogether new for the participants. Therefore, we continually communicate creativity (Lindfors, 1980). (Lindfors' text concerns language intervention in children.)

Behavioral, operationally written objectives ignore the fact that content and form are developed and used within the context of a speech act. The individual develops communicative competence "through discerning rules underlying the diverse interaction contexts which she observes and in which she participates" (Lindfors, 1980, p. 311).

Behavioral, operationally written objectives ignore the fact that the speaker's intent in producing an utterance and a hearer's intent in hearing an utterance are the essence of communication and meaning. The intent of the message is the reason we communicate. The intent is the function that language serves. We use verbal utterances to express an intention or function. We use language to question, request, and inform. Our attention as speakers and listeners is on the meaning, the intention of what someone is trying to say (Cazden, 1976). Language forms are heard through the meaning that is intended (Cazden, 1976). Thus, communication is idea oriented, not word oriented. Language is rooted in meaning, not in surface structures. Language is used for communication. It is a tool, not an end in itself. Language is an aid to communication.

Clinical aphasiologists may wish to encourage regulating agencies to realize that language is facilitated by an environment that focuses on meaning rather than on form. Getting the message across is more important for individuals than the form they use to do so.

These agencies should realize that "language is not labeling or matching pictures to words or repeating what someone else said" (Holland, 1975, p. 518). (Holland's article concerns language intervention in children.) Instead, language is "an active, dynamic interpersonal interchange" (Holland, 1975, p. 518). If we focus on tasks like labeling, matching pictures to words, or repeating what someone else said, then "we run the risk of inadvertently teaching the

erroneous principle that language is a skill on the order of playing the piano. This helps the [individual] . . . miss the point of communicating" (Holland, 1975, p. 518). In fact:

Language training must be to some very significant extent concerned with helping [the individual] . . . discover his potential as a verbal communicator. Without this discovery, language will remain something akin to a well practiced talent, a recital, not a . . . part of him. (Holland, 1975, p. 519)

Verbalizations must not replace language. Drill is not language. According to Lindfors (1987), "there is no language apart from meaning" (p. 217). Language "is communicating—the back and forth, the give and take of ideas, not . . . the mindless parroting of rigid, fixed forms" (Lindfors, 1980, p. 218). Where in a language drill is the meaning that we know to be the very base of language (Lindfors, 1980)? Where is the creativity, the novel expression, that is the core of language? Where is the communicating—the interacting with someone, about something, for some reason (Lindfors, 1987)?

Drill is opposed to language in its meaninglessness, in its rigidity, and in its purposelessness (Lindfors, 1987). Drill may make clients very good at doing drills, but not at using language and communication. Indeed, according to Lindfors, drill may adversely affect language growth and retrieval. She maintains that problem solving, planning, discussing ideas, brainstorming, recording ideas, presenting ideas, and selecting the best ideas involve listening, speaking, reading, and writing with a purpose. The real question is, then, is the individual a more effective user of language after completing an exercise or drill? The answer is no. We become more effective communicators as a result of using language in communication with others. According to Lindfors (1980):

labeling syntactic (or semantic) items simply makes you a better "syntactic item labeler" (at least for a few days). Talking about forms doesn't help you express meaning more effectively. (p. 220)

Lindfors apparently believes that it is inappropriate to structure a simple-to-complex sequence of forms. Rather, the communication itself will determine the language forms that the individual uses and responds to. She believes that we need to focus on language use for effective communication. When we do so, our clients may then use the language forms that help them to accomplish effective communication.

Individuals, Lindfors (1987) claims, become effective interactants as they have more opportunities to interact. Language intervention should reflect the individual's interests, goals, activities, concerns, and life participation. Natural shaping of semantics and syntax happens not through sequenced curriculum but, rather, through feedback as to whether one has been understood and whether one has achieved the purpose of the communication.

New meanings find expression as individuals wonder, question, inform, argue, and reason through language in

real-life situations rather than in contrived situations (Lindfors, 1987). Language lives in shared experience, in decision making, and in planning. Language is stimulated and facilitated by an environment that is rich in diverse verbal and nonverbal experiences. Language lives and grows in rich experiences.

As human beings, we develop a theory of the world in our head (Smith, 1975). Our theory shapes how we look at past experience (recall and interpret it) and how we look at new experience. We comprehend or interpret the world by relating new experience to the already known—that is, by placing new experiences in our existing cognitive structure or “theory” (Smith, 1975). To learn is to alter our existing cognitive structure when experience does not conform to our theory (Lindfors, 1987).

Language helps us to comprehend and learn—especially as language is used in questioning (curiosity and procedural or social-interactional questioning), focusing attention, making understandings more precise, making understandings more retrievable, reinterpreting past experience, and going beyond present personal experiences (Lindfors, 1987). Interaction is essential to both comprehension and learning. In real gut-level, meaningful learning, what is to be learned cannot be specified in advance. Such learning is characterized by curiosity, exploration, problem solving, planning, decision making, discussion of ideas, brainstorming, and evaluative thinking (Chapey, 1988, 1992; Guilford, 1967; Lindfors, 1980, 1987).

The present pressure to establish accountability has actively discouraged exploration, curiosity, and problem solving. Skills, drills, rules, and facts have become ends in themselves (Lindfors, 1987). We have packaged clinical programs with a renewed emphasis on memorizing words, defining words, and identifying parts of speech in sentences that no one ever said or ever will say, and all so that individuals can get higher standardized test scores and move on to the next-higher level of memorization, definition, and identification (Lindfors, 1987).

As a profession, we are first and foremost concerned that our clients become competent communicators (Frattali, 1992). Emphasis on learning rote skills and specified sets of behaviors means increased emphasis on the use of lower-level cognitive processes (Lindfors, 1987). Lower-level cognitive behavior means that clients can give back the same information they received (recalling, memorization), but to display higher-level cognitive behavior, they must go beyond the given information in some way—for example, relating it to something else, reorganizing it, inferring from it, and using it as a springboard for creatively solving new problems. It involves applying, analyzing, synthesizing, and evaluating. Questioning is the individual’s most important tool for learning—especially curiosity questioning (Lindfors, 1987). Conversation should be the locus, process, and goal of language intervention (Warren & Rogers-Warren, 1985).

Content-centered discussion therapy and embellishment of ideas within a topic (Wepman, 1972, 1976) should be our focus.

OBJECTIVES OF THERAPY

The objective of a cognitive approach to rehabilitation is to stimulate the five cognitive processes—cognition (awareness/attention, immediate discovery, recognition, comprehension), memory, convergent thinking, divergent thinking, and evaluative thinking—to improve overall functional communication. Whenever possible, the focus should be on the stimulation of these abilities within the context of conversational discourse. That is, conventional discourse is seen as the procedural plan for intervention. Whenever possible, turn taking, cueing, modeling, and reinforcement are essential components of therapy.

General Objectives

The general objectives are:

1. To stimulate ability to recognize and comprehend language.
2. To stimulate ability to fix new information in memory to improve communication.
3. To stimulate ability to generate logical information or conclusions during communication.
4. To stimulate ability to generate logical alternatives to given information, produce a quantity and variety of responses during communication, and elaborate on ideas and plans during communication.
5. To stimulate ability to make judgments or appraisals or to formulate evaluations in terms of criteria such as correctness, completeness, identity, relevance, adequacy, utility, safety, consistency, feasibility, social custom, and so forth to communicate more effectively and efficiently.
6. To stimulate the integration of all cognitive operations through the use of problem-solving, decision-making, and planning tasks and through conversational discourse to communicate more effectively and efficiently.

This approach contains four levels of specific objectives. This model of therapy, however, suggests that, regardless of the level at which the patient is functioning, the initial stage of intervention should focus on language-related cognition: knowing, awareness, immediate discovery, recognition, comprehension, and understanding. This suggestion is based on the rationale that individuals with aphasia should be provided, over and over again, with opportunities to hear and grasp the language behavior of others. That is, auditory stimulation is seen as an essential component of language retrieval in patients with aphasia (Schuell et al., 1955). Thus, for example, the clinician might videotape a

group of normal adults responding to a divergent task, such as “Can you think of a problem that anyone might have in eating lunch?” Concomitantly, the patient could be reinforced for all listening and attending behavior. Specifically, movements of the eye that result in a better visual stimulus for the patient or of the ear that result in a better auditory stimulus (Staats, 1968) of the videotape would be reinforced. Although no verbal responses would be required during this phase of therapy, all verbal responses that relate to the task at hand could be highly reinforced.

Exposure to the videotaped responses of others may prove to be a vicarious learning experience (Bandura & Walters, 1963; Harris & Evans, 1974) for the individual with aphasia. This suggestion appears to be in consonance with the finding by Cooper and Rigrodsky (1979) that persons with aphasia are able to model the verbal behavior of normal subjects and improve their explanations of the material presented. If modeling is to occur, however, it may be helpful to consider several facts. First, it may be beneficial if the subjects on the videotape are of comparable age and sex as the individual with aphasia; this way, the patient will identify with the person who is producing the divergent responses. Second, the clinician could attempt to choose tasks that are interesting and relevant to the particular subject. Third, considering that Pieres and Morgan (1973) empirically determined that a relaxed, receptive, and uncritical environment increased the divergent behavior of normal subjects, it may be important to provide this type of climate for persons with aphasia. This exposure to the divergent semantic behavior of others, perhaps filed in competitive “game show” style (Torrance, 1974), can continue to be a component of the intervention strategy throughout the process of therapy.

Principles

Intervention should be oriented toward the following traditional therapeutic principles:

1. Begin with the tangible (here and now), and move toward the representational.
2. Begin with the concrete, and move toward the abstract.
3. Begin with the simple, and move toward the complex.
4. Begin with the real, and move toward the complex.
5. Begin with actions on objects, and move toward verbalizations concerning these actions.
6. Begin with simple classifications, and move toward reclassifications and multiple classifications.
7. Begin with exaggerated sensory stimulation—for example, talking through a microphone or using a variety of inflectional patterns (McConnell, Love, & Smith, 1974)—and then gradually decrease this exaggeration.
8. Begin with short stimuli/responses, and move toward longer stimuli/responses.

9. Begin with continuous reinforcement, and move toward intermittent reinforcement (Grant, Hake, & Hornseth, 1951; Jensen & Cotton, 1960).
10. Begin with clinician reinforcement, and move toward self-reinforcement (Staats, 1968).

During the course of both diagnosis and therapy, the aphasiologist will attempt to isolate specific conditions under which language retrieval is maximized and to increase the number and variety of these conditions. That is, with whom and under what conditions does language behavior increase? The clinician may wish to manipulate some of the following variables and observe their effect on patient behavior: listener, referent, intent, situation, cueing devices, repetition and reauditorization, intonation, level of abstraction, cognitive complexity, linguistic complexity, length of stimuli, and frequency of occurrence of word stimuli. The conditions that augment semantic retrieval for each cognitive operation should become an integral component of all subsequent sessions. Examples of specific objectives at each of the four levels of therapy are presented below.

Level I: Specific Objectives

To stimulate ability

Cognition

- To be aware of time/space/speech/emotional voice tone
- To recognize stimulus equivalence, such as matching letters, matching objects to objects, matching objects to pictures, matching words to pictures, and matching words to objects
- To recognize very high-frequency, concrete objects/events/relationships named
- To recognize own name/family names
- To follow one-part, simple commands
- To understand simple greetings/requests/questions

Memory

- To remember one to two letters/words/pictures
- To remember one to two high-frequency, concrete objects/events named

Convergent Thinking

- To repeat one-syllable, high-frequency objects/events/relationships
- To produce automatic language
- To complete high-probability closure tasks

Level II: Specific Objectives

To stimulate ability

Cognition

- To recognize concrete, high-frequency, familiar objects/events/relationships
- To recognize family names/body parts/community helper occupations
- To recognize high-frequency objects given their function
- To recognize high-frequency events described
- To recognize concrete, brief ideas
- To comprehend simple conversation with one person
- To understand concrete, high-frequency statements about objects, such as existence, nonexistence, recurrence, rejection, denial, possession, food, clothing, and personal care objects
- To understand concrete, high-frequency, brief statements about events, such as playing, eating, and activities of daily living
- To comprehend concrete agent-action and action-object constructions
- To comprehend concrete yes/no questions
- To comprehend concrete active and negative phrases/sentences
- To comprehend articles
- To comprehend morphologic inflections, such as plural /s/, /z/, possessive /s/, /z/, and past /t/, /ed/
- To comprehend concrete noun phrases and verb phrases
- To recognize forms/letters/pictures
- To recognize high-frequency printed words and pictures
- To match high-frequency printed words to spoken words
- To recognize printed letters

Memory

- To remember one to three concrete, high-frequency objects/events/relationships, serially
- To execute one- to two-step commands, serially
- To remember one to four pictures, serially
- To group items to facilitate ability to recall

Convergent Thinking

- To produce automatic language
- To complete high-probability phrases/closure tasks
- To name high-frequency objects/events/relationships
- To comment on objects noting their existence, nonexistence, recurrence, location, possession, and so forth
- To talk about common objects, such as food, clothing, furniture, and transportation
- To comment on events, such as cooking, eating, and activities of daily living
- To produce agent-action and action-object constructions
- To produce concrete speech acts, such as requesting, informing, greeting, and questioning
- To name members of categories
- To list many words that start with a specific letter

- To generate numerous and varied objects within a class
- To list numerous possible topics of conversation

Level III: Specific Objectives

- To stimulate ability

Cognition

- To recognize high- and low-frequency objects/events/relationships
- To recognize high- and low-frequency objects/events/relationships described by function
- To recognize letter/color/form/number names and rhyme words
- To recognize phonetically similar words
- To recognize categories
- To comprehend concrete ideas/sentences
- To understand relationships between words
- To understand statements about objects, such as existence, nonexistence, recurrence, rejection, denial, possession, attribution, food, furniture, clothes, personal care objects, health, kitchen utensils, and family/other people/places/locations
- To understand statements about events, such as play, entertainment, eating, activities of daily living, cooking, feelings, sports, school, work, travel, time, and news
- To understand concrete speech acts, such as requesting, ordering, advising, warning, questioning, describing, greeting, repeating, and protesting
- To hold the thread of discussion in mind, identifying main ideas
- To distinguish between relevant and irrelevant information
- To understand television/movies
- To comprehend inferences
- To comprehend short paragraphs
- To recognize the existence of problems
- To recognize own errors and errors of others
- To comprehend simple, concrete analogies
- To comprehend active and negative sentences
- To comprehend pronouns, such as personal, reflexive, indefinite, demonstrative, interrogative, and negative
- To comprehend adjectives, such as color, size, shape, length, height, width, age, taste, temperature, speed, distance, comparative, and superlative
- To comprehend adverbs with “-ly”
- To comprehend conjunctions
- To comprehend prepositions, such as locative, temporal, and directional
- To read concrete, high-frequency and low-frequency sentences
- To read and comprehend sequences of material
- To read and comprehend short paragraphs
- To read and identify main ideas

- To read and obtain facts
- To read and locate answers
- To read and draw conclusions
- To read and grasp relationships
- To read and grasp inferences
- To read street signs
- To read newspaper headlines/newspaper stories/newspaper ads

Memory

- To identify one to five names serially
- To follow one- to five-part directions and commands
- To remember one to five ideas/facts just presented
- To group items to facilitate recall
- To remember meaning in sentences/short paragraphs/stories/songs

Convergent Thinking

- To answer questions about self/family/everyday life
- To name high- and low-frequency objects/events/relationships
- To name categories
- To name objects/events/relationships within categories
- To describe objects/events/relationships
- To tell the function of objects and the purpose of events
- To define words
- To judge the suitability of class inclusion
- To judge the similarity of relationships
- To judge the suitability of class properties
- To identify absurdities
- To evaluate implications
- To express simple ideas with specificity
- To sequentially order ideas or topics toward a purpose
- To retell stories—both the literal (who, when, what, and where) details and the inferential implications
- To describe procedures
- To state the relationship between objects/events, such as similarities/differences
- To predict possible outcomes
- To make inferences and draw conclusions
- To answer true/false, yes/no, and “wh-” questions
- To write letters and numbers
- To write own name and address
- To write sentences with high-frequency, concrete words

Divergent Thinking

- To produce numerous logical possibilities/perspectives/ideas where appropriate
- To provide a variety of ideas where appropriate
- To change the direction of one’s responses
- To generate categories of objects/events/relationships/ideas
- To predict many different possible outcomes of situations

- To generate many different solutions to problems
- To list many different problems inherent in situations
- To generate numerous steps in a plan
- To elaborate on a topic

Evaluative Thinking

- To judge the correctness, completeness, identity, relevance, adequacy, utility, safety, consistency, logical feasibility, and social acceptability of facts
- To judge the suitability of words to a topic

Level IV: Specific Objectives

- To stimulate ability

Cognition

- To comprehend high- and low-frequency objects/events/relationships
- To recognize concrete and more abstract classes/concepts
- To understand relationships among objects/events/ideas
- To comprehend analogies
- To recognize problems
- To recognize own errors and errors of others
- To comprehend concrete and more abstract speech acts in conversation with one to five partners
- To follow changes in the topic of conversation
- To hold the thread of discussion in mind and identify main ideas
- To understand changes in interpretation
- To comprehend TV/movies
- To comprehend more rapid, complex conversations
- To comprehend longer sentences/directions/commands
- To comprehend more complex/abstract relationships, such as comparative, possessive, spatial, temporal, inferential, familial, part-whole, object-action, action-object, cause-effect, sequential, degree, and antonym and synonym relationships
- To comprehend negative, passive, and question transformations
- To read both short and concrete as well as longer and more abstract sentences/paragraphs
- To read and identify main ideas
- To read and obtain facts
- To read and locate answers
- To read and draw conclusions
- To read and grasp relationships
- To read and draw inferences
- To comprehend newspaper stories/ads
- To comprehend catalog/mail-order forms
- To comprehend a menu
- To comprehend a table of contents/index
- To use a dictionary/telephone directory

Memory

- To remember one to nine high- and low-frequency objects/events/relationships/categories
- To remember facts and commands of increasing length and complexity
- To remember meaning in sentences and paragraphs
- To use hierarchical organization to facilitate recall
- To cluster information to facilitate recall

Convergent Thinking

- To describe high- and low-frequency objects/events/relationships
- To indicate the function of high- and low-frequency objects/events/relationships
- To specify attributes of objects
- To specify the defining attributes of concepts
- To define words
- To express ideas clearly and with variety
- To use language to communicate specific ideas
- To use language to elicit specific responses
- To express relationships between and among objects/events/relationships and ideas, such as similarities and differences
- To produce analogies
- To sequentially order ideas toward a purpose
- To use language to request, inform, explain, question, greet, advise, thank, order, and negotiate
- To keep meaning going in conversation
- To produce class names for groups of words/pictures
- To logically deduce the most predictable outcome of a set of facts
- To tell the literal (who, what, when, and where) details of a story
- To make inferences and draw conclusions
- To write high- and low-frequency words, sentences, and paragraphs

Divergent Thinking

- To produce numerous logical possibilities and perspectives where appropriate
- To provide a variety of ideas where appropriate
- To change the direction of one's responses
- To stimulate ability to generate many different uses for common and uncommon objects
- To predict many possible outcomes of a situation
- To list many different problems inherent in a common situation
- To think of many different ways to initiate a conversation
- To think of many different ways to maintain a conversation
- To define many possible rules for communicative partners and communicative contexts
- To think of many different ways to repair conversation
- To elaborate on topics

- To elaborate on or list many different steps needed to do a particular task

Evaluative Thinking

- To make appraisals, comparisons, and formulate evaluations regarding correctness, completeness, relevance, adequacy, utility, safety, consistency, logical feasibility, and social acceptability
- To judge the intent of messages
- To judge the coherence of a conversation
- To judge what can and cannot be said in different contexts and to different partners
- To use context and partner variables to decipher between what is said and what is meant
- To determine the meaning of proverbs
- To judge a situation in which a proverb could be used
- To select the word that best fits a single criterion
- To select the best of given reasons why a briefly described plan is faulty

Integration of the Five Cognitive Processes

Within the present therapeutic approach, all five mental operations are integrated in therapy by requiring responses that involve composite abilities. Problem solving, planning, decision-making tasks, and conversational interaction are excellent for this purpose, because they are composite operations or processes depending on the content of the problem, decision, or conversation and on how the problem/decision/conversation is worded or phrased. Thus, whereas conversational interaction, such as the use of speech acts, sometimes is convergent in nature, it also often will involve the use of other mental operations and become problem solving, planning, and decision making in nature, depending on the listener, the context, and the intent. Individuals can be stimulated to use language to question, request, inform, wonder, argue, reason, and comprehend such speech acts.

In addition, formulating solutions to problems posed in the "Dear Abby" or "Dear Meg" column of the local newspaper can be used to stimulate all five cognitive operations. If carefully chosen, such tasks reflect "real-life" situations that patients face—or can allow patients to increase their self-concept, because their opinion is being sought and valued. The use of such tasks is conversational in nature and, frequently, allows reciprocal role reversal. These tasks therefore can be used to stimulate brainstorming, discussing, recording and presenting ideas, and selecting best outcomes. They also can be used to stimulate individuals to question (curiosity, procedural, and social-interactional), focus attention, make understanding more precise, reinterpret past experience, and go beyond present personal experience. In addition, conversational management, conversational turn taking, topic

manipulation, and conversational repair management can be targeted using these tasks.

Thus, whenever possible, intervention should involve the stimulation of two or three (or more) mental operations. For example, the clinician might begin a session by asking the client, "Can you list all of the things that can be folded?" After the patient has produced some responses, the clinician summarizes these responses and asks, "Can you think of any more?" (Table 17-2). When the client has finished responding, the clinician then uses convergent techniques, such as those described by Aurelia (1974); Butfield and Zangwill (1946); Goldstein (1948); Keenan (1975); Sarno, Silverman, and Sands (1970); Schuell and colleagues (1955); Vignolo (1964); and Wepman (1953), to stimulate retrieval of appropriate and desired responses that the patient had not produced. Such techniques might involve confrontation naming, recognition naming, oral spelling, reading, categorizing similar responses, creating sentences with a word, and so forth (Table 17-2). In an attempt to develop each patient's ability to correct his or her own errors, the clinician may use cueing techniques, such as those suggested by Berman and Peelle (1967). For example, the initial letter of a word could be used as a cue technique. Alternative stimuli for self-cueing might include (a) the first phoneme of a word, (b) the association of a word with a gesture, or (c) the use of an incorrect associational response to cue the correct verbal response. Subsequently, the aphasiologist attempts to transfer the semantic material retrieved in the convergent context and integrate this information into a divergent one. For example, the clinician might ask another divergent question that would call for some of the responses that the patient has been able to retrieve, such as "Can you think of all of the things that we could pull over our heads?" (Table 17-2). Progress is evaluated by keeping a record of the number and variety of responses produced by the patient (Table 17-2).

Spontaneous language tasks that have divergent, convergent, and/or evaluative components also are used in therapy. For example, the clinician might present a picture description task, such as the cookie theft picture from the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1972), and encourage the client to produce as many responses as possible (see Yorkston & Beukelman, 1977). Clients also can be encouraged to produce functional spontaneous communication related to a specific theme (Wepman, 1976), such as food, nutrition, food service, restaurants, great parks, interesting sights, vacation destinations, health and diet, sexual issues, social security, legal and money issues, current events, and pharmaceutical issues (the American Association of Retired Persons' magazine, *Modern Maturity*, provides interesting and timely topics for the audience age 50 years or older). In each instance, the clinician records the number and variety of ideas produced by the client.

Levels III and IV: Specific Objectives to Stimulate Use of Composite Abilities

- To stimulate ability
- To use language to explain, request, correct information, report, advise, question, greet, thank, argue, and negotiate
- To comprehend speech acts produced by another
- To overcome obstacles in communication
- To keep meaning going in conversation
- To role play (especially to take the viewpoint of someone else) during communication
- To select, introduce, maintain, and change the topic of conversation
- To initiate and maintain conversation
- To use language to discuss objects, events, and relationships
- To use language to communicate specific ideas
- To use language to elicit specific responses
- To use language to verbalize a variety of possibilities and perspectives, such as the pros and cons of ideas and issues, the advantages and disadvantages of certain actions, and ideas
- To vary language depending on the context
- To vary language depending on the partner
- To comprehend various speech acts and intents in relationship to various partners and contexts
- To produce stylistic variations to meet situational requirements
- To overcome obstacles in communication
- To repair and revise communication
- To use cues as a signal to repeat or modify messages
- To provide feedback to the speaker, as listener, such as requesting message clarification/repetition/restatement, requesting that the message slow down, requesting the message in alternate form, and indicating agreement/disagreement with message
- To define the problems and solutions inherent in certain objects, events, and relationships
- To use a telephone
- To use a telephone directory, a dictionary, and a television schedule item
- To use street and store signs and maps

THERAPY TASKS AND MATERIALS

Guilford and Hoepfner (1971) developed a number of tasks for each of the five mental operations. Some of these tests have been listed previously under "Assessment." All of these tasks can be readily used to stimulate specific mental (cognitive) operations during therapy. Most traditional workbooks in the field of aphasia have presented tasks that stimulate cognition (recognition/comprehension) and convergent thinking. Within the last few years, however, a number of workbooks have been published that focus on the stimulation of divergent thinking, evaluative thinking, problem solving, and decision making.

TABLE 17-2

Sample Therapeutic Plan That Includes Both Divergent and Convergent Tasks

Objective	Tasks ^a	Cue	Evaluation
<i>General</i> —to stimulate the communication of ideas	Greeting <i>Divergent Tasks</i>		
<i>Specific</i> —to stimulate language related to a holiday, Christmas, through divergent and convergent thinking	1. We're coming close to Christmas. What are all of the things that you think of when you think of Christmas? 2. Someone mentioned that Santa carries a sack. Can you think of all of the things that could fit into Santa's sack? 3. What are all of the things we might get for Christmas that: Could be folded? Couldn't be folded? Might break if they were dropped? Wouldn't break if they were dropped? We could wash? Could be hauled in a truck? We could pull over our head? Might have buttons? Could be worn in summer (winter)? Could be made of paper? Could come in a box? Could be round (square)? Are made of glass (plastic, rubber)? Someone could drink? Someone could eat? Has handles? Has a neck? Moves? 4. List all of the things that you could possibly use a Christmas box for (or bells, string, ribbon). 5. How could you improve ____ so that it would be more useful (better, more fun)? 6. If Santa didn't have a sack, he could use ____. If Santa lost his belt, he could use ____.	After 2 minutes, summarize responses given and ask, "Can you think of any more?" Same as above Same as above Same as above Same as above Same as above Same as above	1. (a) List responses _____ _____ Total fluency _____ (b) List categories _____ _____ Total flexibility _____ 2. Score as in question 1. 3. Score as in question. 1. 4. Score as in question 1. 5. Score as in question 1. 6. Score as in question 1.

(continued)

TABLE 17-2

Sample Therapeutic Plan That Includes Both Divergent and Convergent Tasks (continued)

Objective	Tasks ^a	Cue	Evaluation
	7. Imagine you are in a department store (church, living room) at Christmas time. What are all of the things that you might possibly see?	Same as above	7. Score as in question 1.
	8. Let's make up a story about Christmas.	Same as above	8. Score as in question 1.
	9. The word <i>Christmas</i> begins with the sound "k." What other words can you think of that start with "k"? The word <i>bell</i> begins with the sound "b." What other words can you think of that start with "b"?	Same as above	9. Score as in question 1.
	10. What are all of the possible questions that you could ask about this Christmas picture?	Same as above	10. Score as in question 1.
	11. List all of the different parts of Santa's suit. How could we change each one to make it better?	Same as above	11. Score as in question 1.
	12. Suppose that we did not celebrate Christmas anymore. What do you think might happen? Can you guess?	Same as above	12. Score as in question 1.
	13. List all of the problems that someone might have in shopping for a Christmas present.	Same as above	13. Score as in question 1.
	14. Someone mentioned a cymbal and a drum. They make noise. Can you list all of the things that could be used to make noise?	Same as above	14. Score as in question 1.
	15. Santa's suit is red. What are all of the other things that could be red?	Same as above	15. Score as in question 1.
	16. Tomorrow we will have a Christmas party. What are all the different things we'll need to do before the party?	Same as above	16. Score as in question 1.
	<i>Convergent Tasks</i>		
	Present responses given to question 1. Oral and/or visual representation of responses can be used. (Later, responses to question 2, then question 3, and so on, can be presented.)		
	Responses that might be appropriate to this question but that were not given by the patient are now presented.	Give first sound of a word	Use Porch's (1971) multidimensional scoring system to evaluate responses

TABLE 17-2

Sample Therapeutic Plan That Includes Both Divergent and Convergent Tasks (continued)

Objective	Tasks ^a	Cue	Evaluation
	Convergent techniques that might be used to stimulate retrieval of items not produced are: a) Confrontation naming b) Definition naming c) Closure naming d) Recognition naming e) Repetition naming f) Following oral and/or printed directions or commands g) Yes/no comprehension h) Word associations: antonyms, synonyms i) Rhyming j) Description k) Recognition spelling l) Oral spelling m) Analogies n) Recognition of categories o) Spontaneous generation of categories p) Concept learning q) Reading r) Writing s) Copying t) Creating sentences with words u) Creating sentences telling the function of an object v) Memory tasks w) Read a story, and ask questions x) Read a story, and retell a story y) Role play	Give first letter of a word Give semantic association	

^aTurn taking, cueing, modeling, and reinforcement are essential components of therapy.

RELATIONSHIP OF COGNITIVE INTERVENTION TO WEPMAN THOUGHT PROCESS THERAPY

Wepman (1972) notes that the aphasic patient frequently substitutes a word that is associated with the word that he or she is attempting to produce, and that the remainder of the individual's communicative effort often relates to the approximated, rather than to the intended, word. In addition, the inaccurate verbal formulation of the person with aphasia may feed back an altered message to the thought process and, thereby, change the thought process so that it is in consonance with the utterance. For example, if the patient is trying to say "circle" and, instead, utters "square," his or her concept of circle may change so that it agrees with the utterance, and the patient will begin to think of a circle as a

square. Wepman suggested that aphasia may be a thought process disorder in which impairment of semantic expression is the result of an impairment of thought processes that "serve as the catalyst for verbal expression" (p. 207).

Individuals who cannot retrieve the most appropriate lexical symbol for a context are impaired in their ability to communicate a number and variety of specific propositional ideas. When the remainder of the person with aphasia's communication relates to the approximated rather than to the intended word, spontaneous language will be even more impaired, because in this instance, the patient becomes incapable of using the learned code to communicate his or her true feelings and thoughts.

For Wepman (1972, 1976), the first stage of therapy is content-centered, discussion therapy, in which the patient is

stimulated to remain on a topic. Similarly, cognitive therapy is content centered and idea oriented; the individual is encouraged to generate functional communication and produce a variety of ideas related to topics.

During Wepman's (1972, 1976) second stage of therapy, individuals are encouraged to elaborate on various topics. The ability to elaborate on a topic is a divergent ability. Thus, Wepman's thought process therapy involves stimulating convergent, divergent, and evaluative thinking as well as recognition/comprehension and memory.

RELATIONSHIP OF COGNITIVE INTERVENTION TO RESPONSE ELABORATION TRAINING

Response elaboration training (RET) is a program developed by Kearns (1985, 1990; see also Gaddie, Kearns, & Yedor, 1991; Kearns & Potechin, 1988; Kearns & Yedor, 1991) to increase the length and information content of verbal responses of patients with nonfluent aphasia. RET is a "loose training" program that attempts to loosen control over stimuli and response during therapy by using client-initiated responses as the primary content of therapy. The emphasis is on shaping and chaining client-initiated responses. Patients are encouraged to elaborate (think divergently) on "whatever they are reminded of" when they are responding to picture stimuli of everyday activities and sports. Naming and describing are discouraged. Informational content rather than linguistic form is reinforced.

Specifically, according to Kearns (1990),

The basic RET sequence entails (1) eliciting spontaneous responses to minimally contextual picture stimuli, (2) modeling and reinforcing initial responses, (3) providing "wh-" cues to prompt clients to elaborate on their initial responses, (4) reinforcing attempted elaborations and then modeling sentences that combine initial and all subsequent responses to a given stimulus picture, (5) providing a second model of sentences that combine previous responses and then requesting a repetition of the sentence, (6) reinforcing repetitions of combined sentences and providing a final model of the sentence. Throughout this sequence clients' responses are not directly corrected by the clinician. Instead, naturalistic feedback is provided during the structured interactions through conversational modeling.

Progress during RET is measured by counting the number of content words per stimulus picture (fluency) and the variety of responses to the same stimulus picture (flexibility). Novel and varied responses are encouraged. Thus, RET stimulates fluency, flexibility, originality, and elaboration—or divergent semantic thinking as well as functional spontaneous speech, which necessitates all five mental operations.

Kearns' (1990) data demonstrate that RET procedures facilitate an increase in the amount of information (i.e., number of content words) generated by individuals with

aphasia. Further, a moderate degree of generalization across stimuli, people, and settings was reported.

RELATIONSHIP OF COGNITIVE INTERVENTION TO LIFE PARTICIPATION APPROACH TO APHASIA

Communication creates and is created by life participation. Therefore, the Life Participation Approach to Aphasia (LPAA) model directs our choice of goals, priorities, activities, and strategies used in intervention to the purpose, direction, meaning, comfort, pleasure, needs, and life participation decisions and problems of each individual affected by aphasia. Such life participation necessitates the use of effective and efficient problem-solving and decision-making skills (Tables 17-3 and 17-4). In addition, various life-span theorists emphasize the importance of social integration and participation for the physical and emotional health and well-being of all individuals. Indeed, such participation in mundane yet meaningful, valued activities of everyday life provided the structure and meaning for living life (Duchan, 1999).

Case Study

P is a 67-year-old, mild to moderately impaired man with aphasia, 3 months poststroke, with a left cerebrovascular accident and right hemiplegia who lives with his wife, T. Before the stroke, both were active in the local church, but they had not returned since P's stroke. Both reported feeling isolated and cut off from life and wanted to go to an upcoming church-sponsored event—a trip to Atlantic City (famous for its gambling casinos, reasonable meals, beaches, and shopping). Both had reservations about how practical and advisable their involvement might be and about the reaction they might receive from others.

Goals

Life-enhanced participation governed management from day 1 (Tables 17-1 and 17-2). The main goal was to restore purpose, direction, meaning, comfort, and pleasure in the daily lives of P and T by facilitating their access to communication partners and events of their choice and to train caregivers, family, friends, and neighbors to communicate more effectively with both individuals. Therefore, the initial goals were:

- To determine the extent to which P and T and persons associated with them could partake in and achieve life participation goals
- To determine the extent to which P and T and persons associated with them were being hindered in the attainment of such goals

TABLE 17-3

Pre- and Post-Therapy Questionnaire for Life Participation/Communication: For the Person with Aphasia and Significant Others; Both Observational and Self-Reported—With and Without Support

Identity
Autonomy of life participation
In social context
In family
In medical context
Degree of life participation
In life events
With other people
Relationships
Value as participant
Role
Count of number of people seen
Of places
Of activities
Environmental barriers (and changes)
Changes in social connection
Communication function (Simmons, 1993)
Interactional (sharing ideas, thoughts, and opinions)
Verbal, gestural, cued
Transactional (transfer of information)
Verbal, gestural, cued
Ability to communicate independently
Personal competence revealed
Impairment (and changes in)
Ability to cope with impairment
Degree of comfort
Function
Involvement
Pleasure
Success
Quality of daily life
Feelings of self-esteem
Feeling of being in control of one's life
Level of flow in one's life
Analysis of specific life events (Duchan, 1999)
Participants: Who is participating?
Goal: Why are they participating?
Type of interaction: What is the type of social interaction required?
Part of activity: What part of the activity are they engaged in?
Attitudes: What are the attitudes of the participants:
Toward activity?
Toward their partners?
Toward goals?
Expectations (e.g., for social connection; general improvement in sense of well-being)
Perception of (and changes in perception)
Health-care worker
Family
Significant others

- To identify and increase personal and environmental factors facilitating harmony, comfort, purpose, and participation in life
- To identify and decrease personal and environmental obstacles disrupting harmony, comfort, purpose, and life participation
- To identify and facilitate attainment of the needs and goals of all individuals in the environment
- To increase/maximize P's ability to initiate and direct conversation/discussions, convey a number and variety of ideas across (with or without prompts, props, and cues), convey a message using whatever strategy might be useful (e.g., to encourage use of graphic and drawing representations, natural gesture, pictures, travel brochures, menus, and books), and practice conversational skills within the context of conversational exchanges
- To focus on conversation as a collaborative achievement, to provide communication/conversational support, and when appropriate and necessary, to train partners/communities in these techniques to use volunteers as conversational partners
- To provide and demonstrate a problem-solving, decision-making approach model for P and T and to encourage them to structure theme-oriented, problem-solving, decision-making, conversationally based interactions using the five mental operations.

Goals were constantly assessed, weighed, and prioritized to determine which personal and environmental factors should be targets of intervention and how best to provide freer, easier, and more autonomous access to activities and social connections. Every attempt was made to have consumer-based/self-generated rather than clinician-generated goals and activities and to provide autonomous choice whenever possible.

Methods

The upcoming trip to Atlantic City appeared to be an attractive initial target of intervention, both because it meant so much to P and T and because it focused on doing things that result in communication as participation rather than on communication itself. Therefore, intervention focused on developing strategies and skills to increase the possibility of success directly related to reengagement/participation in the upcoming event. Most therapeutic tasks were problem-solving, decision-making, role-playing tasks focused on the five mental operations. When appropriate, however, therapy also made use of Wepman's (1972, 1976) content-centered discussion therapy (see above), conversational prompting (Cochrane & Milton, 1984), conversational coaching (Holland, 1991), training of conversation partners (Kagan & Gailey, 1993), RET (Kearns, 1985) (see above as well as Chapters 1, and 14), PACE (Promoting Aphasic Communicative Effectiveness) therapeutic techniques (Davis &

TABLE 17-4

Reengagement, Enhancement/Inclusion Strategies to Facilitate Meaningful, Functional, Optimal Access to Participation in Life, Well-Being, Wellness, and Quality of Life: A Plan for Action

Goals	Outcomes
Foster optimal meaningful, purposeful life participation, autonomy, and choice of lifestyle and activities	Increased meaningful ties to others
Facilitate optimal inclusion in and meaningful, purposeful connection to social and community activities/life	
Encourage strong social connections with people who matter, such as spouse, caregiver, family, and close friends	
Facilitate the restoration of function, purpose, direction, pleasure, comfort, and sense of well-being in daily life	Mastery of environment
Encourage optimal mastery of daily life events	
Encourage and facilitate support from significant others to optimize meaningful, purposeful life participation	Purpose/direction
Encourage and facilitate support for significant others to optimize meaningful, purposeful life participation	Self-acceptance
Recognize and remove environmental, structural, attitudinal, and informational barriers that limit or prevent participation in normal social and community life	Harmony/well-being
Increase community resources that support life participation	Wellness
Work to build protected communities where individuals are valued participants	Quality of life
Enhance psychological adjustment, promote health and wellness, and foster a healthy sense of identity through life participation	Communication effectiveness
Reflect the fact that adaptation to the changes brought about by stroke is a complex, dynamic process that requires time and skill	Consumer satisfaction
Recognize and recalibrate the psychological effects that aphasia has on personal, social, and collective identities as well as on self-esteem, relationships, and role definitions	
Promote healthy psychological adjustment to grief and stress associated with the changes imposed by aphasia	
Facilitate the development of self-actualization, self-assertiveness, and self-advocacy skills	
Recognize and reduce negative internal barriers that decrease or prevent individuals from actively participating in life	
Reflect the curative factors in group work and the healing power of intimacy	
Increase feelings of harmony/well-being and quality of life	
Reflect that:	
Communication is a medium through which humans share life's experiences, happenings, and outcomes as well as ideas and feelings about them.	
Communication is inseparably bound to people, places, and purposes for its use.	
Communication creates and is created by participation in life.	
Communication is flexible and dynamic.	
Focus on conversation—and on conversation as a collaborative achievement	
Foster reasons to communicate	
Strive to enhance level of participation in conversation	
Promote abilities/opportunities:	
To communicate to maintain social relationships	
To communicate in natural, authentic contexts and social units or dyads	
To communicate to transmit information	
To communicate basic needs	
Empower individuals to demonstrate or reveal communicative competence and acknowledge such competence	
Work to increase ability to communicate independently	
Provide communication/conversational support, when appropriate and necessary, and train partners and communities in these techniques	
Work to reduce impairments while focusing on revealing competence/function	
Work to reduce impairments in the context of reducing barriers to life participation	
Relate functional communication to environmental factors as well as impairment	
Increase continuity and access to intervention ^a	

^a*Intervention* is a consumer-driven, dynamic, assistive, advising, empowering, interactive, collaborative process that responds to the significant, immediate, and long-term consequences that aphasia imposes on the flow of daily living and recognizes both that communication is inseparably bound to people, places, and purposes for its use and that communication creates and is created by participation in life. All intervention goals reflect the complexity of aphasia and the multiple contexts that it affects. Such goals are established collaboratively and are constantly assessed, weighed, prioritized, and renegotiated to decrease the devastating negative consequences of aphasia, foster adaptation to change, and increase meaningful social participation, purpose, harmony, and well-being in the lives of all those who are affected by aphasia. It is a process that evolves and changes over time, increasingly empowering those who receive it to be responsible for their own care. Outcomes are measured qualitatively and quantitatively.

Wilcox, 1981), and for restorative, impairment-centered, skill-level work, both stimulation therapy (see Chapter 15) and thematic stimulation therapy (see Chapter 16).

Education

The church social committee, several participants of the upcoming trip, and the home care nurse attended two meetings in which they viewed the video *What Is aphasia?* and discussed the language, psychological, and social consequences of aphasia. Sample tasks under the five mental operations included:

- What are all the possible environmental barriers that will make functioning (including communication) in a bus difficult?
- What are all the possible things that we could change in the environment to make communication more successful?
- What are all the environmental factors that will make functioning (including communication) in the casino difficult?
- What are all the things that we can do to increase the chances of communication success in this environment?
- What are all the environmental barriers that make group communication more difficult than individual communication?
- What are all the things that we can do to decrease the level of this difficulty?
- What are all the things that we can do to increase our (our partner's) communication success/failure?
- What are all the things that communication partners can do to help someone be more successful in getting his or her ideas across?

In addition, the therapist led the group in a discussion and modeled strategies for facilitating communication, such as those suggested by Simmons-Mackie; interactive drawing (Lyon, 1994, 1995); alerting to topic initiation and change; cueing/retrieval feature analysis, as suggested by Boyle and Coelho (1995); and communication consequences, as developed by Norris and Hoffman (1990).

For example, the communication consequences discussed by Norris and Hoffman (1990) include (1) acknowledgments or confirming the truth value of an utterance, (2) using very specific language, (3) extensions or adding new ideas within the same topic, (4) nonverbal responses, (5) verbatim repetitions, (6) restating or rewording what was said, (7) summarizing and integrating, (8) negation or indicating how and why what was said is untrue or unclear, (9) self-talk, (10) parallel-talk, (11) semantically contingent remarks, (12) sharing personal reactions, (13) questions and comments, (14) predictions and projections, (15) requests for repair or clarification, (16) requests for repetition, and (17) concept formation.

Interaction with Patient and Spouse

During intervention, both partners discussed some of the same questions as above. In addition, other tasks, such as those discussed below, were used with the partners.

Comprehension and Memory

The POSSE strategy suggested by Englert and Mariage (1991) was used to facilitate comprehension of and memory for content for stories:

P = **PREDICT** what ideas may be in the story.

O = **ORGANIZE** your thoughts (What happens? Where is it? What does it look like? Main idea?).

S = **SEARCH the STRUCTURE** (draw the structure out schematically).

S = **SUMMARIZE** the main idea.

E = **EVALUATE**, compare, clarify, and predict.

For example, the patient and spouse were asked to predict what the article "Stay Busy, Live Longer, Experts Suggest" (*New York Times*, August 24, 1999, p. F8) might be about and what the author might possibly mean by the word "busy."

Later, the patient and spouse were asked to draw a picture of the information in the article by putting the main idea in the middle of the page (stay busy = live longer; sense of purpose = live longer) and other ideas around it (physical activity; social activity; productive activity: cooking, shopping, volunteering, gardening).

Questions relating to divergent thinking in relation to this article include:

- What are all the things that people can possibly do to live longer?
- What are all the ways that you could possibly apply this information to your everyday lives?
- What are all the personal and environmental factors that can increase (and decrease) life participation for individuals with aphasia, their families, and their communities?
- What are all the things that add purpose, direction, and meaning to our daily lives?
- What are all the things that can possibly lead to comfort and pleasure in our lives?
- What are all the things we can do to restore the purpose, direction, and meaning in the lives of P and T?
- What are all the ways that the trip to Atlantic City relates to this article?
- What other things can you think of that relate to this article?

Pre-Trip Questions

- Who are the possible participants in the group?
- What are all the things we could possibly think of to plan a trip to Atlantic City?
- What are all the things we could possibly need to consider in planning a bus trip?

- What are all the things you can think of about Atlantic City?
- What are all the things you can think of about the Jersey Shore?
- What are all the things you might possibly see in Atlantic City?
- What are all the possible things that someone might bring with him or her on a trip to Atlantic City?
- What are all the possible things that someone might do (participate in) in Atlantic City (e.g., go to the beach, nightclubs, restaurants, go shopping, walk on the boardwalk, swim, sightsee)?
- What are all the possible things we need to take care of before we go to Atlantic City (e.g., personal care, banking, and medical)?
- What are all the safety rules we might possibly follow on a trip (to Atlantic City)?
- What are all the topics someone could possibly talk about on a trip?
- What are all the possible ways that someone can be a good conversational partner?
- What are all the things a good citizen should do when he or she goes to a new place?
- What are all the things we could possibly change that could increase our ability to go on these trips?
- What are all of your strengths that will make this a successful trip?
- What are all the possible things that someone can do to make a trip successful?
- What are our weaknesses that could possibly hinder you from having a successful trip?
- What are all the possible community resources that someone could use in preparing for a trip?
- Who are all the possible people who might be able to help us make a trip more successful?
- What are all the things that could possibly restrict your access to a trip to Atlantic City?
- What are all the possible problems we might have in going to Atlantic City with a church group (e.g., getting to the bus, on the bus, in the casinos, in the restaurants, at the beach/boardwalk, in the shops, and on the way home)?
- What are all the possible environmental/structural, attitudinal, and informational obstacles that limit or prevent participation in a trip to Atlantic City?
- What are all the possible things we might be able to do to avoid these problems?
- What are all the possible ways we could solve each of these problems?
- What are all the possible ways to cope when we have a problem?
- What are all the things we can possibly eat in Atlantic City?
- What are all the possible foods that someone can eat in a restaurant?

- What are all the things we should eat to be healthy?
- What are all the things we should not eat to stay healthy?
- What are all the things that we can bring to Atlantic City that can be folded? Cannot be folded? That someone could drink? That someone could eat?
- What are all the ways that someone can get to Atlantic City?
- What are all the things that could fit into a bus?
- What are all the possible places that someone can go by bus?
- What are all the possible activities that we can attend through the church?

Post-Trip: Consumer Satisfaction Questionnaire

- What were all the possible benefits of going on the trip?
- What were all the possible benefits of being members of the group?
- What are all the feelings that you have about the trip?
- What are all the positive things that happened on the trip?
- What were all the problems that occurred that we did/did not anticipate?
- What are all the ways we could possibly have anticipated them?
- What are all the ways we could possibly have solved them or coped with them?
- What are all the ways that we (or others) could have been better conversational partners?
- What are all the things we did before the trip that made the trip more successful?
- What are all the things we did that gave us a feeling of connection with others? A feeling of comfort and harmony?
- What are all the things we could have done to have made the trip more successful?

Memory

To facilitate P's memory, several strategies were used. First, the scaffolding techniques or prompts suggested by Norris and Hoffman (1990) were used. These included various prompts to cue P for more information. They included:

- **Additive** (and . . .)
- **Temporal** (and then; first; after; next; and when; while . . .)
- **Causal** (because; so; since; so that's; in order to . . .)
- **Adversative** (but; except; however; except that . . .)
- **Conditional** (of; unless; if-then; in case; or . . .)
- **Spatial** (in; next to; until he got to; which was on . . .)
- **Contingent Queries** or "Wh-" questions to prompt for agents, actions, objects, locations, or relational information
- **Summarization** or **Evaluation** to give the individual a second opportunity to communicate
- **Binary Choices** to offer alternative utterances
- **Phonemic Cues** to offer the initial sound or syllable of a target word

In addition, the semantic feature analysis developed by Boyle and Coelho (1995) was used. This technique prompts

the individual to identify the specific features of target pictures that they find hard to retrieve or name. For example, for “a quarter,” P needed to identify the following:

- **GROUP:** money, coin
- **USE:** buy things
- **ACTION:** give, get, spend
- **PROPERTIES:** round, shiny, large
- **LOCATION:** in a pocket, at a bank, in the casino
- **ASSOCIATION:** spending, getting things

Cognition

Recognition/comprehension tasks included:

- Reading and following signs, directories, menus, travel brochures from the chamber of commerce, the casinos, and the AAA
- Comprehending the video *What Is Aphasia?*
- Comprehending the video *Casino*
- Comprehending other videotaped material
- Comprehending newspaper stories (e.g., “Ruling in California Crimps Indian Plans for a Casino Empire” [Todd Purdum, *New York Times*, August, 24, 1999, pp. A1 and A11]; “Little Tribe, Casino Threatened, Battles U.S.” [New York Times, August 28, 1999, p. A7]; and “Stay Busy, Live Longer, Experts Suggest” [New York Times, August 24, 1999, p. F8])
- Reading short stories about gambling, Atlantic City, and the Jersey Shore

Skill-building, impairment-level recognition and understanding tasks included:

- **Matching Related Words** (e.g., draw a line from each word in the left-hand column to the related word in the right-hand column.)
- **Word Categorization Tasks** (circle the words that belong in the category “Atlantic City.”)
- **Word Categorization Exclusion** (e.g., cross out the word on each line that does not belong)
- **Write in a New Word that Does Belong**
- **Yes/No Questions** (e.g., read each question, and mark “yes” or “no.”)
- **Sentence Arrangement** of scrambled sentences for targeted core vocabulary items (e.g., Rearrange these words to form correct sentences: Atlantic City are we to going.)

Convergent Tasks

Answering “Wh-” question tasks include:

- What can I do when someone doesn’t understand me?
- What can I do when I don’t understand someone else?
- What can I do to get my partner to help me when I can’t get my idea across?
- What can I do to help my partner to get his idea across when I can’t understand him?

Other convergent tasks that might be useful are discussed below:

- **Using social greetings**
- **Object manipulation and description** (e.g., a slot machine).
- **Acting out and describing sequences with props** (e.g., using the slot machines or ordering lunch).
- **Picture description** (e.g., Describe this picture of “Taj Mahal Casino” or “Caesar’s Palace Casino”).
- **Event description** (e.g., Describe roulette).
- **Discussing videotaped material**
- **Structured answers** (e.g., What does the dealer deal? How many cards are in a deck?)
- **Identifying places and activities**
- **Answering questions** about reading material or videos
- **Barrier tasks**

Skill/impairment level convergent tasks included:

- **Repetition** of core vocabulary (e.g., Atlantic City—To Atlantic City—We’re going to Atlantic City)
- **Closure tasks** (e.g., We’re going to Atlantic City. We’re going to ____.)
- **Naming tasks** (e.g., What do we swim in?)
- **Category naming**
- **Defining core vocabulary**
- **Using core vocabulary words**
- **Giving directions**
- **Creating sentences** for target core vocabulary items (e.g., create sentences for these words and phrases, such as game-play)
- **Multiple choice questions** relating to core vocabulary

Evaluative thinking or judgment tasks included:

- Which activity should we work on first? Atlantic City or the Garden Club lecture?
- Which trip means more to you: the trip to Atlantic City or the lecture on roses?
- Which game is easier to play: the slot machines or poker?
- Because the trip is in August, which would be more useful to have with us: a bathing suit or gloves? A beach towel or a coat? Suntan lotion or a lamp?
- I can’t read the menu. Should I ask the waitress to tell me the choices or just point to anything?
- Which is more important for a pay phone call: a quarter or a five-dollar bill?
- Which is closer to New York: Atlantic City or Florida?
- Which is faster: a plane or a bus?
- I don’t know how to play a game. Which should I do first: Watch others play, or start to play myself?
- The sign says “Wet floor.” Should I walk across it or wait until it is dry?

Integrative tasks included:

- Conversation
- Procedural discourse

- Narrative discourse
- Unstructured discussions (e.g., the pros and cons of gambling, of a group trip, and of going to the beach)
- Role playing talking to fellow travelers on the bus
- Role playing being in the casino
- Role playing ordering in a restaurant
- Role playing shopping in a store
- Role playing being at the beach
- Watching video tapes about Atlantic City and discussing them
- Reading stories about the New Jersey shore and Atlantic City and discussing them

CONCLUSION

In summary, the model of problem solving and decision making presented here appears to be applicable to the LPAA approach because of its relevance to everyday life participation through its very specific structure or strategy for solving problems and the proven validity of the five mental operations both in “normal” individuals and in those with aphasia. It is hoped that use of this model, especially in conjunction with other models such as those cited in this chapter, will help those who use it to become more active, accurate, thorough, and effective problem solvers and decision makers, thus making it possible to achieve workable and effective solutions, resolutions, and adaptations to changing opportunities for participation in contexts that really matter and, thereby, facilitating optimum social, vocational, and recreational activity and reintegration.

Most of the literature on cognition, however, specifies what is learned, or the products of cognition. Similarly, the literature in language intervention specifies therapeutic objectives, or what is to be learned. Therapeutic objectives emphasize the types of tasks used. The goal of therapy is the appropriate accomplishment of these tasks. The criterion of success is based on the percentage of appropriate versus inappropriate responses.

Today, speech-language pathologists are shifting from an orientation of simplistic listing of tasks used in therapy, which define them as technicians, to a comprehensive understanding of the rationale behind the selection of these tasks and a description of why these tasks stimulate complex events to happen in the brain. This latter focus defines them as true clinicians.

An attempt to separate tasks into input, processing, and output components and, more important, the identification of the subsystems whose interaction is necessary for processing and specification of the complex events that happen in the brain may save us from performing therapeutic tasks backward. That is, we recognize that, during therapy, what we are attempting to stimulate is the patient’s mental operations or processes, because these appear to be the complex events that happen in the brain. We also stimulate these mental operations because functional language requires the use of these

mental processes. Thus, language therapy must reflect the fact that language is communicating—that it is the give and take of ideas. It must reflect the belief that meaning is the essence of language; that communication is idea oriented, not word oriented; and that it is purpose/intent oriented. It must be recognized that the speech act involves creativity and novelty of expression. This is the core of language. Language is an aid to communication.

Applying the Guilford model to adult aphasia has several other advantages. Most importantly, it enables us to identify and operationally define the action elicited within the patient by the stimuli presented, the complex events that happen in the brain, and/or the cognitive processes that are used in generating language products, such as words, classes, rules of languages, and semantic implications. It enables us to make use of an empirical statistically documented model or taxonomy of behaviors to give the concepts of cognition, information processing, and problem solving a firm, comprehensive, and systematic theoretic and yet operationally defined foundation. Guilford supported the separate and distinct existence of each of the 120 abilities in normal individuals through the use of repeated research studies using factor analysis. Some of these abilities, such as memory, divergent thinking, convergent thinking, evaluative thinking or judgment, and semantic and behavioral content, also have been documented in persons with adult aphasia, right brain damage, and closed-head injuries and in elderly individuals (Braverman, 1990; Chapey, 1977b; Chapey & Lubinski, 1979; Chapey et al., 1976; Diggs & Basili, 1987; Law & Newton, 1991; Lubinski & Chapey, 1978; Schwartz-Crowley & Gruen, 1986). In addition, this model provides a set of tests whose validity and reliability have been established. These tests can be used in therapy to stimulate specific parameters of the model and to assess, evaluate, and describe patient behavior. Use of these tests may help us to someday make a statement about the efficacy of treatment based on this model.

FUTURE TRENDS IN COGNITIVE SEMANTIC INTERVENTION

Recovery today is very documentation oriented—very focused on cost containment. This orientation generates a “pricing by activity” mentality in which governmental and insurance agencies emphasize unimportant but measurable goals, activities, and abilities. Many of these do not help the patient to regain as much functional, meaningful propositional language as possible or increase his or her ability to become better adept at the back and forth—the give and take of ideas.

The current emphasis on measurable, operationally written behavioral goals should be reconsidered. In the future, we need therapeutic goals and procedures based on rich and shared experiences that encourage individuals to apply, analyze, synthesize, and evaluate such real-life experience; relate it to something else; reorganize it; infer from it; and

use it as a springboard to solve new problems creatively. A cognitive approach to recovery appears to meet this need. In addition, it has the added advantage that stimulating thinking and cognitive processing may facilitate the individual with aphasia's natural acquisition ability—that is, the ability to acquire language independently.

A cognitive approach also may stimulate generalization. Therefore, a strong need exists to develop additional therapeutic materials appropriate for this approach. A strong need also exists to develop assessment protocols that will measure these cognitive-semantic processes separately and within the context of functional, meaningful communication. Such a measure may help clinicians to assess progress in therapy and generalization and, therefore, sharpen our quality-assurance systems.

KEY POINTS

1. The Guilford SOI model contains four types of content, five mental operations, and six types of products or associations.
2. Intelligence can be defined within this model in terms of 120 abilities (content $\times$ operation $\times$ product). Therefore, we can assess the individual's intelligence for each ability.
3. Cognition can be operationally defined by the use of one or more of the five mental operations in the Guilford model: recognition/understanding, memory, convergent thinking, divergent thinking, and evaluative thinking.
4. Communication is a problem-solving, decision-making task that usually involves the back and forth, give and take of ideas between partners in a specific context. This usually involves the use of one or all five mental operations or cognitive processes.
5. Language involves the use of three types of knowledge: content, form, and use or function. Each of these can be defined within the context of the Guilford model as semantic and behavioral information processed by one or more of the five mental processes and resulting in one or more associations or products.
6. Spontaneous speech, communication, problem solving, decision making, learning, and information processing are composite abilities, often requiring several abilities to function together to achieve a desired goal.
7. The objective of cognitive stimulation therapy is to stimulate the five mental operations at various levels of complexity and in composite abilities, such as spontaneous speech, to increase ability to participate in meaningful and personally relevant activities and life goals.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Write a definition of language based on the five mental operations in the Guilford model. How would aphasia be defined within this definition?
2. Create an interactive exercise for clients to practice the use of divergent thinking using two of the following topics: gardening, travel, dining out, food shopping, meeting a stranger, and World War II. List vocabulary that you would consider to be important to this exercise.
3. Compare and contrast Chapey's cognitive definition of aphasia with those of:
 - Wepman
 - Schuell
 - Goldstein
 How are they the same, and how are they different?
4. List 10 questions that you would include on an assessment protocol for each of the following models of aphasia:
 - a. Chapey's cognitive definition
 - b. Wepman's definition
 - c. Schuell's definition
 - d. Goldstein's definition

Chapter 18

Early Management of Wernicke's Aphasia: A Context-Based Approach

Robert C. Marshall

OBJECTIVES

The early post-onset period encompasses the first 1 to 3 months after a stroke causing aphasia. This is a time when persons with aphasia and their families struggle with the uncertainties of the future and with day-to-day communication (Lyon, 1998; Marshall, 1997). Many patients with aphasia do not talk at this time, or they talk very little. Those with Wernicke's aphasia are an exception. These patients talk, but their aphasia interferes with communication in other ways. A different approach to clinical management therefore is required for these patients compared with that used for patients with other types of aphasia.

This chapter provides information on a context-based approach to management for patients with Wernicke's aphasia. This approach blends science, art, and common sense. Science comes from knowing and applying judiciously to treatment what research tells us about people with aphasia. The art is associated with knowing when to do what and with good clinical decision making. The common sense involves using therapy to improve communication skills relevant to the patient's daily life communication contexts. The material herein focuses on management during the early post-onset period, because this is when the patient's aphasia is most severe, when therapy occurs, and when the patient needs help the most. The chapter's objectives are (1) to provide a rationale for using the context-based with patients with Wernicke's aphasia, (2) to describe how context-based treatment is used to improve comprehension and information exchange in communication contexts, and (3) to increase clinicians' confidence and willingness to apply this unique approach to patient management.

WERNICKE'S APHASIA

Lesions responsible for Wernicke's aphasia occur posterior to the fissure of Rolando (Benson, 1967), leaving the patient

with few, if any, associated deficits. Some patients may have a right visual field deficit, but usually, no sensory loss or paralysis occurs (Kirshner, 2002). Often, Wernicke's aphasia results from blockages in the smaller, posterior branches of the left middle cerebral artery. These damage the primary auditory cortex (Brodmann areas 41 and 42), Wernicke's area (Brodmann area 22), and portions of the second temporal and angular gyri (Brodmann areas 39 and 40), sometimes with white matter extension (Bachman & Albert, 1990).

Damage to Wernicke's area may produce severe loss of speech understanding, even though the patient may hear nonverbal sounds and music normally (Boatman, 2002). Some patients' comprehension deficits appear to be related to attention difficulties and inability to effectively ignore distracting stimuli (LaPointe & Erickson, 1991; Wiener, Connor, & Obler, 2004). Classic descriptions of Wernicke's aphasia indicate these patients have disproportionately impaired auditory comprehension in relationship to their fluent speech (Goodglass & Kaplan, 1983; Kertesz, 1979). Often, speech is perceived as rapid, with preserved rhythm, melodic line, and articulatory agility (Geschwind, 1970; Goodglass & Kaplan, 1983), but disrupted in other ways. Verbal output may be (1) devoid of content or empty (e.g., "Before the one, my son took another of them over to the one there."), (2) full of circumlocutory phrases (e.g., "The one you eat soup with") and indefinite words (e.g., "thing") rather than specific words (e.g., "spoon"), and (3) contaminated by paraphasia (unintended word substitutions not caused by motor difficulties). The paraphasias may be verbal (e.g., "tiger" for "knife"), semantic (e.g., "knife" for "spoon"), or phonemic ("spoot" for "spoon"), and if they contain several unrelated sounds, even neologistic ("veehall" for "trailer").

Unlike the halting, agrammatical speech of patients with nonfluent aphasia, the speech of the patient with Wernicke's aphasia contains a variety of grammatical forms. Some patients, however, make para-grammatical errors in which the substitution of one small word for another (e.g., "him" for "her" or "she" for "he") disrupts communication markedly. Self-correction effort and successful repair occur less often in Wernicke's aphasia (Marshall & Tompkins, 1982), and patients with severe cases of Wernicke's aphasia

may be mistakenly diagnosed as being confused or mentally ill. Because Wernicke’s area is the crossroads for all incoming meaningful sound patterns, these patients also have severe deficits in repetition, reading, and writing (Goodglass & Kaplan, 1983; Kirshner, Casey, Henson, & Heinrich, 1989).

Some writers have suggested patients with Wernicke’s aphasia have a poorer prognosis for improvement compared with patients having other types of aphasia (Brookshire, 2003; Nicholas, Helm-Estabrooks, Ward-Lonergan, & Morgan, 1993). Research indicates that Wernicke’s area and adjacent regions of the posterior language zones are vital to language processing and that extensive damage to these areas results in severe aphasia (Boatman, 2002; Metter et al., 1990). Lasting comprehension deficits and persistent aphasia usually are associated with larger lesions and, in some cases, complete destruction of Wernicke’s area (Goldenberg & Spatt, 1994; Naeser, Helm-Estabrooks, Haas, Auerbach, & Srinivasan 1987; Selnes, Niccum, Knopman, & Rubens, 1984). Conversely, improvement in Wernicke’s aphasia is associated with restored metabolic activity in the temporoparietal cortex (Metter, Hanson, Kempler, & Jackson, 1992) and the ability of this region of the brain to reperfuse

(Hillis & Heidler, 2002). It generally is believed that patients who improve their comprehension evolve to anomic aphasia (Goodglass, 1981; Kirshner, 2002; Pashek & Holland, 1988; Rosenbek, LaPointe, & Wertz, 1989).

RATIONALE FOR CONTEXT-BASED TREATMENT

An early question from the spouse of the person with aphasia is “when is my husband or wife going to talk again?” The field of clinical aphasiology has a long-standing practice of emphasizing what the person with aphasia produces (Doyle, Goda, & Spencer, 1995). Conversation is probably the biggest loss for many persons with aphasia, because it is via conversation that we illustrate our knowledge and capabilities as well as establish and maintain our human connections (Kagan, 1995). For the patient with Wernicke’s aphasia, *talk-ing* is a strong point—as long as the individual is talking in a conversational context rather than a noncontextual situation. Examples of the differences in noncontextual and contextual communication for three patients with Wernicke’s aphasia—Glen, Marie, and Vern—are shown in Table 18-1.

TABLE 18-1

Differences in How Patients with Wernicke’s Aphasia Communicated in Noncontextual and Contextual Situations

Patient: Glen, a 52-year-old man with severe Wernicke’s aphasia <i>Noncontextual:</i> I tested Glen with the Minnesota Test for Differential Diagnosis of Aphasia (MTDDA) (Schuell, 1965). He talked a blue streak but performed poorly on the easiest subtests of the MTDDA: repetition, matching, copying, and naming. To my chagrin, he often conveyed to me that the assessment was “stupid” and showed little appreciation for the help I was trying to give him. After an hour, I was frustrated, because Glen did all the talking and all I had to show for my efforts was a blank test form. <i>Contextual:</i> As I pondered what to put in my report, I realized Glen had actually communicated a lot of information about his aphasia. It just did not relate to what the MTDDA tested. For example, when I asked him to name pictures, he informed me he hated this task and every time his wife asked him “What’s this?” became angry. When I asked him to repeat short phrases, he was able to convey that he had no earthly idea why his doctors kept asking him to say “No if’s, and’s, or but’s.” He was unable to repeat single words accurately, but when I asked him to say the word “screw,” he responded enthusiastically “I’d sure like to” and made an inappropriate gesture. Patient: Marie, a 90-year-old woman with moderate Wernicke’s aphasia <i>Noncontextual:</i> I gave Marie the Porch Index of Communicative Ability (PICA; Porch, 1967) in the nursing home. Her overall score placed her at the 29th percentile in a large, random sample of adults with aphasia. Her only relevant performance during testing was on the matching and reading subtests. Marie lived alone, did not drive, and aside from her aphasia, was perfectly healthy. However, her physician felt that her communication deficits were so severe that she would be unable to live independently. <i>Contextual:</i> When therapy began, all Marie would talk about was going home. She clearly understood the discharge plan and argued that she could, indeed, go home because she was essentially a recluse and had few communication needs. She asked that I talk to her neighbors about helping out in an emergency. She told me how she did her shopping and that her major responsibility was her cat. Marie was able to convince us all that she should go home, and the result was positive. Patient: Vern, a 63-year-old man with moderate Wernicke’s aphasia <i>Noncontextual:</i> Vern could not name any of the common objects on the PICA accurately. Usually, he responded “No way” or “Can’t get that today” after several aborted attempts to produce a specific verbal response. <i>Contextual:</i> One day I asked Vern how things were going at home. He said, “Not so good.” I asked, “Why?” Vern was able to convey he had been having trouble with insects (earwigs) and that the bugs were winning. He did this by (1) pointing to his ear and (2) then pointing to his bald head and saying, “I don’t have any, so I need one up here.” From this, I put together the word “earwig.”
--

Context: A Common Denominator

Glen, Marie, and Vern had obvious aphasic deficits, but when communicating in a context about something relevant to them, they were remarkably successful, even though they appeared to be totally impaired when tested with the Minnesota Test for Differential Diagnosis of Aphasia, or MTDDA, or with the Porch Index of Communicative Ability, or PICA. Context was the common denominator that allowed them to communicate successfully despite pervasive aphasic deficits. The context-based approach exploits the differences in noncontextual and contextual communication with patients like Glen, Marie, and Vern.

A communicative context allows the participants to make inferences and derive interpretations about what transpires in a conversation (Paradis, 1998). When adults share knowledge about people, topics, events, and the world in general, the shared information guides the generation of appropriate requests for information.

Context is a multifaceted concept. It relates to the physical and social situations of the conversational participants as well as to their points of view (Winograd, 1977). Linguistic context refers to verbal behavior that occurs before and after a given utterance (Davis & Wilcox, 1985). Paralinguistic context refers to the “trappings” of utterances (e.g., intonation, prosody, facial expression, vocal quality, and rate of speech) that help us to convey affective information, highlight new information, and govern our behavior in communicative interactions. Research has shown that manipulation of linguistic and paralinguistic context enhances the comprehension of persons with aphasia (Freiderici, 1983; Hough, Pierce, & Cannito, 1988; Pierce, 1988; Pierce & Beekman, 1985; Pierce and DeStafano, 1987; Waller & Darley, 1978) and improves information exchange in general.

Of course, communicative contexts also vary in terms of where people live, whom they live with, what they do, where they go, and other factors. One thing is certain, however. Real-life communication always takes place in a context, and real-life communication is what persons with aphasia, especially Wernicke's aphasia, need to be prepared to do.

Rapid Discharges

One reason for using a context-based approach is that patients with Wernicke's aphasia are put into situations where effective communication is needed shortly after their stroke. This is because they rarely have major associated deficits (e.g., right-side weakness or paralysis) and do not require the same rehabilitation services as do other survivors of stroke. Frequently, they are sent home instead of to the rehabilitation center. The early transition from the hospital gives the patient no time to adjust to the residuals of the aphasia in the relatively “safe” environment of the rehabili-

tation center. Once home, the patient is thrust into decision-making situations where he or she needs to be able to communicate effectively. The context-based approach is well-suited for coping with this sudden transition. It forms the scaffolding for the clinician to provide the needed partner training, education, and counseling to help the patient cope, adjust to, and compensate for the residuals of the aphasia.

The Therapeutic Window

Context-based treatment is preferable when treatment time is limited (Hinckley & Carr, 2005). For patients with Wernicke's aphasia, individual speech-and-language therapy may not extend beyond the early post-onset period. For example, if the patient is funded for 20 speech-and-language treatments and is seen once a day, the funds for therapy will be exhausted in 4 or 5 weeks. Unless alternative monies are available or the patient should be fortunate enough to qualify for services elsewhere, the patient and the family will be left to their own devices approximately a month after the stroke. The context-based approach is a better way to prepare them for this possibility, because it focuses on communication situations that come up in real life.

Personalizing Treatment

The aphasia research indicates that persons with aphasia perform better when personally relevant materials are used as stimuli (Gray, Hoyt, Mogil, & Lefkowitz, 1977; Van Lancker & Klein, 1990; Van Lancker & Nicklay, 1992; Wallace & Canter, 1985). Most clinicians have experienced this firsthand in their practices. For example, the patient who might not be able to point to the “cigarette” on subtest 10 of the PICA might respond readily to “Have you got a cigarette?” or “Don't you know smoking is bad for you?” The context-based approach is all about personalizing treatment. This is congruent with life participation approaches to aphasia treatment (Byng & Duchan, 2005).

Clinician as a Communicator

Another advantage of the context-based approach is that it is naturalistic. That is, it stresses speaker-listener interactions to fulfill the language facilitation function. It keeps the focus of therapy on communication, and it inhibits the tendency to engage in forced production drills, convergent tasks, or pseudo-communication exchanges. Because the clinician takes the role of participant-communicator rather than director of operations, the patient and the clinician are both stakeholders in therapy. This also makes the clinician-patient relationship horizontal rather than vertical, thus reducing the performance pressure that typically is placed on the patient to come up with specific words and responses.

Improved Outcomes

Outcomes reflect the results of interventions (Fratalli, 1998). The chapters in this book indicate many routes are available for achieving favorable outcomes with persons who have aphasia. I believe, however, that outcomes may be better for patients with Wernicke's aphasia when a context-based approach is used. The context-based approach increases their "degrees of freedom" to communicate. This allows patients to increase problem-solving efforts to communicate about something important to them rather than searching for specific words. The belief that these patients have poorer prognoses may come from the fact that treatment success often is measured with standardized tests (e.g., PICA, MTDDA, and Wostein Aphasia Battery (WAB)) rather than with a conversational measure. When treatment outcomes are based on the ability to converse and/or communicate information relevant to day-to-day functioning, the prognoses of patients with Wernicke's aphasia may be as good as—or, perhaps, even better than—those of other patients.

ASSESSMENT

Early assessment of the patient with Wernicke's aphasia usually takes place in the acute-care hospital. All patients need to be evaluated before they are discharged. Those with severe language deficits need immediate attention from the speech-language pathologist, because their incomprehensible speech and faulty comprehension can result in a misdiagnosis (e.g., confusion, agitation, or psychiatric disease) and get them into trouble. For example, Leroy developed severe Wernicke's aphasia while having a beer with friends after work. He became upset when he could not be understood because of his garbled speech. The police were called and took Leroy to jail before it was discovered he had had a stroke and was taken to the hospital.

Individuals with less severe aphasia also are vulnerable. Joe's mild Wernicke's aphasia quickly evolved to an anomic aphasia during his brief hospitalization. Assuming he would soon be back to normal, the physician discharged Joe before he could be evaluated and counseled by the speech-language pathologist. After he got home, Joe became so frustrated with his anomic deficits that he contemplated selling his thriving garage business. His wife insisted Joe come back to the hospital for a speech-and-language evaluation. This evaluation revealed that Joe's anomic deficits, although still obvious, would not interfere with his ability to work on cars. Joe returned to work successfully and made good progress as an outpatient.

Some patients with Wernicke's aphasia can be given a standardized aphasia test during the early post-onset period. Many, however, perform poorly on any type of formal test. Moreover, the results provide little information to help guide treatment during the early post-onset period. Several

strategies, however, are available to the clinician for obtaining information to identify the patient's strengths and weaknesses, answer the physician consult, and plan early intervention. Early assessment is all about (1) doing the necessary homework to personalize the assessment and (2) using this information in an interview to engage the patient in the process so you can learn as much as possible.

Obtaining Patient-Relevant Information

Knowing as much as possible about the patient before the interview and the beginning of treatment aids the clinician in providing the perceptual support for the conversations that drive the context-based approach. Patient-relevant information comes from (1) the medical chart, (2) observation, (3) learning about the patient's premorbid communication habits, (4) biographies, and (5) staff observations. This information helps clinicians to ask questions with a reasonable expectations as to what a given patient's answers should be. This also allows clinicians to compare what they already know with the patient's actual performance and eliminates some of guesswork from the assessment process.

Medical Chart

The medical chart contains identifying (date of birth), demographic (work history), medical (previous illnesses), and other information. Suppose the clinician learns from reviewing the chart that the patient is a Harvard graduate. In the interview, the clinician could make an open-ended comment, such as "I understand you went to school in the East" and see if the patient comes up with relevant information about Harvard. This might be followed with a statement such as "I understand Ivy League schools are expensive," which would be expected to evoke a response from the patient such as "Wow, they sure are." This one simple fact from the medical chart could set the scene for an entire conversation.

Observation

Because patients with Wernicke's aphasia have few associated deficits, they often move about the hospital rather than remain in their rooms. It may be possible to observe how or if the patient communicates in other situations (e.g., day room, cafeteria, or nurse's station) and with other people (e.g., family, friends, physicians, or staff) and if the patient attempts to resume normal communication activities (e.g., phone calls, reading the paper, writing, or watching television). Holland (1982) has commented on the importance of observing communication of the patient in other situations; in her early paper on observation of persons with aphasia, she provides a convenient form for this purpose.

Premorbid Communication Skills

Knowledge of the patient's premorbid communication habits should be collected before the interview. For example, if the clinician knew a patient was a quiet person who rarely initiated communication or elaborated on what was said, the clinician would have different expectations from the interview than if the patient was a highly verbal individual. Swindell, Pashek, and Holland (1982) have developed a form that can be filled out by the spouse to obtain information about a patient's communication style, and Green (1984) has published a checklist of factors that the clinician should consider in determining the patient's premorbid communication habits.

Biography

Family members should be included in the assessment process. One way get them involved is to ask a family member to write a short biography that gives information about the patient's work, friends, hobbies, interests, likes, dislikes, accomplishments, and related factors. Some family members may choose to include photos, artifacts (items of personal interest to the patient [e.g., sculptures, paintings, or wood-work]), and related materials. The clinician needs to tell the volunteer biographer that (1) the information is confidential, (2) the task is not a writing exercise and need not be perfect, and (3) how the information will be used in treatment.

Staff Observations

Staff (e.g., physical therapists, occupational therapists, and nurses) also can participate in assessment and treatment. One way to facilitate this is to give staff members a brief synopsis about the patient's background. For example:

John Marks is a 54-year-old college graduate who worked as an architect for Pitney-Wilson before his stroke on 10-7-06. He's married (Camilla), and his wife teaches math at St. Joseph High School. His daughter, Jocelyn, age 20, is a junior majoring in international business at Duke. His older child, Brian, is a professional baseball player in the Mets organization and currently plays third base for a farm team. John (nickname Duke because of his height and resemblance to John Wayne) is a 4-handicap golfer and longtime member of the Olympic Club. His daughter is getting married in the summer following her graduation in 07.

Staff can be trained to use this information to probe comprehension and expression in their interactions with the patient. With respect to John, the physical therapist might say, "Show me with your fingers, the position your son plays in baseball" to probe comprehension of directions. As an expression probe, she might ask John to tell her where his daughter is attending college. Successes and failures can be noted in the patient's chart. This is a way to include all staff in the effort to improve communication and provide the patient with more communication opportunities.

The Interview

During the early post-onset period, the interview forms the basis of the clinician's assessment of the patient with Wernicke's aphasia. The patient should be prepared for the interview with an advanced visit from the clinician. At this visit, the clinician should tell the patient that he or she is setting up a time to "find out a little more" about the patient's communication. It may be helpful to leave the patient a note to remind him or her about the time of the appointment. The interview should take place in a quiet, distraction-free space. What the clinician does in the interview itself largely depends on the patient's status. The suggestions for conducting the interview that follow are not prescriptive and constitute only a few of the things that might be accomplished.

Para-Standardized Testing

Para-standardized testing procedures are well-suited to assess the patient with Wernicke's aphasia. Para-standardized guidelines published by Sparks (1978), with some modifications of my own, are shown in Table 18-2. As shown in the table, the guidelines cover four broad content areas—therapeutic set, pragmatics, auditory comprehension, and verbal expression—within which specific behaviors (e.g., following conversational rules) are examined with respect to their presence or absence and positive or negative impact on communication. Para-standardized testing procedures are certainly applicable, but not necessarily to patients with Wernicke's aphasia. Most importantly, the guidelines are flexible and permit the clinician to obtain information regarding what aids and disrupts comprehension and expression. This gives the clinician information that is immediately useful for planning early treatment and counseling the patient and the family. For example, the para-standardized format allows the clinician to determine the variables that can be manipulated to aid comprehension and enhance information exchange by testing certain hypotheses (e.g., Will the patient comprehend better if I reduce his talking?). Videotaping the examination or developing a form for recording observations may aid in writing the consult and in counseling the patient and family at a later time.

Bedside Items

Holland and Fridriksson (2001) suggest that early assessment of the patient with aphasia center on activities relevant to the hospital stay. They suggest that clinicians make use of items in the patient's room when carrying out an initial assessment. Representative examples include reading get-well cards, selecting foods from the menu, choosing television programs, naming objects in the room, testing memory for the therapist's name, and writing the names of one's children.

TABLE 18-2

Modified Para-Standardized Examination Guidelines

Feature 1. Therapeutic Set		
<i>Area of Concern</i>	<i>Negative Signs/Behaviors</i>	<i>Positive Signs/Behaviors</i>
Ease or difficulty establishing and maintaining a therapeutic set	Hostility toward examiner; distractibility because of ambient noise	Accepts the therapist in the situation; displays a realistic appraisal of situation; acknowledges clinician is there to help
Presence of rigidity or perseveration	Continuing to produce a response without regard to change in stimulus; difficulty switching tasks	Recognizing task switches; awareness of errors and effort to correct them
Behavioral rigidity	Ego-minded responses (e.g., when asked "What do you wear on your head?" says "I don't ever wear hats.")	Ability to role play and pretend
Feature 2. Pragmatics		
<i>Area of Concern</i>	<i>Negative Signs/Behaviors</i>	<i>Positive Signs/Behaviors</i>
Follows conversation rules	Limited turn taking; not aware when to terminate a conversation; violates social conventions	Obeys conversational conventions
Realizes the reasons for language processing deficit	Blames problems on outside forces (e.g., missing dentures, people talking too fast, no glasses)	Understands a stroke has occurred
Initiate communication	Initiates few communication interactions; only responds when asked to	Initiates communication to make needs known
Persistence in face of failure	Gives up when communication snag occurs	Persists until thought has been communicated
Feature 3. Auditory Comprehension		
<i>Area of Concern</i>	<i>Negative Signs/Behaviors</i>	<i>Positive Signs/Behaviors</i>
Peripheral hearing loss	Asks for repeats; phonetic confusions (e.g. rake-lake); history of working in noise	Examiner judges hearing acuity to be within normal limits
Understanding a conversation	Looking confused or perplexed; difficulty following conversation containing personally relevant material	Responds more enthusiastically to conversation about personal interests (e.g., sports, family, work)
Comprehension in structured auditory comprehension tasks	Difficulty pointing to objects, body parts, following simple commands	Once oriented to task, points to objects and body parts and follows simple commands
Responses to different methods of presentation	Not helped by slower rate, alerting phrases, shorter and simplified messages, orientation to topic	Comprehension of conversation and structured material when clinician uses different methods of presenting material
Comprehension when verbal output is restricted	Examiner is unable to halt "press of speech" or patient's comprehension does not improve when speech is restricted	Comprehension in conversation and on structured tasks improves when patient is asked to "listen" rather than talk
Intrapersonal monitoring	Does not ask for repeats or verify what has been said	Asks for repetitions; verifies what has been said
Comprehension when treatment materials are thematically organized	Comprehension does not improve when questions flow from mutually known topic (e.g., family)	Comprehension improves when task is organized (e.g., "I want to know about your family. Are you married? Do you have any children? Are the children still at home?")
Effect of visual supplementation	No improvement when provided a visual cue (e.g., written word "Military")	Comprehension improves with visual cue in form of written word (e.g., "Were you in the service? What branch of the military were you in?")
Self-criticism	No awareness of errors in speech output	Aware of errors and possibly upset by them

TABLE 18-2

Modified Para-Standardized Examination Guidelines (continued)

Feature 4. Verbal Expression		
<i>Area of Concern</i>	<i>Negative Signs/Behaviors</i>	<i>Positive Signs/Behaviors</i>
Accuracy and use of substantive words	Not aware when correct target has been produced; empty speech; rejects target word when it is provided; errors do not resemble target word	Aware that speech lacks content words; recognizes target word when provided; errors are variable and sometimes approximate the target word
Quantity of speech	Unrestricted verbal output with no awareness of its content	Fluent speech that sometimes becomes less fluent as the patient evidences concern for his errors
Grammatical structure	High number of para-grammatical errors (e.g., he/she, from/for, they/we) and lack of awareness of them	Speech reflects full range of grammatical constructions with few para-grammatical errors
Degree to which paraphasic errors approximate target word	Errors bear no resemblance to target word (e.g., for "pillow": "grabbitz, rafunta")	Errors contain some of the constituents of the target word (e.g., pister/pillar) and may "in the ball park"
Self-correction accuracy and effort	No awareness of errors; makes no effort to correct errors; overcorrects a response when its meaning has been conveyed	Recognizes most errors; makes efforts to correct errors and sometimes succeeds
Stimulability	No improvement when errors are pointed out and model provided; response does not improve with semantic or phonetic cue	May improve production when model provided; responds to semantic or phonetic cues
Response to restriction in verbal output	Brief responses continue to be in error	Verbal expression is improved when shorter responses are elicited
Verbal compensations	Unable to find alternative means of verbal expression to convey intended word (zebra)	Conveys meaning of target word through description (e.g., "black-and-white horse thing") or other means
Compensations in other modalities	Uses only speech to express thoughts	Uses alternative modalities (e.g., writing, gesturing)

Author's modifications based on Sparks (1978).

Everyday Language Test

The Everyday Language Test is a verbal test that elicits responses to specific questions and/or situations (Blomert, Kean, Koster, & Schokker, 1994). For example, for one of the test items, the clinician says, "You are at the florist. You want a bouquet of flowers delivered to a friend. I am the salesperson. What do you say?" Responses are scored on a 0-to-4 scale for understandability (content) and intelligibility (perception of the message regardless of the content or meaning). A complete listing of items on the test can be found in the article by Blomert and colleagues (1994). Because the Everyday Language Test is not readily available in the United States, clinicians may want to make up their own version.

Inpatient Functional Communication Interview

The Inpatient Functional Communication Interview, or IFCI, is a measure of functional communication to be used in

an acute hospital setting (O'Halloran, Worrall, Toffolo, Code, & Hickson, 2004). Specifically, the IFCI measures the patient's ability to communicate during everyday tasks, actions, and situations that might occur in a hospital. The test is administered in four steps. Step 1 consists of documenting information about the patient from the medical chart. Step 2 involves a structured bedside interview using the IFCI. The clinician first establishes a communication context so as to evaluate the patient's performance in 15 situations that are relevant to the hospital environment. For example, one situation seeks information about whether the patient can give relevant information concerning their pre-admission history. Based on the amount and quality of the information provided, the patient receives a score of 2 (successful communication), 1 (partially successful communication), or 0 (unsuccessful communication). Step 3 consists of discussing the necessary information with the staff, and step 4 involves writing a report of the findings. The IFCI comes with a test manual, instructions, and recording and scoring forms.

TREATMENT

During the early post-onset period, many patients with Wernicke's aphasia will have severe communication problems. Their communication status often changes from day-to-day as well, because spontaneous recovery is ongoing. Some patients may begin early treatment with obvious "press of speech," nonstop talking, and pay little or no attention to their errors. Once a therapeutic set has been established and comprehension improves, however, patients may try to correct themselves, and their speech will become less fluent. With these patients, the clinician functions as a "behavioral engineer"—keeping the train (patient) on the track; changing speeds and routes; and heeding the signals regarding what the clinician should—and should not—do. The clinician's job is to steer the patient, family, and staff through the early post-onset period and make the trip as smooth as possible. The goals of treatment are to improve the patient's comprehension and ability to exchange information in contextual situations.

Therapeutic Set

The term "therapeutic set" describes the patient's attitude toward therapy and its environment and to being helped in general (Sparks, 1978). It is important that the patient understand the clinician is there to help and that he or she needs help. This may be difficult with patients who are improving so rapidly that they feel treatment is unnecessary. At the very least, the clinician should try to explain to the patient and family what aphasia is and leave the door open for later evaluation and treatment.

Establishing a therapeutic set for patients who are not improving also is difficult. These patients may be unaware or unwilling to admit that anything is wrong. The useful cues and prompts that help patients with nonfluent aphasia to produce accurate verbal responses (e.g., counting, sentence completion, and repetition) rarely help and/or sometimes are confusing to them. To show these patients that help is available and establish a therapeutic set, I have found it beneficial to identify something important that the patient needs to communicate to the staff, physician, or family and work to help the patient with that. Often, this is a problem the patient wants to solve, and it is a time-consuming process of trial and error that delays evaluation and treatment. It can pay dividends, however, as it did with Wes, a 47 year-old man with severe Wernicke's aphasia. I knew that Wes wanted to tell me something important. I wanted to evaluate him, but it seemed prudent to try and figure out what he wanted to tell me instead. Using yes/no questions, writing, and a lot of guessing, I learned that Wes was worried about his dog. He lived alone, and no one was around to take care of the animal. I dealt successfully with the situation, and that succeeded in establishing a therapeutic set for Wes.

Establishing a Communication Context

The clinician establishes a communication context to prepare the patient for a conversation. In the conversation, the clinician and the patient function as receivers and senders of messages. During the early post-onset period, the patient will be most interested in talking about personal issues (e.g., going home, returning to work, the family, health, and finances). Discussing these concerns requires the clinician to have some personal knowledge about the patient's situation. Should the clinician not have the necessary information to communicate with the patient about these issues, other, less personal topics *shared* by the clinician and the patient can be used to establish a conversational context. For example, how could anyone living in or around Boston not be able to converse about the Red Sox, the Patriots, or the "Big Dig?" Certainly, I would be hard-pressed to find a patient in Lexington that would not be able to talk about Kentucky basketball. Also, communicative contexts do not always need to be pre-established. An enterprising clinician can establish a communicative context on the "spur of the moment" by using humor, emotion, or absurdity. Further, different perceptual props and items in the patient's room (e.g., maps, pictures, newspapers, pictures of family, and books) can be used to establish contexts for communication. In a pinch, general topics (e.g., the weather, upcoming holiday, or quality of hospital food) also can be used to create a communicative context. Table 18-3 provides several examples of communication contexts and what type of information stimulated their creation.

Improving Comprehension

Auditory processing involves comprehension of spoken messages and their retention in memory. Most would agree that disorders of auditory processing in persons with aphasia reflect difficulties understanding spoken messages that are not attributable to sensory, (hearing loss), cognitive, or attention deficits (Boller, Kim, & Mack, 1977). Clinical diagnosis of Wernicke's aphasia is based on the patient's performance on receptive language tests of standardized aphasia test batteries (Boatman, 2002). Two models of auditory processing have received widespread attention in the aphasia literature. The bottom-up model suggests that understanding a message is the cumulative result of analyzing the sounds of an utterance (phonemes), combining the sounds into word representations, retrieving the meanings of the words, and constructing a mental representation for the meaning of the message (Brookshire, 2003). The top-down model has more to do with how listeners comprehend messages in naturalistic conversations. Here, the starting point is the knowledge shared by listeners in the communication situation. This shared knowledge leads to the development of inferences and expectations. The result is that participants interpret what they hear in the conversation on the basis of what they know.

TABLE 18-3

Establishing Communication Contexts

Strategy	Stimulus	Clinician Comment	Patient Response
Shared knowledge	Clinician learns from chart review that she and the patient share the same birthday	"I learned that you were born on the same day as I was."	"Oh wow, October 7 too."
Bedside prop	Picture of patient's family on the bedside table	"You have beautiful children."	"Right." [looks at picture] "Three of them."
Emotion/humor	Clinician notices patient is not eating a rather unappetizing meal	"Are you really going to eat that crap?" "I bet you would prefer a steak."	"Oh yeah. I gotta." "Right rare." [gestures thickness of steak]
Spur of the moment	Sees the patient is wearing a ring from Stanford	"Good-looking ring on your finger. Does Stanford have a good team this year?"	"I think all the way."

During the early post-onset period, the patient's comprehension deficits are relatively severe. For some patients, it is difficult—if not impossible—to work on comprehension with structured tasks, particularly at the single-word and sentence level. Working to improve comprehension in conversational contexts is a better approach to use at this time. With the context-based approach, this involves (1) identifying and manipulating linguistic and temporal variables to improve comprehension in conversations, (2) encouraging the patient to take responsibility for comprehension, and (3) training caregivers how to talk to the patient using demonstration and modeling.

Linguistic Variables

The aphasia literature indicates that linguistic variables can be manipulated to improve comprehension of spoken messages. Normal speakers do this naturally in relation to whom they are speaking. For example, when talking with my 99-year-old father, I do things that the aphasia literature shows improve the auditory comprehension of persons with aphasia. I use short, syntactically simple, plausible sentences that do not contain unfamiliar or "big" words. The aphasia literature on auditory comprehension, as reviewed by several writers (Boller et al., 1977; Marshall, 2002), suggests these tactics facilitate auditory comprehension for persons with aphasia (Marshall, 2002). Comprehension is improved in other ways as well. Some of these include:

- Highlighting the main ideas of what is being talked about in relationship to less important details (Brookshire & Nicholas, 1982, 1984, 1993; Wegner, Brookshire, & Nicholas, 1984).

- Giving added prosodic stress to the important words of the message so that they stand out (Kimelman & McNeil, 1987; Pashek & Brookshire, 1982; Swinney, Zurif, & Cutler, 1980).
- Stating information directly (e.g., "Time to eat. It's six o'clock.") rather than indirectly (e.g., "Now it's time for dinner, and we better go in to eat.") so that the patient does not have to make inferences about implied information (Katsuki-Nakamura, Brookshire, & Nicholas, 1988; Nicholas & Brookshire, 1995).
- Using repetition and appropriate synonyms to create lexical ties to link the information of a message together (e.g., "Susan and Andy got out of the car. Susan wore a blue dress. Andy wore a black tuxedo.") (Brookshire, 2003; Halliday & Hasan, 1976).
- Using repetition, paraphrasing, and expansion to increase message redundancy (Gardner, Albert, & Weintraub, 1975; Graville & LaPointe, 1983; West & Kaufman, 1972).

Temporal Variables

People with aphasia like to talk to clinicians. This may be because clinicians adjust certain temporal variables to help the patient understand what is said. This was seen in a novel experiment (Salvatore, Strait, & Brookshire, 1975) that compared speech rates of experienced and inexperienced clinicians giving Token Test commands to patients with severe and mild aphasia. The experienced clinicians intuitively slowed their rate of speech when giving the commands to the severe, but not the mild, patients; the inexperienced clinicians did not make these differential adjustments. Similar to what it tells us about manipulating linguistic

components of messages, the aphasia literature provides information about the effects of temporal manipulations on auditory comprehension of persons with aphasia:

- Patients benefit when spoken to at slightly slower, but not unnatural, rates of speech (Cermak & Moreines, 1976; Lasky, Weidner, & Johnson, 1976; Pashek & Brookshire, 1982; Weidner & Lasky, 1976).
- Rate slowing is best achieved by inserting brief pauses at syntactic boundaries within sentences (Fehst & Brookshire, 1980; Salvatore, 1979). This serves to group information into meaningful “chunks,” and it permits the patient to catch up to facilitate storage and processing of the message.
- Attention deficits may cause the patient to miss the initial portions of message and/or not pick up shifts in topic, a problem referred to as “slow rise time” (Brookshire, 1974). These deficits can be compensated for by alerting the patient to an incoming message. This helps the patient to reallocate his or her attention and may improve comprehension (Campbell & McNeil, 1983; Loverso & Prescott, 1981; Marshall & Thistlethwaite, 1977).

Finding the Hole in the Screen

To understand how the clinician might manipulate linguistic and temporal variables in a conversational context to maximize comprehension, imagine you are looking at a screen at which someone has thrown mud. You probably would see that some of the squares were plugged with mud but that others were open. Consider that the message sender, in this case the clinician, is on one side of the screen and that the patient with Wernicke’s aphasia, Pete, is on the other. For Pete to understand the clinician’s message, it needs to be sent through an “open square.” If the message hits a “plugged square,” Pete will not comprehend it. The clinician’s challenge is to manipulate linguistic and temporal variables so as to get the message through an “open hole” so that the patient will comprehend it. This is shown in the following example of a conversation with a patient with Wernicke’s aphasia centering on the patient’s family. In the example, the bolded information provides a rationale for what the clinician is attempting to accomplish:

Clinician: I would like to talk to you about your family.
(**Establish context**)

Patient: Oh boy.

Clinician: I know you have a *large* family [presents written word “FAMILY”]. (**Stress; visual supplement**)

Patient: Oh, my family, well it’s a big one.

Clinician: I understand you have quite a few children. How many do you have? (**Increased redundancy**)

Patient: Let me see, Tony, Markee, Martee, Muckee—Oh no.

Clinician: That’s a hard word to say, but I’m interested in HOW MANY [stresses this word]: four, five, six [gestures higher]. (**Redirect to topic; stress; gesture supplement**)

Patient: No more than that [holds up 10 fingers].

Clinician: Wow, 10 kids. That must keep you busy. All boys? (**Humor; syntactic simplification**)

Patient: No way, no way. Lots of girls [holds up seven fingers].

Clinician: Seven girls. That means you have three boys [holds up three fingers]. (**Verify, gesture supplementation**)

Patient: Yep, three of them.

Clinician: I understand one of your *boys* is quite *famous*. (**Stress key words; put words at the end of the sentence**)

Patient: Huh? [looking quizzical] What did you say?

Clinician: I’m glad you asked me to repeat that question. Any time. I was asking about your FAMOUS son. (**Reinforce for asking for repeat; stress word famous; redundancy**)

Patient: Oh, you mean Buddig, Bodie, Booby.

Clinician: Right, Buddy. I understand he’s a rather good football player? [Buddy is really a baseball player.] (**Give false information to help patient integrate and consolidate response**)

Patient: Not that one, the other one.

Clinician: Sorry, wrong sport. You mean golf? (**Humor; again give information to integrate and consolidate response**)

Patient: Nope.

Clinician: Tennis? (**Humor; continue to consolidate and integrate**)

Patient: Get out of here.

Clinician: Baseball? (**Syntactic simplification; one word; salient word**)

Patient: That would be the one. He’s a [gestures pitching motion] you know.

Clinician: A pitcher? Wow. Is he right or left handed? (**Emotion and facial expression; redundancy**)

Patient: One of these [gestures with his left hand].

In the example provided, the clinician established the context by telling the patient that the conversation would be about his family. Once the patient understood this, the clinician selectively manipulated linguistic and timing variables (see bolded text) to work on comprehension. Because the objective was to improve the patient’s comprehension, the clinician paid little attention to the production errors, and only short verbal responses were required. The clinician noted those manipulations that were helpful in getting messages “through the open holes of the screen” and made adjustments accordingly. For patients with Wernicke’s aphasia and severe comprehension deficits, many holes of the screen will be plugged at first, but as comprehension improves, more squares in the screen will open. During the early post-onset period, much of the work done to maximize comprehension for the patient with Wernicke’s aphasia is a

trial-and-error process. As treatment progresses, the tactics that aid—and hinder—comprehension become clearer, and some strategies are abandoned and others retained and expanded on.

Taking Responsibility for Comprehension

Patients with Wernicke's aphasia look and move perfectly normally. Sometimes, they pretend to understand so that the listener will not know they have aphasia. Signs of pretending to understand include vigorous bobbing of the head “yes” and lots of “uh-huh's.” A necessary part of improving the patient's comprehension integral to the context-based approach involves encouraging the patient to take responsibility for comprehending what is said. At first, clinician need to demonstrate what they want the patient to do. Thus, the clinician might (1) ask for a repetition (e.g., “Could you run that by me again?”), (2) give the patient a quizzical look to indicate the patient has not been understood, (3) verify what the patient says by paraphrasing the message (e.g., “You said your wife is coming at three o'clock? It's almost here.”), or (4) ask a rhetorical question (e.g., “When is your wife coming?”). The clinician also promotes the patient taking responsibility for comprehension by liberally reinforcing the patient's requests for repetitions and use of verification strategies. There also may be times when the patient cannot listen anymore, because his or her auditory system is overloaded. In such cases, the patient needs to withdraw from the competitive listening situation and take a break. The clinician needs to reassure that patient that it's all right to take a break from listening and that this may help in the long run.

Training Caregivers

The patient with Wernicke's aphasia will have more conversations with family, friends, and other people than with the speech-language pathologist. To improve the patient's comprehension in conversations outside the therapy room, these individuals need to be trained how to talk to the patient. Specifically, this involves the clinician teaching them how to do what the aphasia literature tells us to do that helps in comprehension.

It will not help to tell these communication partners that the “test results” suggest the patient has comprehension problems. A study by Czvik (1977) found that family members tended to disagree with the speech-language pathologist's test results documenting the patient's comprehension deficits and viewed aphasia as an expressive problem only. It is necessary for clinicians to show, through demonstration and modeling, what they want family, staff, and friends to do. This is powerful therapy, and it is apparent that good coaching helps.

Several recent studies have provided empirical evidence that a variety of conversational partners can be trained how to talk to people with aphasia and that training improves the

information transaction of persons with aphasia (Hickey, Bourgeois, & Olswang, 2004; Hopper, Holland, & Rewenga, 2002; Kagan, Black, Duchan, Simmons-Mackie, & Square, 2001; Legg, Young, & Bryer, 2005; Lyon et al., 1997; Purdy & Hindenlang, 2005; Simmons-Mackie, Kearns, & Potechin, 2005). When the training involves professional staff, clinicians may want to refer to a recent paper by Marshall and English (2004) that provides functional strategies physical therapists can use to enhance the auditory comprehension of persons with aphasia in the physical therapy gym. This is practical information that can easily be posted in the clinic and used in providing in-service training for staff.

Improving Information Exchange

Speech output of patients with Wernicke's aphasia may be unchecked. Excessive speech flow is associated with a “rambling” style of communication, which seems to occur when the patient's comprehension deficits are severe and talking is less punitive than listening (Marshall, 1983). If the patient's speech output is markedly defective, a situation is created in which the “defective utterances” are fed back to an impaired auditory system, a condition I have referred to in the past as “the garbage-out/garbage-in cycle” (Marshall, 1994). Information exchange also can be impeded by (1) perseverations, (2) pervasive word-finding difficulties, (3) lack of or excessive self-correction, and (4) prolonged circumlocution.

Breaking the Cycle

A “stop” strategy can be used to break up the garbage-out/garbage-in cycle. This involves directing patients to listen to themselves, stop when they make an error, and try to correct themselves. At first, the clinician may need to signal the patient to stop and say, “What do you need to do now?” Ultimately, the goal is to have the patient identify and correct his or her errors, first in treatment and then outside the clinic. At times, merely stopping the patient from talking so much, encouraging shorter replies, and framing questions so that answers are within his or her capabilities will suffice.

Some patients, however, are not able to benefit from the stop strategy, because their comprehension and self-monitoring skills are too impaired. Martin (1981a) offers an alternative. He suggests that, rather than stopping patients and having them try to correct an error, the clinician should translate a patient's defective utterance as best possible. (This often is easy to do, because the clinician is working in a context.) The clinician's translation and ensuing paraphrasing or modeling of the defective utterance in a correct form gives the patient some positive feedback for communicative adequacy (getting the message across) and breaks the garbage-out/garbage-in cycle. For example:

Patient [waving an issue of the *American Kennel Club Magazine*]: Here's the one smasher, master boy, oh nuts! It's there, where is it? My caster, the ones out there where I live. I know it. What's wrong with me? [Pause]. Smash. M-A-T-T-E-R. Matteree. Oh, God.

Clinician: I understand you are a dog breeder. What types of dogs do you raise?

Patient [opening the magazine]: Well they're not in here but they are big and mean. [Opens the page to show Bulldogs.] Almost like this, but bigger. Smasbees, masters, mastees, on nuts. Why can't I say it? [now frustrated]

Clinician: Do you mean Bull Mastiffs? They are big fellows?

Patient: Bull Mastiffs, Bull Mastiffs, that's it. You got it. Those are my boys. [now enthusiastic]

Clinician: Very protective animals?

Patient: Oh you bet, they'll bite your head off if you mess with me.

In the above example, the *American Kennel Club* magazine was the prompt that established the communicative context. The clinician's knowledge of the situation and the patient's interests in dogs allowed him to interpret the patient's defective utterances and break the cycle.

Perseveration

Perseveration is the repetition of a response when a new response is called for. For example, I asked Jim to tell me about his work. He replied, "I own a flower shop." Then, I asked, "Do you have a family?" and he said "Yes, I have a flower shop." Wepman (1972) believed that perseveration was the result of not taking enough time to consolidate and integrate a response. He suggested that the mind operates like a camera shutter. When the shutter is open, stimulation is possible. If the shutter is closed, however, new information cannot be processed, and calling for a new response will result in perseveration. He suggested that clinicians take time to consolidate and integrate the patient's accurate response before calling for a new response to reduce perseveration. With Jim, I could have done this by following up with his correct response with questions such as "How's business?" and "What's your busy time of the year?" Helm-Estabrooks, Emery, and Albert (1987) also have proposed a mechanism for treating perseveration errors in aphasia that highlights the fact that a new response is called for.

Anomic Difficulties

Anomic difficulties are a hallmark of patients with Wernicke's aphasia in conversation and whenever a specific word is needed. Anomic struggle takes place at both the pre- and post-lexical levels. The latter suggests that the patient is having problems accessing word meanings and/or forms. For example, if the target word is "Wal-Mart," the patient might produce a semantic error ("Rite Aid"), a description

("Where we buy medicine cheap"), a phonemic approximation ("Swalmart—that's almost it."), or an indefinite word ("the place"). Post-lexical anomic difficulties are reflected in a variety of behaviors that suggest the patient has accessed the word's meaning and form but cannot map the phonologic shapes of the word onto the lexical entries for outputting. For example, if the patient is having problems coming up with the word "pillow," he or she might make several near-attempts to produce it, write the word or a portion of it, or point to the pillow on the bed. Finally, some patients simply choose to talk around the anomic difficulty (circumlocution) or simply say, "I don't know." Anomic difficulties of the patient with Wernicke's aphasia can be dealt with indirectly (by teaching compensations) and directly.

Indirect Approaches

Indirect approaches minimize the impact of anomic struggle by keeping the focus on communication. The clinician or trained communication partner makes "on the spot" decisions as to how best to keep communication on track—or get it back on track—when anomic difficulties threaten to interfere. Golper and Rau (1983) have described this as "taking your cue from the patient."

The first example in Table 18-4 shows that the clinician has determined the patient's struggle will not result in successful production of the word "cigarette." The clinician has elected to *fill in* the blank, terminate Joanne's 3-minute effort, and move on. In the second example shown in Table 18-4, the clinician sensed that the patient was close to producing the target word. This clinician's decision was that it

TABLE 18-4

Examples of Anomic Struggle in Conversations that Require a Clinician Decision as How Best to Keep Communication on Track (Target Word in Parenthesis)

(Cigarette)	
Patient PJ:	"You smoke a cig, a sigg, oh what is it? I want one now. Smittring, ciggerthing, almost, what is it called? You put in your mouth and smuch it. Smucher, smuch, smukker, chitter, No." [clinician fills in]
(Alaska)	
Patient HB:	"I always wanted to go to Alasta, where its cold, Alasta, Alaskan, Alasker." [pause; clinician signals to go on] "Alaska."
(Coffee)	
Patient BB:	"Well since my heart went bad, my doctor said no more cokkee, I mean coffee. It's not good for my blood pressure." [clinician lets it go]

was better to let the patient work through the difficulty. The clinician gave the patient an *encouraging gesture* that signaled him to keep going. Encouragement could be verbal (e.g., "You're almost there."). The last example in Table 18-4 shows that the clinician has decided the patient has successfully communicated that "he does not drink coffee because of a heart condition." This clinician deduced that the patient communicated successfully what he wanted to say and elected to *let it go*. Thus, the clinician said, "Oh, yes, I drink too much coffee myself" to give him feedback that he had communicated his message adequately. It also has been shown that information provided by patients with aphasia as they search for specific words (self-cues) could be used to make decisions to fill in the missing word, encourage the patient to keep trying to produce the target word, or accept what has been produced and move on (Tompkins & Marshall, 1982; Tompkins, Scharp, & Marshall, 2006).

Wepman's content-centered therapy also puts communication at the forefront (Martin, 1981b; Wepman, 1972). In this approach, the clinician and the patient discuss topics of prestroke interest to the patient. Wepman recommends ignoring the patient's struggles to find specific words and keeping the discussion on track by reflecting back the individual's intended thoughts and paraphrasing when anomic difficulties occur. His rationale for this unique, but empirically untested, approach is that speech should be the "handmaiden of thought" and not visa versa (Wepman, 1976).

Compensations

Using alternative modalities of communication (e.g., drawing, gesture, writing, and pointing) is highly recommended for individuals with nonfluent aphasia, primarily because these patients generate little speech. It is also helpful, however, for the patient with Wernicke's aphasia to be able to communicate using other modalities if talking fails. Some studies show that these patients make little use of alternative modalities (Marshall, Freed, & Phillips, 1997), but reports also show that patients with Wernicke's aphasia can use gestures (Simmons & Zorthian, 1979) and body movements (Ahlsen, 1991) to aid communication. In treating many patients with Wernicke's aphasia, I have seen individuals compensate for what they could not immediately communicate in several ways. Some examples include going through things in a series (e.g., numbers, days of the week, months, or names of family members) to come up with specific words, writing, gesturing, and pointing. I remember that Paul used to write words that were important to him on small scraps of paper. Then, when he needed one of these words during therapy, he would pull all the scraps from his jacket pocket and search through them diligently. This worked for Paul and suggests that the best guide to using compensations for patients with Wernicke's aphasia is whether the compensatory efforts aid or hinder communication.

Direct Approaches

Numerous direct approaches to the treatment of anomia have been described in the aphasia literature (Nickels, 2002). Three specific methods—circumlocution-induced naming, personalized cueing, and semantic feature analysis—are presented here. These do not necessarily fit within the context-based treatment approach. Many patients with Wernicke's aphasia are concerned about their naming errors, however, and the end-point for most of them is anomic aphasia. Thus, some specific methods for treatment of naming may be useful in therapy for Wernicke's aphasia, especially as the early post-onset period comes to an end and the patient is able to be treated directly.

Circumlocution-induced naming is a novel approach to the treatment of anomia. A recent report described its use in treatment of a patient with pervasive anomia (Francis, Clark, & Humphreys, 2002). When the patient could not supply the name of a picture, she was encouraged to "talk around" the topic to try and access the specific name. When she had trouble, the therapist joined in the conversation and reinforced the information provided by the patient, but the therapist did not provide the name. During therapy, the therapist did not provide the name. Results of the study revealed improved naming from pre- to posttest assessments.

Personalized cueing is a procedure for treating anomia that has been used successfully with patients having a variety of types of aphasia (Freed, Celery, & Marshall, 2004; Freed & Marshall, 1995; Marshall & Freed, 2006). When using this method, the clinician and patient work together to create a personally relevant associational cue to help the patient remember an important word. For example, in one study (Freed et al., 2004), a patient created the cue "old red one" to help her remember the word "bathrobe." In therapy, the cue and the target word are repeatedly paired. The success of personalized cueing is assessed with naming probes administered at later points in time when the cues are not provided. Several studies have shown that the benefits of this training are highly durable and result in improved naming of target words as long as 6 months after the end of treatment.

Semantic feature analysis is a procedure for treating anomic deficits that has widespread popularity. The patient is presented with a picture that is difficult to name (e.g., a giraffe) and is asked to respond to questions about its semantic features, such as location (Africa), actions (eats leaves), color (brown and yellowish), and characteristics (tall, long neck). Several studies have shown that semantic feature analysis (Boyle, 2004; Boyle & Coelho, 1995; Coelho, McHugh, & Boyle, 2000) and other semantic treatments (Davis, Harrington, & Baynes, 2006; Drew & Thompson, 1999) improve naming and that the benefits of this treatment generalize to untrained words and other speech tasks, such as connected speech. It has been argued that

these improvements result from possible repair of a damaged semantic system, increased the specificity of semantic representations, and increased activation of the semantic network surrounding the target word, all of which elevate the word's threshold for being retrieved (Boyle & Coelho, 1995; Hillis, 1998).

Promoting Self-Correction

Wepman (1958) suggested a continuum of self-correction exists for patients with aphasia and that the patient's location on the continuum was predictive of recovery from the disorder. At the lower end are those patients who fail to recognize or attempt to correct their production errors. In the middle are those who make the effort and sometimes succeed. At the upper end are those patients who always make the effort and who usually are successful. Research has shown that patients with Wernicke's aphasia rank last in terms of their frequency and success of verbal self-correction among various aphasia classifications (Marshall & Tompkins, 1982). In a larger sense, self-correction relates to intra- and interpersonal monitoring (Martin, 1981a).

Intrapersonal monitoring involves attention to language structure and usage, such as selection of a word or determination of word order. Interpersonal monitoring refers to the act of attending to signals from the environment and from the communication partner that are important to sustaining communication. These signals indicate when it is appropriate to change roles or follow certain conventions (e.g., be quiet, move closer, or lower one's voice).

Within the context-based approach, the clinician reinforces the patient for appropriate self-monitoring. For example, after a successful self-correction, the clinician might say, "That's great that you changed to a different word." After a successful struggle to produce a specific word, the patient's persistence should be acknowledged (e.g., "I like the way you stuck with that."). If the patient attempts to self-correct but fails, encouragement remains important (e.g., "That word was tough today."). Also important to the promotion of self-monitoring is to acknowledge and ease the patient's concerns about day-to-day variability in performance. For example, George called his wife "Mildred" on one day and addressed her as "Bernice" (his ex-wife's name) on the next. This upset the him, and he said "Mildred, Mildred, Mildred—stupid. I said it yesterday, why not today?" In this case, the clinician needs to help George understand day-to-day fluctuations in word retrieval efforts are a product of the stroke will get better with time.

Other Individual and Group Approaches

Other individual and group treatment approaches also can be used within the context-based approach with the patient who has Wernicke's aphasia. Most of the therapeutic

approaches that follow are not exclusive to patients with Wernicke's aphasia. All are applicable to context-based treatment, however, because they emphasize communication and give the patient options to reflect his or her communicative competence.

Promoting Aphasic Communicative Effectiveness

Promoting Aphasic Communicative Effectiveness (Davis, 2005; Davis and Wilcox, 1985), or PACE, was developed to make treatment situations more like natural conversations. The PACE principles include (1) the use of new information, (2) equal participation by patient and clinician as sender and receiver of messages, (3) freedom of communication channel selection (e.g., patient can gesture, write, draw, point, or speak), and (4) giving feedback based on communicative adequacy rather than on production accuracy. In the traditional PACE format, the clinician and patient take turns describing pictures unknown to each other following the PACE principles. Several studies have shown that PACE improves the communicative effectiveness of persons with aphasia (Glindemann, Willmes, Huber, & Springer, 1991; Li, Kitselman, Dusatko, & Spinelli, 1988; Springer, Glindemann, Huber, & Willmes, 1991). This body of research has not focused on patients with Wernicke's aphasia, but PACE could be used with these patients inasmuch as their verbalizations do not always conveying their intended messages (Ahlsen, 1991; Marshall et al., 1997). Also, since PACE was developed, other researchers (Carlomagno, Losanno, Emanuelli, & Casadio, 1991; Pulvermuller & Roth, 1991) have expanded it to incorporate other speech acts (e.g., bargaining, requesting, and arguing) and tasks (e.g., describing pictures, cartoon sequences, and talking about famous people) that fit within context-based approach.

Response Elaboration Training

Response elaboration training (Kearns, 1985, 1986), or RET, is a loose-training procedure based on the premise that highly structured and constrained-task therapies will restrict the patient's use of creative language (Stokes & Baer, 1977). In using RET, the clinician elaborates on the patient's novel utterances with the goal of increasing the length and content of those utterances. Several studies by Kearns and colleagues (Gaddie, Kearns, & Yedor, 1991; Kearns, 1985, 1986; Kearns & Scher, 1989; Kearns & Yedor, 1991; Yedor, Conlon, & Kearns, 1993) have shown that RET increases the verbal productions of speakers with aphasia. A recent study indicated that a modification of RET successfully increased the number of content information units produced in response to picture stimuli by three speakers with chronic apraxia-aphasia (Wambaugh & Martinez, 2000). Although RET has been used sparingly with the patient who has aphasia and is talking, its goal is to facilitate generalized improvement of the patient's ability to elaborate on

TABLE 18-5

How the Game of Blackjack Could Be Used to Work on Improving Word Retrieval and Other Skills

<i>Materials:</i> Cards, betting tokens (e.g., chips, pennies, beans) allocated to clinician (dealer) and client (player).		
<i>Representative skills and abilities needed:</i> 1 = attention; 2 = decision making; 3 = simple computation; 4 = auditory comprehension (following simple command); 5 = differential responding verbally or gesturally (e.g., signaling for “hit” or “stay”), 6 = turn taking; 7 = correcting erroneous information		
Using the Game of Blackjack as a Treatment Module: Examples of Clinician and Patient Actions		
<i>Clinician Actions</i>	<i>Patient Responses</i>	<i>Skills and Abilities</i>
Mixes cards; gives cards to player to cut	Cuts cards; signals he does not want to cut the cards	1, 2
Place your bet	Puts out chips or tokens	1, 2, 4
Deals king and six to patient; shows an ace for dealer	Signals for “hit” or “stay”	1, 2, 3, 5
After “hit” signal, deals a queen to the patient	Turns up cards to show “busted”; pushes money to dealer	2, 3, 5
Deals eight and two to patient; dealer shows queen	Signals for hit and receives an ace; signals he’s “just right”	1, 2, 3, 5
Dealer pays patient too much money	Corrects error and gives money back to clinician (dealer)	2, 7
Deals king and ace to patient; dealer shows a four	Turns up cards and smiles; says, “Oh boy.”	3, 5
Dealer pays even money instead of the blackjack rate	Patient corrects error	7

conversational topics and share communicative burden. Thus, it seems ideal for use with certain clients with Wernicke's aphasia.

Games

Games provide an excellent resource for working on communication in a context. These might include blackjack, poker, checkers, Monopoly, and other similar games. McDonald and Pearce (1995) have described how the “dice” game can be used to assess pragmatic language skills in patients with closed-head injuries. With their appropriate pragmatic and turn-taking skills, patients with Wernicke's aphasia can work on communicating in a context using such games. An added advantage is that some games provide the opportunity to work on cognitive and executive function skills that support language, such as attention, decision making, and planning. Table 18-5 provides relevant examples of the skills that would be worked on in the game of blackjack.

Reminiscence

Reminiscence therapy (Harris, 1997) capitalizes on the patient's ability to recall and converse about events, people, and places from earlier times. Usually, these are salient events deeply imbedded in one's episodic memories, such as buying a first car, how you met your wife, and what you were doing when the World Trade Center was destroyed. Reminiscence therapy can be used in a group or individual setting.

Problem-Focused Treatment

Problem-solving activities also are suitable for use with the context-based approach to treatment. Marshall (1993) describes a problem-focused group treatment approach that could easily be used to treat, support, and guide patients with less severe Wernicke's aphasia in managing day-to-day communication difficulties. During treatment sessions, group members discuss problems that arise in their daily lives. Members work together to come up with solutions, alternatives, and plans to solve problems. For example, Roy was upset that it now took him more time to disassemble and reassemble his furnace than before he had his stroke. His group came up with several organizational strategies to improve his speed. Credit card woes caused another group member (Cecile) to develop hypertension. She failed to read the information on interest when presented with several credit card offers and went over her credit limit. The problem was discussed in the group and resulted in her (1) seeking individual treatment to learn how interest worked, (2) meeting with a consumer credit counselor to develop a plan to pay off the debt, and (3) tearing up her credit cards.

DEVELOPING CONFIDENCE IN THE CONTEXT-BASED APPROACH

Eisenson (1964) defined “language therapy” as a relationship between the clinician and patient in which both recognize and understand that improvement of communication is

the purpose and the goal. His view of therapy captures what the context-based approach is designed to do—specifically, to improve communication. To use the context-based approach with confidence, however, clinicians need (1) to select the appropriate measure or measures to document treatment outcomes and (2) to increase their cognitive flexibility as therapists.

Measurement

Many direct and indirect measures are available to document treatment outcomes (Fratalli, 1992, 1998; Marshall, 2000). Direct measures, such as the Amsterdam Nijmegen Everyday Language Test (ANELT) and IFCI (reviewed earlier), require the patient to respond in some way, and the examiner scores those responses. Indirect measures, such as the Functional Independence Measure (1993), or FIM, require the clinician to rate the patient's ability to do certain tasks based on what is known about the patient, but they do not require the patient to do anything.

Regardless of whether the clinician measures treatment outcomes directly or indirectly, the documentation measure must be representative of the treatment given (Marshall, 2000). For the context-based approach, this should be a measure related to conversational success. Using a standardized test, such as the PICA, with a patient who has Wernicke's aphasia and is being treated with the context-based approach would be ill-advised, because success on the PICA is integrally linked to retrieving the labels of 10 common objects that make up the core of the test. Some representative measures of transactional success that can be used to document the effects of context-based treatment follow.

Message Exchange Task

The message exchange task was used in a study of information transfer with four patients with articulatory apraxia (Fawcus & Fawcus, 1990). For this task, the patient is given a message to convey to a partner. The patient is allowed to convey the message in any way that he or she chooses. The patient and the partner interact until consensus is reached. The partner rates the efficiency and speed of message exchange and records how each of the critical elements of the message were conveyed (e.g., pointing, gesture, speech, writing, or drawing). Table 18-6 provides an example.

Interaction Competence Scale

Table 18-7 provides another scale, the interaction competence scale (Garrett & Sittner, 1995), that can easily be used to rate the communication success of the patient with Wernicke's aphasia in a conversational interaction.

TABLE 18-6

Example of Message Exchange Task

Message: I am canceling therapy next week because I have to go to Chicago for my sister's wedding

Step 1. Patient conveys message to partner.

Step 2. Partner translates and notes elements of the message conveyed by speech (S), writing (W), drawing (D), gesture (G), or pointing (P).

Canceling (G) therapy (S) next week (P); wedding (S) in Chicago (P)

Step 3. Partner rates efficiency of message exchange:

4 = highly efficient; 3 = efficient; 2 = somewhat efficient; 1 = inefficient; 0 = no basis for understanding.

Step 4. Partner rates speed of message exchange: 4 = prompt, within normal limits; 3 = delayed, but not noticeable; 2 = markedly delayed; 1 = delay made listener uncomfortable; 0 = message not delivered.

Transactional Success

Ramsberger and Rende (2002) have recently developed a way to measure what has been understood and exchanged at the end of a conversation between persons with aphasia and their conversational partners. Those authors did this by examining the conversations of 14 adults with aphasia about a series of *I Love Lucy* episodes. The participants with aphasia had to relay information about each of the episodes to four different partners. Transactional success was measured by examining the amount and type of information the partners could convey after having a conversation with the patient with aphasia.

Increasing Cognitive Flexibility

Clinicians who like order, control, and certainty may have difficulty working with individuals who have Wernicke's aphasia. In particular, this could be the case during the early post-onset period, when the patient's deficits are most pronounced. Clinicians steeped in the use of structured treatment approaches will not be comfortable with the context-based approach, because it is a treatment demanding flexibility and a willingness to experiment. Flexibility connotes a willingness to switch, to deviate from a plan, and to make on-the-spot decisions to enhance communication. Experimentation involves balancing the science and the art—and having the common sense to focus on what is important to the patient. Importantly, clinicians who choose to use a context-based approach need to free themselves of the guilt associated with conversing with the patient and not evoking a specific number of preselected responses.

TABLE 18-7

Scale of Interaction Competence

1. How much did the communicator participate in the interaction?						
1 none	2	3	4 some	5	6	7 a lot
2. How much of the time was Communicator X able to get his or her message across?						
1 none	2	3	4 some	5	6	7 a lot
3. How much of the time did Communicator X take an active role in the interaction by asking questions, generating unsolicited comments, or expressing opinions?						
1 none	2	3	4 some	5	6	7 a lot
4. How frequently did Communicator X use different ways of communicating when trying to get his or her message across (e.g., speaking, writing, or Augmentative Alternative Communication (AAC) system)?						
1 didn't use methods	2	3 used some different methods	4	5	6	7 used many methods
5. How flexible and strategic was Communicator X when trying to convey messages that were not understood by others?						
1 not flexible	2	3	4 some flexibility	5	6	7 very flexible
6. How many communication functions (e.g., asking questions, arguing, giving advice, greeting, or commenting) did the communicator use when conveying messages?						
1 none	2	3	4 some	5	6	7 a lot
7. On a scale of 1 to 5, how would you rate Communicator X's total communication ability?						
1 poor ability	2	3	4 some ability	5	6	7 good

Cognitive flexibility refers to the ability to shift cognitive set, thought, or attention so as to respond in different and, hopefully, successful ways (Rende, 2000). Cognitive flexibility can be reactive and involve altering one's behavior in response to a situation; it also can be spontaneous and involve considering alternatives and formulating ideas on one's own. Successful communication by persons with aphasia is associated with a greater degree of cognitive flexibility (Chapey, Rigrodsky, & Morrison, 1977; Keil & Kaszniak, 2002; Purdy & Koch, 2005; Wepman, 1972). Patients manifesting this trait recognize their errors, come up with solutions to correct them, and to do what is needed

to communicate successfully despite the aphasia. This is what clinicians want them to do.

Cognitive flexibility is important to the patient's success, but clinicians also need to increase their own cognitive flexibility. Patients with aphasia do not use compensatory strategies unless they see the clinician doing the same thing (Simmons-Mackie & Damico, 1997). The patient learns to compensate from the modeling and the demonstrations of the clinician who uses the context-based approach. Using a context-based approach is hard work, because this approach has no script or set of steps to follow. What clinician do, they do based on antecedent events, and this requires continuous

decision making. This underscores that using a context-based approach is more than just talking to the patient but, rather, is something that requires a great deal of skill and experience.

FUTURE TRENDS

Before the fourth edition of *Language Intervention Strategies in Adult Aphasia and Related Disorders* was published in 2001, Holland (1995) noted that the crystal ball looked “cloudy” for specialists in neurogenic communication disorders, because the rising costs of health care and the growth of managed care threatened to reduce funding for treatment of aphasia. Holland’s fears have been realized. In slightly more than a decade, the crystal ball is no longer just cloudy—the crystal ball is black. Most old-guard clinical aphasiologists remember that, not long ago, aphasia clinicians were under fire from the medical profession, because they lacked empirical data to support the efficacy of aphasia therapy (Darley, 1972). That time has long past. Today, a plethora of group, single-subject design, case reports, and qualitative research demonstrate the benefits of therapy for aphasia (Holland, Fromm, DeRuyter, & Stein, 1996; Robey, 1994, 1998; Robey, Schultz, & Crawford, 1999; Wertz & Irwin, 2001). Nevertheless, funding for therapy remains scarce, prompting Rogers, Alarcon, and Olswang (1999) to describe the present-day situation as ironic.

It is obvious what the future does not hold. This is hope for the U.S. Congress to drop a boatload of money into the hands of service providers to pay for more treatment of persons with aphasia. It is only possible to speculate what could be done in the future to improve things. Three possibilities are discussed here: (1) increasing advocacy for aphasia treatment, (2) directing more research effort at people with acute rather than chronic aphasia, and (3) training future aphasia clinicians for what their jobs will be instead of what those jobs used to be.

Advocacy

People get terribly frustrated with aphasia, but they do not die from it (Marshall, 1997). Regrettably, an international survey of public awareness of aphasia indicated most individuals have little knowledge of what aphasia is (Simmons-Mackie, Code, Armstrong, Stiegler, & Elman, 2002). Another study examined the frequency with which the word “aphasia” occurred in newspapers in comparison to other chronic conditions (Elman, Olgar, & Elman, 2000). Results indicated that “aphasia” was found far less often than references to less frequently occurring conditions, such as Parkinson’s disease and muscular dystrophy. So perhaps, as recommended by Elman and colleagues (2000), something that we will see in the future will be greater unification and effort from those affected by aphasia (e.g., patient, families,

friends, and professionals) to “energize and pressure politicians and insurance companies” (p. 459) to increase funding for aphasia treatment.

Research

More aphasia research has not increased funding for treatment of the disorder. In fact, things are worse now than when Holland looked into the crystal ball in 1995 and the Balanced Budget Act was passed in 1997. Perhaps aphasia research has had little effect on funding because it has not, for several years, focused on the patient and the family during the early post-onset period, when concern is greatest about the impact of aphasia on the future, but has focused instead on those living with chronic aphasia who may have adjusted to the condition. It appears that the only clinicians who are able to see patients with chronic aphasia work in universities, VA hospitals, or socialized medical-care systems; these are the people doing most of the research on aphasia. This research, however, is being carried out with very chronic patients. Of course, this research is valuable. Rarely, however, front-line clinicians are able to treat patients with aphasia much past the early post-onset period (1–3 months), because no money is available to pay for it. Ongoing research is studying people with aphasia who are being provided pharmacological and other medical treatments shortly after the onset of aphasia to minimize the impact of brain injury (Hillis & Heider, 2002; Hillis et al., 2002; Shisler, Baylis, & Frank, 2000; Walker-Batson et al., 2001). Thus, the future may see more aphasia treatment research being done closer to the time of the patient’s stroke, and perhaps, the results of that research will impact funding decisions.

Training

Hopefully, the future will see graduate students being trained for the jobs they will have rather than for the jobs of the past. This might involve the following:

1. Introducing students to contemporary measures of assessment that capture how treatment impacts the patient’s day-to-day life and psychosocial functioning.
2. Teaching students how to talk to physicians to help them understand that communication is as important as swallowing.
3. Educating students about and providing them with experiences in group treatment.
4. Including information about social approaches to treatment of aphasia in the graduate curriculum.
5. Promoting altruistic behavior in students to stimulate the initiation of support groups and involvement in groups such as the National Aphasia Association.
6. Developing mechanisms to keep abreast of the aphasia literature, which continues to grow exponentially.

KEY POINTS

1. Neurological damage in Wernicke's aphasia affects the posterior language zones, causing aphasia, but spares the primary motor cortex. Clients with Wernicke's aphasia therefore do not suffer motor deficits, seldom need physical and/or occupational therapy, and are discharged early from the hospital.
2. Clients with Wernicke's aphasia reflect marked differences in terms of auditory comprehension in situations with and without contextual support. Most clients will perform far better in a conversational situation than on an aphasia test.
3. Individuals with Wernicke's aphasia have been regarded as having poorer prognoses for improvement following language therapy compared with patients who have nonfluent aphasia. Largely, this is because improvement following treatment of aphasia is dependent on changes in test scores on standardized aphasia tests that may not capture improvements made by clients with Wernicke's aphasia.
4. Treatment outcome research and treatment programs for persons with aphasia rarely address clients with Wernicke's aphasia. This may result from the fact that "talking aphasic people" are able to get by in most communicative situations and do not seek further treatment beyond the basic coverage provided by most health-care programs.
5. Training of students and successful use of a context-based approach with clients who have Wernicke's aphasia requires knowledge of personal biographical information about the client that can be used to create client-relevant assessment and treatment procedures.
6. Successful therapy for the client with Wernicke's aphasia is highly dependent on the flexibility of the clinician and on his or her the willingness to try different approaches rather than any single treatment or combination of treatments.
7. Group treatment is appropriate for clients with Wernicke's aphasia and may offer a long-term solution to the management of this condition.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Describe how you would convince a client with Wernicke's aphasia about to be discharged home 2 days after a stroke that it was vital to return to the hospital for an outpatient evaluation of his communication deficits.
2. Prepare an interactive in-service for the rehabilitation staff on how to maximize auditory comprehension for a specific client with Wernicke's aphasia.

3. Create verbatim transcriptions for descriptions of the cookie-theft picture from clients with moderate Wernicke's and Broca's aphasia. Describe how these two transcriptions differ in terms of phonologic, semantic, and syntactical features.
4. Prepare a list of home assignments for a client with Wernicke's aphasia that would supplement your treatment goals and improve generalization.
5. Describe how you would carry out a program of conversational coaching that would improve communication between clients with Wernicke's aphasia and their spouses.
6. Mr. Jones, a man with Wernicke's aphasia now a year post-onset, loves to play poker every week with his friends. They stopped inviting him to their games after his stroke. Develop a plan of action for facilitating Mr. Jones returning to this formerly enjoyed activity.
7. Describe the types of responses on a naming test you expect from a patient with Wernicke's aphasia that would be reflective of semantic, phonologic, and post-lexical errors.
8. Prepare a series of tasks that you could use to measure improvement in receptive and expressive functions for a client with Wernicke's aphasia, and describe how these will be used to measure therapeutic outcomes.

Chapter 19

Rehabilitation of Subcortical Aphasia

Stephen E. Nadeau and
Leslie J. Gonzalez Rothi

OBJECTIVES

The objectives of this chapter are to elucidate features and mechanisms of thalamic and nonthalamic subcortical aphasia, to analyze these aphasia in terms of the impairments they reflect in the neural networks supporting language function, and to review behavioral consequences of subcortical lesions associated with aphasia that may seriously interfere with the rehabilitation process.

Subcortical aphasia is defined as a language disorder associated with damage to subcortical brain structures, such as the basal ganglia, the thalamus, or the white matter pathways in the general vicinity of these structures. Usually, it is caused by ischemic strokes, and less often by intracerebral hemorrhages. When these disorders were first described, the aphasia was assumed to be a direct consequence of the damage to subcortical structures that was revealed by structural imaging studies, such as computed tomography and magnetic resonance imaging. Further research has shown this assumption to be substantially incorrect (Nadeau & Crosson, 1997). Aphasia is actually an indirect consequence of subcortical lesions. In the case of subcortical aphasia stemming from thalamic lesions, the language disorders appear to stem from the impact of thalamic dysfunction on cerebral cortical function (i.e., a disorders of neural systems). In the case of subcortical aphasia stemming from lesions outside the thalamus, the language disorders reflect either invisible cortical damage or dysfunction associated with the vascular event that caused the visible subcortical lesion, or they reflect the impact of the subcortical lesion on pathways between the thalamus and language cortex.

We will begin this chapter by describing the neural mechanisms underlying thalamic aphasia and the pathogenesis of nonthalamic subcortical aphasia. We also will

review the linguistic features of these disorders, with a particular emphasis on the dysfunction of the underlying neural systems that these disorders reflect. We know of no adequately controlled scientific studies regarding the efficacy of therapy for subcortical aphasia. For the time being, therefore, we assume that therapy for specific deficits commonly associated with cortical lesions (e.g., word-retrieval impairment) will show similar efficacy when the lesion is subcortical. Clearly, this idea requires testing. We will conclude with a consideration of nonlinguistic behavioral disorders that frequently are present in patients with subcortical aphasia and that may have a major impact on prognosis.

Thalamic Aphasia

The thalamus is located at the center of the cerebrum at its junction with the midbrain (Figs. 19–1 through 19–3). Although its function is by no means simple, the thalamus is far simpler and better understood than that of any other cerebral structure. In essence, it functions as a *relay device*. Specific groups of neurons within the thalamus (nuclei) relay sensory information from more peripheral neural waystations to the cerebral cortex. For example, visual information is transmitted from the retinas via the lateral geniculate bodies to the primary visual cortex (calcarine cortex) in the occipital lobes. Auditory information is relayed through a chain of nuclei within the brain stem to the medial geniculate bodies, from which it is transmitted to primary auditory cortex (Heschl's gyrus) on the dorsal surface of the temporal lobe deep within the sylvian fissure. Somatosensory information is relayed by two major pathways within the spinal cord and brain stem to two specific thalamic nuclei, the ventral posteromedial (subserving the face) and ventral posterolateral (subserving the body) (Table 19–1), from which it is then relayed to somatosensory cortex on the surface of the cerebral hemispheres. Thus, these three pairs of nuclei relay information derived from sensory organs outside the brain to the cerebral cortex. The remainder of the thalamic nuclei relay information from one part of the brain to another. For example, neural transmission from motor areas of the cerebrum to the cerebellum and the putamen is relayed back to separate portions of the ventrolateral nucleus of the thalamus,

TABLE 19-1

Abbreviations

Cd _H	Head of the caudate nucleus
GABA	γ -Aminobutyric acid
IC _{AL}	Internal capsule, anterior limb
ITP	Inferior thalamic peduncle
MCA	Middle cerebral artery
MRF	Midbrain reticular formation
PCA	Posterior cerebral artery
Thalamus	
CmPf	Center-median parafascicularis nuclear complex
DM	Dorsomedial nucleus
IML	Internal medullary lamina
LP	Lateral posterior nucleus
MTT	Mammillothalamic tract
NR	Nucleus reticularis
NR _{VA}	Portion of NR over anterior pole of VA, interfacing with ITP
VA	Ventral anterior nucleus
VLa	Ventrolateral nucleus, anterior portion
VPL	Ventroposteromedial nucleus
VPM	Ventroposterolateral nucleus

and from there back to motor areas of the cortex. For all these nuclei—as, indeed, for every nuclear group in the thalamus—the cortical projections to the thalamus are at least as extensive as the projections from the thalamus to the cortex. This two-way connectivity is entirely consistent with our emerging understanding of the neural network basis of brain function (Nadeau, 2001).

Of particular interest with respect to language and language-related processes are two other nuclear groups, the dorsomedial nucleus (DM) and the pulvinar-lateroposterior (LP) complex. These nuclear groups resemble the ventrolateral nucleus, in that they relay information originally derived from the cerebral cortex back to the cerebral cortex. The DM, however, relays information from the prefrontal cortex and several subcortical structures back to the prefrontal cortex. The pulvinar-LP complex relays projections from the frontal, temporal, and parietal cortices (including those portions of the dominant hemisphere directly implicated in language function) as well as from some subcortical structures back to these same cortices. As we shall see below, there appears to be a logical relationship between dysfunction in these two nuclear groups and particular features of thalamic aphasia.

It is more accurate to characterize the thalamus as a regulated or gated-relay device. This gating feature helps to address two questions. First, what could conceivably be the purpose of long connections descending from, for example, the temporoparietal cortex to the pulvinar-LP complex only

to be sent right back to the very same cortex? One product of passing cortical information through the thalamus may be that this information—and, by implication, the originating cortex—is subjected to the regulatory mechanism provided by the thalamic gate. Second, considering that ischemic strokes involving either the DM or pulvinar-LP complex (the thalamic regions being linked most directly to the language cortex) are extremely rare, how do we explain thalamic aphasia in terms of dysfunction of these two regions? To do so, we must look for a cause of dysfunction other than direct damage. It appears that thalamic strokes sparing these nuclear groups produce aphasia by damaging key components of the thalamic gating mechanism. At this point, we must address four questions: (1) how does the thalamic gating mechanism work, (2) how do strokes impair its function, (3) what purpose could such a gating mechanism serve, and (4) what is likely to be the specific impact of disorders of the gating mechanism on cortices supporting higher neural function, most specifically language function? The neuroscientific data needed to answer these questions are limited, so our answers necessarily involve considerable inference and speculation.

How Does the Thalamic Gating Mechanism Work?

Nearly the entire thalamus is enveloped by a paper-thin layer of cells comprising the thalamic reticular nucleus (NR; Fig. 19-3). The cells of this nucleus, unlike those in the remainder of the thalamus, send their projections back into the thalamus, where they synapse both on thalamic relay neurons and on inhibitory thalamic interneurons. They employ an inhibitor neurotransmitter (γ -aminobutyric acid [GABA]). Thus, they are admirably suited to regulating thalamic transmission to the cortex, either by directly inhibiting thalamic relay neurons or by indirectly potentiating their activity through inhibiting the inhibitory interneurons within the thalamus.

The neurons of the NR are regulated by a host of brain systems. Two systems appear to be particularly important. The first is the midbrain reticular formation (MRF), a complex network of neurons within the core of the midbrain immediately below the thalamus. The MRF defines the level of wakefulness or arousal. With high levels of arousal, the MRF inhibits the NR at the same time that it excites thalamic relay neurons, thereby allowing all neural transmission to pass readily through the thalamus. Thalamic relay neurons fire at a rate that is a linear function of input, thereby functioning to relay the input to their cortical projection targets faithfully. With low levels of arousal, as in deep sleep or coma, because of low input from the MRF, the NR neurons exert maximally inhibitory effects on thalamic relay neurons at the same time that these relay neurons receive little excitatory input from the MRF. In this state, relay neurons fire in intermittent, high-frequency bursts that convey

little information about temporal fluctuations in their input amplitude. Cortical relay of thalamic input is effectively blocked. In this way, the impact of the MRF on thalamic transmission is global and nonselective.

The second major regulatory system is provided by projections from the entire cerebral cortex to the NR. Two subsystems can be defined within this set of projections: a *direct* system, involving modality-specific cortical projections to individual thalamic nuclei that largely reciprocate thalamocortical projections and synapse on NR neurons as they pass through the NR; and an *indirect* system, involving projections from the prefrontal cortex to the NR via the inferior thalamic peduncle (ITP), providing a potential basis for multimodal regulation of thalamic transmission. Both systems provide a mechanism by which thalamic transmission from specific regions of specific nuclei can be selectively gated to the cortex.

The mechanisms underlying selective NR regulation of thalamocortical transmission are currently the subject of intense study and much debate, and the last 10 years have seen a surge of interest in the role of NR in attentional processes (Bezudnaya et al., 2006; Crabtree & Isaac, 2002; McAlonan, Cavanaugh, & Wurtz, 2006; Pinault, 2004; Sherman, 2005). This work has focused almost exclusively on the direct corticothalamic system. Corticothalamic neurons synapsing on the NR and thalamic relay neurons are glutamatergic and, therefore, excitatory. Because this excitatory input to NR neurons inhibits thalamocortical transmission (NR neurons are GABAergic and, therefore, inhibitory), it is difficult to understand how this mechanism could serve to selectively release thalamic transmission to cortex.

Two possible explanations have emerged. First, a given NR neuron may project to neurons in several specific regions of the thalamus, and NR neurons have extensive dendrodendritic contacts with one another. This anatomy provides a mechanism by which a given region of the cerebral cortex could shape thalamocortical transmission from one or more nuclei both spatially and temporally. Evidence also has emerged that NR neurons not only have ion channel-linked glutamate receptors (uniformly excitatory) but also metabotropic (non-ion channel) glutamate receptors, some of which may exert inhibitory effects (Cox & Sherman, 1999). Second, although in our previous discussion of MRF effects on NR activity we linked the intermittent burst mode of thalamic relay neuron activity to low arousal states and closing of the thalamic gate, evidence in multiple species, including humans, now suggests that brief epochs of intermittent bursting can be observed in the awake state. Because these bursts are associated with a particularly high signal to noise ratio, they could effectively break through ongoing cortical activity to signal the need for a change in focus of attention or function. They are associated with onsets of stimulus change and occur either when the subject is awake but not attentive or when the subject is

attending to a stimulus in one modality and a salient stimulus is presented in another. It has been suggested that this mechanism may serve to give the cortex a “wake-up call,” either during drowsiness or during attention to another stimulus, that will lead the organism to focus on a stimulus that, by virtue of its sudden appearance, may be particularly important (Sherman, 2005). In this way, the thalamic intermittent burst mode could serve as one mechanism underlying reactive attention—that is, attention elicited by the intrinsic properties of the stimulus (Nadeau & Heilman, 1991).

The indirect corticothalamic regulatory system, involving a pathway from the prefrontal cortex to the NR via the ITP, provides a mechanism by which thalamic transmission to specific regions of the cortex might be regulated volitionally. Because language largely is produced volitionally, it would seem logical that, to the extent the thalamus is involved in language, dysfunction of this system would lead to aphasia. Empirical studies bear this out (see below). Unfortunately, little neuroscientific study of this system has occurred since our last review (Nadeau & Crosson, 1997).

How Do Strokes Impair the Function of the Thalamic gate?

The projections from both the MRF and the prefrontal cortex to the NR terminate in a dense neural complex near the anterior pole of the thalamus (NR_{VA}), which is immediately adjacent to the ventral anterior (VA) nucleus of the thalamus (Fig. 19-3). This NR_{VA} neural complex appears to play a role in regulating the entirety of the NR. The mechanism by which the prefrontal cortex regulates the thalamic gate also appears to require the participation of the center-median parafascicularis (CmPf), a nuclear complex buried deep within the posterior portions of the thalamus (Figs. 19-2 and 19-3). Fibers from the prefrontal cortex to and from the CmPf pass within the thalamus in a neural fascicle, the internal medullary lamina (IML), which also envelopes the CmPf. Immediately in front of the thalamus, these fibers pass through the ITP, which is continuous with the anterior limb of the internal capsule and the deep white matter of the frontal lobe (Figs. 19-1 and 19-3). Although the means we use to localize strokes within the thalamus are prone to error, all the thalamic strokes that have been reported to result in aphasia appear to have involved either VA at the nexus of the connections between the prefrontal cortex (the ITP), the MRF, and the NR_{VA}; the IML carrying connections from the prefrontal cortex to CmPf; or the CmPf itself. Thus, it appears that all ischemic strokes causing thalamic aphasia disrupt the regulatory system for the thalamic gate for the entire hemithalamus by damaging either the prefrontal-NR_{VA} junction or the prefrontal-NR_{VA}-IML-CmPf axis. This disruption would implicate transmission from all thalamic

nuclei, including the pulvinar-LP complex, which is heavily connected to language cortices. Thalamic strokes that are not associated with aphasia appear to spare these structures and pathways. Disorders of executive function also often occur with lesions of the prefrontal-NR_{VA}-IML-CmPf axis (Van der Werf et al., 2003), perhaps because of associated dysfunction of the DM, which is heavily interconnected with prefrontal cortex. Hemorrhages, which do not respect vascular territories, may directly damage the pulvinar-LP or DM.

What Purpose Could Such a Gating Mechanism Serve?

The brain contains approximately 100 billion neurons organized into hundreds of systems, each of which is nearly infinitely malleable. It appears logical that there should be, given this situation, that some systems function simultaneously to maintain order and to optimize the resources that are brought to bear on a particular problem—that is, systems that allocate processing demands either among the multitude of different neural networks or within parts of particular networks. Several lines of research have begun to delineate executive systems that serve this purpose.

More than 20 years ago, Moran and Desimone (1985) performed a clever experiment that provides particular insight into the fundamental nature of one of these allocation processes. Scientists were recording the activity of single neurons in the inferotemporal cortex (visual-association cortex) of macaque monkeys. In one study, they identified a neuron that was sensitive only to red light. If the monkey had been trained to pull a lever to be rewarded with a squirt of apple juice whenever a red light came on, this neuron fired vigorously in response to the red light. If the monkey had been trained to expect reward for a pulling a lever in response to a green light, however, this neuron failed to fire in response to a red light. In other words, this neuron required two inputs to fire, one from visual cortex signaling the presence of red and one from elsewhere in the brain, almost certainly the frontal lobes, signaling that red was behaviorally important, because it indicated an opportunity to get a reward. During the red-light rewarded condition, input from the frontal lobes preferentially sensitized red-sensitive neural systems; that is, it recruited red-sensitive neurons to working memory. This corresponded to particular attention by the monkey to red lights. The process exhibited by the monkeys in the experiment of Moran and Desimone can be termed “intentional attention,” because it subserves attentional behavior and constitutes a deliberate, volitional allocation of sensory (visual) resources to achieve a particular end (get a juice reward).

Recently, Minamimoto and Kimura (2002) reported an experiment that sheds light on the potential role of the prefrontal-NR_{VA}-IML-CmPf axis in intentional attention.

They trained macaque monkeys in the Posner paradigm.¹ When CmPf was inactivated by injection of the GABA_A-agonist muscimol, the validity effect was abolished—that is, correct cues to the side on which the stimulus would appear no longer produced a reduction in reaction time. No other aspect of task performance was affected. Thus, inactivation of the CmPf produced a selective deficit of intentional attention. An earlier experiment by Weese, Phillips, & Brown (1999) showed that a cellular lesion at a different locus along this pathway, the NR, had the same effect.

Attention also may be reactive (Nadeau & Heilman, 1991). For example, we orient to a brilliant flash of light or a sudden movement in our environment because of the intrinsic value the brain assigns to these types of stimuli. A precise but flexible balance must be maintained between intentional (volitional) and reactive attentional systems. For example, a rat must engage intentional attention to search for edible material but also, simultaneously, must maintain reactive attention to detect approaching predators.

The attentional phenomena we have been discussing so far involve the selection of particular neural networks or components of networks in cerebral association cortices in the service of focusing sensory systems on some particular locus in the environment (i.e., orienting). Abundant reason now exists to believe that precisely analogous processes occur in polymodal or supramodal cerebral cortices, such as those supporting language function, that correspond to thinking and the formulation of behaviors other than orienting. These processes have been the focus of considerable study over the past 20 years (Fuster, 1991; Goldman-Rakic, 1990). The term “working memory” often is used to refer to the information maintained by activation of a selected neural network (e.g., memory that the color red is important, as in the experiment of Moran and Desimone, 1985), although we prefer the more neutral term “selective engagement.” In this conceptualization, attentional processes represent the subtype of selective engagement involved in allocating components of neural networks located in sensory association cortices in the service of attentional behavior.

The thalamus also appears to support selective engagement processes. Nonhuman primate research, however,

¹In the Posner paradigm (Posner, Walker, Friedrich, & Rafal, 1987), the subject begins by focusing on cross-hairs at the center of a computer screen. A cue subsequently appears on either the right or left of the screen that indicates to the subject on which side a subsequent stimulus is likely to appear (with 80% accuracy). As soon as the stimulus actually appears, the subject makes a response. The experimental measure is the reaction time. The cue will lead the subject to volitionally direct attention to the side of the cue, providing the basis for a reaction time advantage if the stimulus actually appears on that side (the validity effect). On those 20% of trials when the cue is misleading, the stimulus engages reactive attentional mechanisms, which ultimately lead the subject to make an orienting response, but with a somewhat longer reaction time.

suggests that, at this stage in the evolution of the brain, very little of this regulation involves thalamic projection to primary sensory cortices. The thalamus appears to be only minimally involved in *ongoing* gated relay to primary sensory cortices of visual or auditory information, but it may be involved to some extent in regulating the relay of somatosensory information. That is, attentional mechanisms (selective engagement) involving visual and auditory modalities have been subsumed by the cerebral cortex.² For thalamic nuclei such as the DM and pulvinar-LP complex that have evolved in tandem with the burgeoning of cerebral cortex in higher primates, indirect evidence suggests that their role in ongoing selective engagement has not been superseded. In nonhuman primates, ongoing attentional modulation of neural activity in the pulvinar occurs in parallel with modulation of neural activity in visual and polymodal association cortices, though to what extent the pulvinar modulation is responsible for cortical modulation cannot be determined from this experiment (Bender & Youakim, 2001). Even so, neglect, extinction, and delayed reorienting of attention have been induced by injection of the GABA-agonist muscimol into the pulvinar (Desimone, Wessinger, Thomas, & Schneider, 1990; Petersen, Robinson, & Morris, 1987). These studies, coupled with evidence of cortical dysfunction after thalamic lesions in human subjects, suggest that the thalamus is responsible for at least certain aspects of selective engagement of cortex. Thus, in humans, thalamic gating mechanisms appear to be most important in regulating selective engagement of *association* cortices (unimodal and polymodal) as well as supramodal association cortices supporting higher neural functions, such as language.

Recent studies have further elucidated this process. Wester, Irvine, & Hugdahl (2001) reported that in consonant-vowel dichotic listening tasks (in which processing likely takes place in the auditory association cortex, Brodmann's area 22, and frontal operculum [Nadeau, 2001]), patients with subacute and chronic thalamic hemorrhages exhibit a strong ipsilesional ear advantage, which they cannot overcome even when told to direct their attention to the contralesional ear. These findings suggest a disorder of selective engagement affecting reactive attention (hence the ipsilesional ear advantage) and intentional (volitional) attention (hence the inability to overcome the contralesional ear disadvantage). Kubat-Silman, Dagenbach, & Absher (2002) reported impairment on letter, object location, and object

shape N-back task performance³ in six subjects with old thalamic infarcts (five right-sided and one left-sided). The N-back tasks are widely accepted as probes of working memory—a function that depends on selective engagement, as discussed previously. Of note, even though both hemispheres likely are engaged by these tasks, unilateral thalamic lesions were disruptive, and no clear differences were found in performance between the patient with the left-side lesion and the five patients with right-sided lesions. In this same study, forward digit span was normal in all subjects, even when articulation was suppressed by the requirement that subjects repeatedly say the word “the” during task performance. This finding is consistent with the evidence that thalamic aphasia relatively spares repetition and, thus, relatively spares the procedural knowledge domain underlying phonologic processing that is engaged in repetition and digit span performance (Nadeau, 2001) (see next section).

What Is Likely To Be the Specific Impact of Disorders of the Thalamic Gating Mechanism on Function of the Cerebral Cortex (Most Specifically the Language Cortex)?

The neuroscience of thalamocortical interaction has not advanced to the point of providing a precise picture of how disorders of thalamic gating impact higher cortical function, and we are dependent primarily on human data in the inferences that we draw regarding this subject. Thalamic aphasia is characterized classically by anomia in spontaneous language (at times severe), some impairment in naming to confrontation, apparently normal grammar, normal articulation, and usually flawless repetition. Naming deficits disproportionately affect low-frequency words (Raymer, Moberg, Crosson, Nadeau, & Gonzalez-Rothi, 1997). In the worst cases, modest impairment in comprehension may be noted. Some patients make semantic paraphasic errors, and rare patients, primarily those with thalamic hemorrhages, transiently produce neologisms. Can we relate this pattern of deficits to any fundamental functional attributes of the cerebral cortices involved? We have proposed that linguistic deficits wrought of thalamic dysfunction reflect selective functional impairment of cortices supporting declarative memories, with sparing of cortices supporting procedural memories (Nadeau & Crosson, 1997).

Declarative or explicit memory consists of knowledge regarding facts and events and ordinarily is available to

²Note that we stress *ongoing* gated relay. As noted in an earlier section (see the section *How Does the Thalamic Gating Mechanism Work?*), the thalamic burst mode state may provide a mechanism to give the cortex a brief “wake-up call” that will result in shifting thalamic relay neurons into a linear transmission mode, thereby opening thalamic transmission to the cortex in a fashion that no longer is regulated at the thalamic level.

³In N-back tasks, the subject hears or sees a steady stream of stimuli (e.g., letters) presented one at a time at a fixed rate. The subjects has to respond when the current stimulus matches the immediately preceding stimulus (i.e., the N=1 N-back task); the current stimulus matches the stimulus that occurred before the immediately preceding stimulus (i.e., the N=2 N-back task), and so on.

conscious recollection. It is represented in association cortices throughout the brain. New declarative memories are encoded by a system comprised of the hippocampus; cortices overlying the hippocampus; several structures in the limbic system, which presumably help to define which facts are worth remembering; and the DM and the anterior nuclear group of the thalamus (Squire, 1987, 1992).

Nondeclarative memory consists of a heterogeneous collection of abilities (including skills and habits), implicit memory, and some forms of classical conditioning. Nondeclarative memory is reflected only in behavioral change, as when one's tennis game improves with practice or an experimental subject demonstrates an autonomic response or a correct decision when reexposed to a stimulus previously presented too briefly to provide even a sense of familiarity, let alone a basis for conscious recognition. Skills, habits, and some forms of classical conditioning are represented in the motor and premotor cortex, the cerebellum, and possibly, the basal ganglia. Unlike declarative memory, nondeclarative memory does not appear to require a special auxiliary processing mechanism like the hippocampal system to be instantiated. Patients with impaired declarative memory generally have preserved nondeclarative memory.

The principal linguistic deficit exhibited by patients with thalamic aphasia is in lexical-semantic access (Nadeau & Crosson, 1997), a process that clearly depends on declarative memories. In contrast, linguistic processes involving phonologic processing and grammar generally are spared. Although we have declarative knowledge of the spelling of words, we rely on entirely automatic processes not available to conscious recollection in the actual production of spoken words. Although we have declarative knowledge of the concepts about which we plan to speak, the process of translating concepts into clause sequences and appropriate phrase structures also largely is an automatic one and largely unavailable to conscious recollection (except to the extent that we deliberately modify grammar to meet situational demands). Thus, the preponderance of data regarding phonologic and grammatical processes in thalamic aphasia appears to indicate substantial sparing of procedural memory systems.

Unfortunately, this tidy picture cannot be reconciled completely with available data regarding phonologic and grammatical function in patients with thalamic lesions. First, patients with thalamic hemorrhages often have been reported to produce phonemic paraphasic errors and neologisms. This phenomenon also occasionally can be seen in patients with ischemic lesions (Ebert, Vinz, Görtler, Wallesch, & Herrmann, 1999; Raymer et al., 1997). Because it appears to represent dysfunction involving phonologic sequence knowledge, which would seem to be procedural in nature (Nadeau, 2001; Nadeau & Gonzalez-Rothi, 1993) (see Chapter 26), this finding is not easily reconciled with a concept that the thalamus is mechanistically involved only in declarative processes. The disproportionate occurrence of neologisms

with acute hemorrhage raises the question of some kind of pathologic excitatory phenomenon. Whether hemorrhage or ischemic lesion, however, we are still left without an explanation for the occasional occurrence of neologisms, but we have offered two possibilities (Nadeau & Crosson, 1997):

1. The process of becoming literate serves to additionally define phonemes, inflectional grammatical morphemes, derivational morphemes, and syllables as lexical elements in their own right, which are consciously retrievable like any item in declarative memory and, therefore, are susceptible to errors of selection, as whole words are (Bertelson & De Gelder, 1989; Semenza, Butterworth, Panzeri, & Ferreri, 1990). This "sublexicalization" may create susceptibility to the production of sublexical paraphasias manifesting as phonologic errors and neologisms in the presence of thalamic injury.
2. Thalamic lesions may sufficiently disrupt mutually inhibitory relationships within cortices supporting semantics that competing semantic entrees can vie simultaneously for translation into a phonologic sequence, with the ultimate outcome being a word blend that constitutes a neologism.

An important recent paper has provided compelling evidence of syntactic simplification and, possibly, agrammatism in a patient with bilateral paramedian thalamic infarcts (De Witte, Wilssens, Engelborghs, De Deyn, & Mariën, 2006). How might this be explained? A concept representation, corresponding to a noun phrase, can be represented in neural network terms as a specific pattern of activation of the neurons in association cortices representing the various features of that concept (see Chapter 26). Production of a sentence invariably involves modification of that distributed concept representation, and it usually involves generation and reciprocal modification of two or more distributed concept representations and the binding of these representations into a superdistributed representation. For example, the sentence "the old man shot the burglar" involves simultaneously generating two distributed concept representations, one corresponding to an old man and one corresponding to a burglar. It also requires reciprocal modification of these representations to yield a new representation corresponding to "shooter old man" that now is linked to another new representation corresponding to "shot burglar." The use of verbs mandating three arguments would correspond to the simultaneous maintenance and reciprocal modification of three distributed concept representations, and addition of embedded clauses will demand still further active distributed concept representations.

The production of normal syntax requires both the ability to generate and maintain multiple distributed concept representations (i.e., selective engagement/working memory) and skill in the modification of these various representations.

Broca's aphasia occurs with lesions that damage the frontal apparatus that is apparently required to modify distributed concept representations and is certainly required to reciprocally modify multiple distributed concept representations (and, hence, simplification of syntax, among other things). It may be that selective engagement mechanisms supporting needed working memory are integral to this apparatus or that frontal networks involved in this selective engagement are, to some degree, anatomically separate. The report of De Witte and colleagues (2006) suggests that disorders of selective engagement caused by thalamic lesions could produce a pattern of language abnormality having some similarities to that of Broca's aphasia. Even some abnormalities of grammatical morphology might be explained in terms of working memory deficits, even though we suspect that in Broca's aphasia, the loss of phonologic sequence knowledge involving words, their affixes, and short phrases (caused by the perisylvian component of the lesions) makes a major contribution to agrammatism (see Chapter 26). For example, the use of articles is particularly dependent on sustained working memory of what has just been said to determine whether the reference should be definite or indefinite. Absent working memory of what has been said, the lack of a concept of definiteness or indefiniteness may result in a failure to produce the article, as in the case described by De Witte and colleagues.

The notion that thalamic lesions can lead to disorders of endogenous generation of distributed concept representations invites comparison with adynamic aphasia (Gold et al., 1997). In adynamic aphasia, subjects appear to be incapable of endogenous generation of any distributed concept representations, hence their extreme nonfluency. When distributed concept representations are generated from without, however, as in a picture description task, subjects with adynamic aphasia perform relatively normally. The report of De Witte and colleagues suggests that, at least with certain uncommon thalamic lesions, distributed concept representations can be generated endogenously to the degree that the patient can translate them into words but that these representations cannot be sustained in the manner necessary for them to be related to each other and modified in the well-practiced ways that instantiate the rules of syntax (see Chapter 26). Thus, we might employ the term "paradynamic" to describe the patient of De Witte and colleagues to indicate that the fundamental problem involves endogenous selective engagement but also that, rather than a complete failure of endogenous engagement, as in adynamic aphasia, it constitutes disjointed, excessively brief, and substantially dysfunctional engagement.

Intimations of the problem observed by De Witte and colleagues can be found in the older thalamic aphasia literature. Goldenberg, Wimmer, & Maly (1983) noted disproportionately impaired ability to elaborate in the spontaneous description of remote memories—a problem reminiscent of adynamic aphasia. Lhermitte (1984) observed evidence of

problems with conceptual delineation and sequencing in patients with thalamic lesions. He noted that "narration is no longer chronologic . . . a passage from one story slides into another story. . . the patient cannot control the order of his ideas" (p. 106). He also noted that disorders of this type are seen in patients with left frontal lesions. Nevertheless, De Witte and colleagues appear to be the first to provide such detailed evidence of syntax simplification and at least some evidence of agrammatism in thalamic aphasia. Does this merely reflect the thoroughness of their investigation, or might it reflect something unusual about their patient's lesion? The lesion in their case might, in fact, have been somewhat unusual. In particular, the lesion was bilateral (as in the case of many paramedian artery distribution infarcts), and it likely involved the prefrontal-NR_{VA}-IML-CmPf axis bilaterally, thus producing bilateral disorders in thalamic engagement involving the pulvinar-LP and DM. It also extended relatively anterior and deep, potentially destroying prefrontal-to-DM pathways that run beneath the thalamus before curving upward to extend into the DM (Nadeau & Crosson, 1997; Steriade, Parent, & Hada, 1984). In contrast, Raymer and colleagues (1997) noted normal syntax in a patient with a very large left paramedian artery distribution infarct, verbal amnesia, severe anomia, and major disruption of prefrontal function.

In summary, if these ideas find support in future investigations of syntactic disorders and agrammatism in subjects with thalamic aphasia, it may still be possible to account for thalamic aphasia as a disorder of declarative knowledge processing.

NONTHALAMIC SUBCORTICAL APHASIA

Whereas the development of aphasia after thalamic lesions is a natural consequence of the disrupted function of neural systems implicated in language processing, the development of aphasia after nonthalamic subcortical lesions appears to be largely a consequence of direct damage to language cortices that is not visible on imaging studies, reflecting mechanisms of stroke pathogenesis. That is, nonthalamic subcortical aphasias are not fundamentally different in character or pathogenesis from cortical aphasias.

At first, the problem of nonthalamic subcortical aphasia seems formidable, given the enormous variety in size and location of lesions as well as the spectrum of linguistic disorders observed. In our approach to this problem, we chose to simplify by focusing on one type of subcortical lesion producing aphasia, the striatocapsular infarct (Nadeau & Crosson, 1997). We did so for two reasons. First, this is a relatively common lesion that is typically fairly stereotyped in size and configuration. Second, because this infarct apparently is confined to structures that appear to have nothing to do with language (i.e., the head of the caudate nucleus, the putamen, and the interleaved anterior limb of the internal capsule) (Fig. 19-1), the very existence of aphasia in patients

Figure 19-4. Anteroposterior view of cerebral vascular anatomy relevant to the problem of nonthalamic subcortical aphasia. (From Nadeau et al., 2004; with permission.)

with this lesion provides compelling evidence of either an unrecognized neural mechanism or a completely non-neural mechanism. In fact, the latter proved to be the case.

The striatocapsular infarct is caused by the propagation of thrombus or the embolization of blood clot into the proximal (M1) portion of the middle cerebral artery (Fig. 19-4). There, the clot occludes the lenticulostriate arteries supplying the head of the caudate nucleus, the anterior limb of the internal capsule, and much of the putamen, causing essentially complete infarction (death) of these structures. It should be noted, however, that this same clot also severely reduces the flow of blood to the middle cerebral artery branches supplying the overlying cerebral cortex. This cortex becomes entirely dependent on blood flowing backward into the middle cerebral artery branches from their connections (anastomoses) with branches of the anterior cerebral artery and the posterior cerebral artery. If these anastomoses are abundant and large, the cortex will be relatively spared; if they are sparse and small, a massive stroke will occur. One might object that if ischemia exists sufficient to cause aphasia, the damaged tissue should be apparent on imaging studies, but this clearly is not the case. Even newer and more sensitive magnetic resonance imaging techniques, such as diffusion-weighted imaging (DWI), may fail to demonstrate any cortical abnormalities, at least within the first 24 hours (Hillis et al., 2002). Studies of cerebral blood flow in patients

with acute striatocapsular infarcts and otherwise normal structural images (including DWI), however, have shown dramatic reductions in cortical blood flow in precisely the regions that would be expected from the character of the aphasia (e.g., hypoperfusion in the posterior perisylvian temporal region in patients with features of Wernicke's aphasia); conversely, patients with subcortical lesions who exhibit no reductions in cortical blood flow do not have aphasia (Hillis et al., 2002, 2004; Nadeau & Crosson, 1997). Functional imaging studies in patients with chronic nonthalamic subcortical aphasia also demonstrate reduced blood flow or metabolism in cortical regions precisely corresponding to the pattern of the language impairment observed (Nadeau & Crosson, 1997). Furthermore, although a year later no focal abnormalities are observed on anatomic imaging studies of the cortex in these chronic patients, the studies demonstrate hemispheric cortical atrophy—unequivocal evidence of earlier cortical damage involving neurons or their connections (Weiller et al., 1993).

This hypothesis regarding the mechanism of nonthalamic subcortical aphasia predicts that cortical damage could occur anywhere within the cortex supplied by the middle cerebral artery, delimited only by the pattern and adequacy of arterial anastomoses. One would then expect aphasias of all types—or even no aphasia at all—with striatocapsular infarcts or any other subcortical infarct reflecting proximal middle cerebral

artery occlusion. In fact, this turns out to be the case. In addition, some subcortical infarcts, as well as hemorrhages into the putamen, disrupt the connections between language cortex and the thalamus. Thus, they likely add features of thalamic aphasia to whatever language disorder results directly from the cortical damage. Striatocapsular infarcts also may disrupt frontothalamic projections traversing the anterior limb of the internal capsule, disrupting thalamic function as well (Tatemichi et al., 1992). Hemorrhages into the putamen can produce pressure on overlying cortex with associated ischemic damage.

One can immediately conclude from this discussion that nonthalamic subcortical aphasias likely are not fundamentally different from cortical aphasias, either in character or pathogenesis, and that they should be treated in the same way. Furthermore, unlike aphasias resulting from thalamic lesions, which appear to be intrinsically limited to impairment in declarative memory systems, cortical aphasias may implicate both declarative and procedural systems. Indeed, nonthalamic subcortical aphasias are as varied as cortical aphasias, and they commonly include impairment in grammatical and phonologic function as well as lexical-semantic function.

NONLINGUISTIC BEHAVIORAL DISORDERS RELEVANT TO THE REHABILITATION PROCESS

During the last 20 years, our estimates regarding the fundamental plasticity of the adult cerebrum have increased 100-fold. In principle, it seems that any type of cerebral dysfunction might be susceptible to rehabilitation. The function of several fundamental cerebral systems, however, appears to be critical to the very conduct of the rehabilitation process. We suggest that, when these systems are substantially impaired, any rehabilitation, but particularly rehabilitation at the level of sophistication and refinement of speech/language therapy, may be problematic and the prognosis for meaningful advances in therapy relatively poor. These functional systems include arousal, attention, and frontal systems. Faced as we are with overwhelming pressures to optimize the use of our treatment resources, it is important to identify these types of deficits ahead of time.

Arousal

Impairment in arousal typically reflects dysfunction of the MRF. A host of disorders commonly produce transient dysfunction of the MRF (e.g., metabolic disorders, drugs, infections, and intracerebral masses). Most often, however, patients develop *persistent* dysfunction because of embolism to the top of the basilar artery, which occludes small vessels supplying the MRF, as well as one or both posterior cerebral arteries (hence abnormalities in vision [e.g., hemianopia or cortical blindness]). Infarcts of the midline thalamus, some

of which produce aphasia, often extend caudally into the MRF. These patients often experience lethargy that, although most severe initially (to the point of coma), often persists for months or years. No treatment has been shown to be effective in mitigating this lethargy. Because these patients behave as if they are constantly half-asleep, they are unable to engage fruitfully in rehabilitation efforts, and their long-term prognosis for an active, interactive life is poor.

Attention

Arousal is a necessary substrate for attention, so patients with impaired arousal will have impaired attention. Patients with frontal system dysfunction also often will have a disorder of intentional or volitional attention, even though their level of arousal is normal. Thus, they are limited in their ability to sustain focused attention, and they tend to be very distractible. This behavior may substantially undermine any rehabilitation program. This type of impairment most often is seen with lesions implicating the dorsolateral frontal lobes bilaterally, but it also may be a feature of patients with midline thalamic lesions.

Patients with nondominant hemisphere dysfunction, most often caused by parietal lobe lesions (cortical or nonthalamic subcortical) and, occasionally, by thalamic lesions, often will exhibit a hemispatial disorder of attention known as hemispatial neglect, in which patients fail to attend or respond to any stimuli presented in the left hemispace. This same disorder sometimes is seen with dominant hemisphere lesions but, characteristically, is much less severe. Nevertheless, even patients with dominant hemisphere lesions (cortical, subcortical, or thalamic) without apparent right hemispatial neglect may benefit from presentation of stimuli in the left hemispace for reasons that are still poorly understood and controversial (Coslett, Schwartz, Goldberg, Haas, & Perkins, 1993; Crosson et al., 2005; Nadeau, Crosson, Schwartz, & Heilman, 1997; Nadeau & Heilman, 1991).

Frontal Systems Dysfunction

Frontal systems dysfunction may impede therapy in other ways. The precise impact depends on the locus of the predominant pathology. Patients with midline frontal systems dysfunction tend to be akinetic in their general behavior and nonfluent in their language. Typically, they are poorly motivated, cannot carry out multi-step commands, and may actively resist any type of intervention by caretakers. Patients with orbitofrontal system dysfunction may appear superficially to be normal, but they tend to be irresponsible, cannot be relied on to sustain goal-oriented activity, and tend to be socially inappropriate. Both of these types of patients pose major challenges for any type of rehabilitation program. Patients with dorsolateral frontal system dysfunction may retain strong motivation and exhibit excellent

cooperation in rehabilitation programs. The side of the lesion often assumes major importance. Patients with dominant hemisphere lesions, such as patients with Broca's or global aphasia, often are excellent candidates for speech therapy. Patients with nondominant hemisphere lesions (seldom seen for aphasia rehabilitation), however, often exhibit anosognosia (denial of illness) or anosodiaphoria (lack of concern for illness). These patients are poorly motivated to participate in any rehabilitation program, because, put simply, they either do not recognize the problem or do not care about it.

Frontal systems disorders manifested in these ways rarely are a significant problem in patients with nonthalamic subcortical aphasia unless bilateral lesions exist. Midline thalamic lesions, however, are almost uniformly associated with prominent frontal systems dysfunction. When not lethargic, these patients often appear superficially to be quite normal in their general demeanor. Often, however, they exhibit the most profound lack of motivation, even to the point of perpetually placing obstacles in the way of any rehabilitation efforts (e.g., "I'm too tired;" "I have another appointment in two hours;" "I'm too busy;" "I think I've already done enough of that this week"). Thus, they reflect some blend of midline and orbitofrontal systems dysfunction.

Concept Formation

Spoken language depends on the translation of concepts into the articulatory motor sequences that will produce sounds that are intelligible to others. Concepts can be generated in two fundamentally different ways. First, if we look at something, a concept is automatically elicited as the visual input automatically generates a distributed representation in cerebral association cortices corresponding to that concept. Second, we have the power to intentionally generate a distributed representation corresponding to a concept from within—a fragment of a process we refer to as thinking. Some rare patients, usually with bilateral lesions, may exhibit impairment in their ability to automatically generate distributed concept representations in response to specific types of sensory input. They will be unable to name or describe the properties or use of objects they are observing. This disorder, most often seen after lesions of visual pathways, is termed "agnosia." Other patients exhibit selective impairment in their ability to generate distributed concept representations from within. These patients typically appear to be profoundly nonfluent in spontaneous language, tending either not to respond or to respond with single words or short phrases. When asked, however, to describe a complex picture (in which case distributed concept representations are automatically generated from without), they typically perform almost normally. This disorder is termed "adynamic aphasia" (Gold et al., 1997). It characteristically is

seen with frontal lobe lesions, most often affecting the dominant frontal lobe or being bilateral in location. It may be seen with nonthalamic subcortical infarcts. In addition, patients with thalamic infarcts associated with aphasia may exhibit some features of adynamic aphasia, although rarely in these cases is the fullest form of this disorder seen. Effective speech therapy is not absolutely precluded in such patients, but spontaneous language is unlikely to become fluent because of the more fundamental underlying deficit (Huntley & Rothi, 1988). For similar reasons, we suspect that patients with paradynamic aphasia (see the section *What Is Likely To Be the Specific Impact of Disorders of the Thalamic Gating Mechanism on Function of the Cerebral Cortex [Most Specifically the Language Cortex]?*) also likely are poor candidates for rehabilitation.

KEY POINTS

Subcortical aphasia is logically divided into thalamic and nonthalamic types. Aphasia caused by thalamic lesions appears to reflect dysfunction of cortical systems involved in language as a result of damage to the thalamic mechanisms for selectively engaging cortical neuronal networks. It is characterized almost exclusively by lexical-semantic dysfunction. Aphasia caused by nonthalamic subcortical lesions predominantly reflects acute hypoperfusion of the cortex or chronic damage to the cortex that is not apparent on structural imaging studies, caused in turn by ischemia in the distal territory of the middle cerebral artery, the proximal occlusion of which is directly responsible for the visible subcortical lesion. Nonthalamic subcortical infarcts therefore may be associated with any type of aphasia, and nonthalamic subcortical aphasia is not fundamentally different from cortical aphasia.

Disorders of brain systems supporting arousal, attention, and frontal systems function and causing lethargy, inattention, or poor motivation, which often are seen with thalamic strokes, as well as lesions impacting frontal systems function (frontal or thalamic) and causing adynamic or paradynamic aphasia, disorders of endogenous concept formation, may limit the effectiveness of speech therapy.

FUTURE TRENDS

The proposed mechanisms of thalamic aphasia discussed in this chapter, although both cogent and supported by human lesion studies as well as animal research, have not been adequately tested empirically. Whether our application of the declarative/procedural dichotomy to language processes in general, and to thalamic subcortical aphasias in particular, made in the hopes of clarifying fundamental mechanisms, ultimately will be vindicated also remains to be seen.

KEY POINTS

1. Aphasia caused by thalamic lesions (hemorrhages or infarcts) appears to reflect dysfunction of cortical systems involved in language as a result of damage to thalamic mechanisms for selectively engaging cortical networks. It is characterized predominantly by lexical-semantic dysfunction.
2. Aphasia caused by nonthalamic subcortical hemorrhages or infarcts stems mainly from acute hypoperfusion of the cortex or chronic damage to the cortex that is not apparent on structural imaging studies. It may be characterized by any of the linguistic disorders seen with aphasia caused by cortical lesions. A good correlation exists between the type of aphasia observed and the pattern of cerebral blood flow or metabolism seen on functional imaging studies.
3. Lesions causing thalamic aphasia also may cause lethargy, inattention, and poor motivation, all of which are behaviors that may limit the effectiveness of speech therapy. This is particularly seen with mid-line thalamic lesions.
4. The thalamus is best understood as a gated relay device. The pulvinar-LP complex of the thalamus relays cortico-cortical transmission from portions of the frontal, temporal, and parietal lobes involved in language function, and dysfunction of this nucleus in thalamic aphasia appears to impair the engagement or spoken word forms by concept representations. The DM relays cortico-cortical transmission from the frontal lobes, and dysfunction of this nucleus in thalamic aphasia appears to cause disorders of endogenous concept formation.
5. The thalamic gate can be opened or closed nonselectively by brain-stem structures, including the MRF responsible for maintaining our level of arousal. The thalamic gate can be opened or closed selectively and volitionally by the frontal lobes acting through a complex system that involves the thalamic NR, which envelopes the thalamus, and the CmPf deep with the thalamus. Thalamic aphasia occasionally is caused by hemorrhage into the thalamic nuclei most directly involved in language, the pulvinar-LP complex and the DM. In most cases, however, thalamic aphasia appears to be caused by disruption of the frontally controlled selective gating mechanism for one entire half of the thalamus.
6. The thalamus is a key component of one of the many mechanisms in the brain that enable selective engagement of cortical systems—that is, the bringing online of particular cortical neural networks needed at any given time to process a particular stimulus and generate an appropriate response.

7. Portions of the thalamus implicated in language function appear to be involved in processes involving declarative knowledge. The predominant deficit observed with thalamic lesions—namely, lexical-semantic dysfunction—is consistent with this idea. The rare subjects with thalamic lesions who produce neologisms or exhibit disorders of grammar appear to challenge this concept. Production of neologisms and grammatical dysfunction may be understandable, however, as disorders involving declarative knowledge.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Why does the brain need selective engagement mechanisms? Discuss these mechanisms in relation to attention and language.
2. Discuss the differences between declarative and procedural memory in terms of the types of knowledge involved, the manner in which the brain acquires these types of knowledge, and the brain systems supporting knowledge acquisition.
3. Lexical-semantic function can be readily understood in terms of factual knowledge—that is, declarative memories. Consider how certain aspects of phonologic and grammatical function also might involve declarative knowledge and, thus, be susceptible to occasional disruption in subjects with thalamic aphasia.
4. Subjects with nonthalamic subcortical aphasia may exhibit nearly any pattern of language impairment. Consider how this can be explained in terms of the aberrations in blood flow to the brain that commonly occur with stroke.
5. Are thalamic and nonthalamic subcortical aphasias best viewed in terms of loss of language knowledge or in terms of loss of access to language knowledge? Why?

Chapter 20

Primary Progressive Aphasia and Apraxia of Speech

Joseph R. Duffy and
Malcolm R. McNeil

OBJECTIVES

In this chapter, primary progressive aphasia (PPA) and primary progressive apraxia of speech (AOS) will be defined; the criteria for their diagnoses reviewed; their common presenting histories and basic demographics discussed; the characteristics of the aphasia, AOS, and associated motor speech impairments summarized; common neuroimaging findings and the variety of possible underlying autopsy-based pathologic diagnoses reviewed; and theoretic and philosophical aspects of management as well as the meager treatment efficacy data summarized and discussed. Because considerably more is known about PPA than primary progressive AOS, the primary emphasis of this chapter will be on PPA.

Because aphasia and apraxia of speech (AOS) are most commonly caused by stroke, what we understand about their nature, assessment, diagnosis, prognosis, and management is overwhelmingly based on data derived from people in whom these conditions were stroke-induced. Despite this, clinicians recognize that the conditions of closed-head and penetrating head injuries, tumors, surgical complications, and infection can cause aphasia and AOS. All of these etiologies usually are acute or subacute in onset, and their natural (i.e., untreated) course usually is considered to be one of sudden or subacute onset, with severity being greatest early post-onset, followed by decelerating physiological improvement, ultimately to a point at which the disorder is considered to be resolved, or improving minimally without intervention and, thus, considered to be in its chronic state.

Twenty-five years ago, most speech-language pathologists and neurologists would have considered aphasia to be incompatible with a diagnosis of degenerative central nervous system (CNS) disease. The generally accepted principle was that degenerative neurologic diseases (e.g., Alzheimer's disease [AD]) impair cognitive functions diffusely and only rarely (or never) in a focal or selective way. Thus, any aphasic-like difficulties in individuals with degenerative CNS disease presumably were embedded within a constellation of cognitive difficulties that might include, but always extended beyond, the language domain.

It now is commonly recognized that aphasia can announce the presence of degenerative neurologic disease and that it may be the only manifestation of CNS disease for a substantial period of time—or perpetually. When this happens, the condition is commonly referred to as “primary progressive aphasia” (PPA). Less well recognized is the fact that AOS can present in the same way, often with aphasia and/or dysarthria but sometimes as the only communication impairment. In such cases, “primary progressive AOS” (PPAOS) is an appropriate diagnostic label.

PRIMARY PROGRESSIVE APHASIA

Basic Definition and Terminology

We reserve the term “aphasia” for language processing deficits that cross levels or domains of language (e.g., semantics, syntax, morphology, and phonology) as well as language modalities (e.g., listening, reading, writing, talking, and gesturing). These deficits are not attributable to sensory or motor deficits or to a loss of the representations or rules of language. They result from deficits of the cognitive apparatus used to buffer, activate, and inhibit, in precisely timed patterns, the rules and representations of language.

Aphasia, in the absence of other CNS deficits, is caused by relatively focal damage to the language-dominant hemisphere (usually the left) and is most often (but not in the case

of PPA) of sudden onset. When, however, language or communication deficits are embedded within a constellation of other cognitive deficits (e.g., those seen in persons with dementia or traumatic brain injury), particularly (but not only) at its onset, it is *not* considered to be aphasia. The reasons for these inclusion and exclusion criteria are both theoretic and clinical, having implications for epidemiologic and other forms of research on prognosis, assessment, and intervention. It is beyond the scope of this chapter to discuss aphasia definitions and their inclusionary and exclusionary criteria in detail; such discussions can be found in Darley (1982), McNeil (1988), McNeil and Pratt (2001), and Mesulam (1987). To use the term “aphasia,” however, modified by its onset and time-course, evidence is required that other cognitive deficits that cross non-linguistic domains of knowledge, such as procedural memory deficits, altered personality, visuo-perceptual impairments, altered personal, temporal or spatial orientation, or psychiatric illness, are not present or are not accounted for by a single or common etiology.

Primary progressive aphasia can be defined as aphasia of insidious onset, gradual progression, and prolonged course, without evidence of non-language computational impairments that are shared by a common etiology to the aphasia, and caused by a degenerative condition that, presumably and predominantly, involves the left (language-dominant) perisylvian region of the brain (modified from Duffy, 1987). Because concomitant non-language processing and computational impairments probably become evident very often during later stages of the disorder, the term PPA is used only when the concomitant impairments are not manifest. At the point in time when non-language cognitive impairments become detectable during formal assessment and are functionally meaningful, the criteria for a different diagnosis are met (e.g., dementia), and the diagnosis changes from one of PPA to one of aphasia plus the other disorder or the other disorder alone. In addition, because aphasia is a behavioral manifestation of neurologic disease, it is important to remember that PPA is a clinical syndrome and not necessarily a reflection of a single, underlying brain pathology. This principle will become evident when the underlying histopathology associated with PPA is addressed.

Similar to many clinical disorders, particularly early in the history of their recognition, definition, and study, PPA has had a number of aliases, some of which can be considered as synonymous with PPA and others of which—under careful scrutiny—probably represent other diagnostic entities. The terms “slowly progressive aphasia” (e.g., Duffy, 1987; Kempler et al., 1990; Kushner, 1990; Poeck & Luzzatti, 1988) and “progressive aphasia without dementia” (e.g., Heath, Kennedy, & Kapur, 1983; Mesulam, 1982; Scheltens, Hazenberg, Lindeboom, Valk, & Wolters, 1990) probably refer to the same clinical entity as PPA; they seem

to have succumbed to PPA as the preferred diagnostic label.¹ In contrast, terms such as “aphasic (or dysphasic) dementia,” “nonfamilial dysphasic dementia,” “familial aphasia,” and “hereditary dysphasic dementia” (e.g., Cole, Wright, & Banker, 1979; Kobayashi, Kurachi, Gyoubu, Imao, & Nakamura, 1990; Mehler, 1988; Morris, Cole, Banker, & Wright, 1984) may or may not be synonymous with PPA as defined here; at least some of the cases in reports using those labels had evidence of widespread impairment of cognition early in their course. It bears repeating that PPA does not include patients in whom language impairment or aphasia is just a prominent manifestation of dementia.²

Historical Perspective

Although modern interest in PPA was sparked by Mesulam in 1982, isolated or relatively isolated progressive language impairment in association with degenerative neurologic disease has been recognized since the late 1800s. For example, Pick published a paper in 1892 titled “On the relation between aphasia and senile atrophy of the brain” (translated by Girling & Berrios, 1994). In 1914, Mingazzini published a paper titled “On aphasia due to atrophy of the cerebral convolutions.” Ironically, Maurice Ravel (1872–1937), whose *Bolero* musically chronicles a slow progression to a climactic conclusion, developed a relatively focal progressive neurologic disease at 52 years of age, with prominent aphasia, apraxia, agraphia, alexia, and loss of musical creativity (Henson, 1988). In a review article, Poeck and Luzzatti (1988) identified 19 cases in the literature before 1950 that, today, might be labeled PPA.

There is no doubt, however, that Mesulam’s 1982 summary of six cases with slowly progressive aphasia without other cognitive deficits is the modern seminal work on the topic. It generated interest in PPA in particular, but also in the general concept that a variety of focal cognitive deficits

¹We adhere to the term “primary” modifying the progressive nature of the aphasia with acknowledgement that it is philosophically inconsistent with our criteria for the syndrome’s identification. We adhere to this term to avoid advancing yet another term to describe the emerging literature on this etiologically based category of aphasia. We believe it is important to recognize that the term does not, in our definition, imply that the aphasic signs and symptoms are simply the most obvious, prevalent, or severe deficit that is accompanied by deficits in other cognitive domains. If other such deficits are validly and reliably identifiable and are attributable to a common etiology, then the diagnosis of PPA probably is not appropriate.

²We *do* believe it is reasonable to include within the scope of the definition of PPA people in whom neuropsychological examination raises questions about impairment of cognitive functions beyond the language domain, but in whom there is no such evidence during basic clinical examination and no complaint of such impairment either by the patient or by those who know the patient well.

can be associated with degenerative neurologic disease. Since then, hundreds of cases have been reported, and subsequent reviews of their cumulative meaning have appeared (e.g., Duffy & Petersen, 1992; Mesulam, 2001, 2003; Mesulam & Weintraub, 1992; Rogers & Alarcon, 1999; Westbury & Bub, 1997). Mesulam (2001) has suggested that “PPA may well be the fifth most common form of degenerative dementia, following in prevalence AD, FLD [frontal lobe dementia], Parkinson-related dementia, and dementia with Lewy bodies” (p.431).

Because in recent years PPA frequently has been tied to more specific neurologic diagnoses, sometimes as a disease subtype (e.g., frontotemporal dementia [FTD]) and sometimes as one of the possible signs of a disease (e.g., corticobasal degeneration [CBD] and progressive supranuclear palsy [PSP]), its demographic features have become intermingled with those of the associated conditions. For that reason, the data reviewed in the basic demographics section of this chapter (and summarized in Table 20–1) rely heavily on reviews that have focused exclusively on PPA (Duffy &

TABLE 20–1**Demography/Epidemiology of Primary Progressive Aphasia**

	Mean	Range	Standard Deviation
Age of onset (years)	Late 50s ^{1,2}	40–70 ^{ab}	
Fluent aphasia	56.8 ^c	40–69 ^c	7.1 ^c
Nonfluent aphasia	62 ^c	40–81 ^c	8.5 ^c

Average (across reports)	5.0	1–15	
Percentage progressing to non-aphasic cognitive impairment	50 ^a		
Fluent aphasia	27 ^c		
Nonfluent aphasia	37 ^c		
“Undetermined” aphasia	<u>73</u> ^c		
Average (across reports)	46.8		
Average time from symptom onset to death (years) ^d			
Fluent aphasia	8.8 ^c	4–17 ^c	
Nonfluent aphasia	6.8 ^c	3–13 ^c	
“Undetermined” aphasia	<u>6.5</u> ^c	<u>3–12</u> ^c	
Average	7.4 ^c	3–17 ^c	
Average age at death (years)			
Fluent aphasia	65.1 ^c	62–67 ^c	2.0 ^c
Nonfluent aphasia	68.4 ^c	48–84 ^c	9.9 ^c
“Undetermined” aphasia	<u>69.0</u> ^c	<u>58–84</u> ^c	<u>11.0</u> ^c
Average	67.4 ^c	48–84 ^c	7.6 ^c

^a Duffy & Petersen (1992).^b Westbury & Bub (1997).^c Rogers & Alarcon (1999).^d These data were computed from those presented by Rogers & Alarcon (1999). These data include those individuals who remained aphasic only and those that progressed to a diagnosis of dementia. The reader should interpret these and the other data reported here cautiously, because they are based on a retrospective analysis of published reports and on small subject samples.

Petersen, 1992; Mesulam & Weintraub, 1992; Rogers & Alarcon, 1999; Westbury & Bub, 1997), supplemented when possible by more recent data that can be linked unambiguously to PPA.

Considerable variability exists in the degree to which published case studies have met current criteria for the diagnosis of PPA. The large number of such cases, however, as well as the commonalities among them are now sufficient to establish that PPA, although representing an uncommon clinical phenomenon, is not an extremely rare one. Today, case presentations with the sole intent of supporting the existence of PPA are no longer of special interest. Of importance now are studies that improve and refine our understanding of its typical and atypical language manifestations, associated non-language clinical characteristics, clinical course, neuroimaging and other laboratory correlates, histopathology and biochemistry, and responses to behavioral and medical interventions.

Diagnostic Criteria

The criteria for establishing the diagnosis of PPA, originally suggested and subsequently slightly modified by Mesulam and colleagues (Mesulam, 2001, 2003; Weintraub, Rubin, & Mesulam, 1990) seem to be generally accepted at this time. They include:

1. A 2-year history of insidious onset and gradual decline in language ability (e.g., word finding, object naming, syntax, and word comprehension).
2. Relative preservation of other mental functions (e.g., patients with prominent language deficits in the first 2 years but who also have apathy, disinhibition, memory, attention or visuospatial or visual recognition deficits, or sensorimotor impairments, would not meet the criteria).
3. Any major limitations in activities of daily living (ADLs) attributable to the language impairment during the first 2 years.
4. Acalculia, ideomotor apraxia, difficulty copying simple drawings, or perseveration, if present in the first 2 years, that do not significantly limit ADLs.
5. A full neurologic workup that excludes other causes of aphasia (e.g., stroke, tumor, infection, or metabolic disturbances).
6. Comprehensive speech-language and neuropsychological evaluation yields results consistent with the complaint and clinical neurologic examination.

Mesulam (2001, 2003) suggests that non-language cognitive functions can be impaired after the first 2 years, but that language must remain the most impaired function and deteriorate faster than other cognitive functions for the diagnosis of PPA to be maintained.

Some of the above diagnostic criteria are worthy of discussion. Of particular importance is the required 2-year history

before a diagnosis of PPA can be established. This criterion presumably has been set to reduce the number of false-positive diagnoses of PPA (or false-negative diagnoses of dementia). The assumption is that an isolated deficit in the domain of language that has endured for a minimum of 2 years will increase the likelihood that the behaviors are not the initial signs of a more general cognitive deficit. In fact, however, not all investigators have required a 2-year history (Neary, Snowden, & Mann, 1993), and more important, the epidemiological research to support this assumption has not been conducted. Thus, no evidence indicates that this criterion helps to better define the PPA population (Knibb, Xuereb, Patterson, & Hodges, 2006). In addition, a 2-year hiatus in the diagnosis can delay aphasia management and general life planning. It seems that the diagnosis of PPA can and should be made without regard to the duration of its existence, recognizing that the diagnosis should be altered or discarded at such time that other criteria for PPA are no longer met.

A second assumption embedded within the diagnostic criteria is that the language deficit is disproportional to any other non-linguistic deficits. Again, the degree to which non-linguistic functions are or are not relatively spared would be the degree to which they meet the criteria for the diagnosis of aphasia of any etiology or type. It is important to remember that the only difference between the definition of aphasia, in general, and the definition of PPA, as provided here, is in the meaning of the adjectival modifiers “primary” and “progressive.”

The third assumption of preserved ADLs is included to help exclude those persons with cognitive deficits outside of the language domain, such as personality, memory, or attention. Persons with aphasia certainly can have deficits of ADLs that involve language and communication. In addition, some individuals’ reactions to their aphasia can affect ADLs outside of the language and communication domains. For example, reactive depression can impair ADLs, and embarrassment or frustration with failed communicative interactions can lead to social withdrawal. If a reduction in ADLs is taken at face value as a criterion for rejecting the diagnosis of PPA, it could lead to a decrease in the legitimate diagnosis of PPA and an increase in the false-positive diagnosis of dementia. It thus seems appropriate to modify this criterion to permit inclusion of persons with reduced ADL abilities that are a direct or indirect consequence of the aphasia.

A fourth assumption is that the diagnosis of PPA requires a relatively focal or asymmetric degenerative process, one that is progressive and is of unknown etiology. It is based on the assumption of an etiology that excludes stroke, tumor, infection, and metabolic disturbances. Stroke is focal, of known etiology, and non-progressive. Tumor is focal, of known etiology, and progressive. Infection and metabolic disorders may or may not be focally localized, are of known etiology, and are non-progressive when they are appropriately treated. Table 20–2 summarizes these distinctions.

TABLE 20-2

Aphasia Etiology by Symptom Distribution, Lesion Distribution, Etiology, Disease Course, and Medical Treatment

Etiology	Symptom Distribution	Lesion Distribution	Etiology	Typical Long-term Course	Medical Treatment
Primary progressive aphasia	Language only	Focal	Unknown	Progressive	Untreatable
Vascular	Can be language only	Focal	Known	Chronic	Some early post onset treatment
Infectious (bacterial)	Typically more than aphasia	Focal or diffuse	Known	Progressive until treated	Treatable
Infectious (viral)	Typically more than aphasia	Focal or diffuse	Known	Progressive	Largely untreatable
Metabolic	Typically more than aphasia	Diffuse > focal	Known	Progressive until treated	Treatable
Neoplastic	Can be language only	Focal or multifocal	Known	Progressive	Treatable
Traumatic	Typically more than aphasia	Focal, multifocal, or diffuse	Known	Chronic	Some early post onset treatment

It has been argued that PPA often is a precursor to generalized dementia or AD, and that it is simply a variant of degenerative diseases that typically present with a broader spectrum of deficits (e.g., Gordon & Selnes, 1984; Poeck & Luzzatti, 1988). Today, however, evidence suggests that PPA is only infrequently associated with AD pathology (Mesulam, 2003), which supports its separate diagnostic status. Regardless of the ultimate outcome in a given person, the early prominence of aphasia and its relative isolation for long periods of time justify its distinction from typical, common dementing illnesses. People with PPA must cope for an extended period of time with a different set of problems than do those with generalized dementia. In addition, the prognosis and the underlying pathology may be different, and management approaches may vary considerably (Duffy & Petersen, 1992).

Issues of Classification and Nomenclature

When PPA was considered solely as an independent clinical entity, as it was for the first decade or so after Mesulam brought attention to it, issues of classification generally were tied to subdividing the aphasia into fluent and nonfluent types or into more specific “classical” categories (e.g., Broca’s, Wernicke’s, or anomic). In the broad context of neurodegenerative diseases, however, it has become evident that PPA also can be thought of as one of several possible manifestations of a general category of disturbances known as asymmetric cortical degeneration syndromes (Caselli & Jack, 1992; Caselli, Jack, Petersen, Wahner, & Yanagihara, 1992) or focal cortical atrophy syndromes (Black, 1996). These generic labels emerged with the recognition of a vari-

ety of isolated cognitive deficits, such as visual agnosia (e.g., De Renzi, 1986), prosopagnosia (e.g., Tyrrell, Warrington, Frackowiak, & Rosser, 1990), and limb apraxia (e.g., Azouvi et al., 1993; Dick, Snowden, Northen, Goulding, & Neary, 1989; Piccirilli, D’Alessandro, & Ferroni, 1990), that can be associated with degenerative neurologic disease, of which PPA may be the most common. Caselli (1995) argues for the term “asymmetric” as opposed to “focal,” because although these cases may present with a progressing focal neurologic syndrome, more diffuse abnormalities often can eventually be demonstrated both clinically and histopathologically.

More recently, the classification of PPA has become intermingled with complex, diverse, and often confusing nomenclature and approaches to the classification of degenerative neurocognitive diseases (Boeve, 2003; Petersen, 2001). This complexity and diversity is fed by “a rapidly expanding body of information on the clinical, neuroimaging, neuropathological, and genetic fronts” (Petersen, 2001, p. 422) but in the absence of a unifying clinical, imaging, histopathological,³ or biochemical basis for classification (Petersen, 2003). The next few paragraphs will provide some

³ Petersen (2001) observes that histopathology does not solve problems of classification, because it is not necessarily distinctively associated with specific clinical diagnoses. For example, people with clinical diagnoses of PPA, FTD, semantic dementia (SD), and so on can have AD as their underlying pathology (although not typically). In addition, some labels have clinical and pathologic criteria that do not always correspond with one another (e.g., not all people with a clinical diagnosis of AD have AD pathology on autopsy).

examples of how PPA currently is being classified neurologically and of its relationship to broad classifications of degenerative neurocognitive diseases. Their content will not resolve the confusion, but it will identify some of the nomenclature in which information about PPA has become embedded within the neurology literature.

At the simplest level, PPA is now classified among many behavioral neurologists as progressive nonfluent aphasia (PNFA) or SD. Others seem to consider PNFA to be the only type of PPA and view SD as a separate entity, although one involving language (e.g., Hodges et al., 2004; Kertesz, McMonagle, Blair, Davidson, & Munoz, 2005; Neary, Snowden, & Mann, 1993). For those who consider SD to be a subtype of PPA, the term seems to have replaced fluent aphasia (e.g., Neary et al., 1998), which essentially means that SD and fluent aphasia can be considered to be synonymous. For others, fluent aphasia remains a major subcategory of PPA, with SD being a subtype of fluent aphasia (e.g., Grossman & Ash, 2004).

For those who consider SD to be a distinct entity (i.e., not synonymous with fluent PPA), the disorder is characterized by a “loss of word meaning”—affected individuals seem no longer able to associate a word with its meaning, stating, for example, that they do not recognize that the spoken word “fork” represents its eating utensil referent—in the presence of preserved grammar and syntax and preserved verbal comprehension that does not rely on understanding words whose meaning has been lost (e.g., Mesulam, 2001; Neary et al., 1998). This difficulty stands in contrast to that of many people with fluent PPA and anomia who recognize target words they have been unable to name when they are provided to them. Strictly speaking, the diagnosis of SD also should be associated with impaired recognition (visual agnosia) of faces (prosopagnosia) or object identity (associative agnosia) (e.g., Mesulam, 2001; Neary et al., 1998). As a result, Mesulam (2003) has argued that the presence of prominent prosopagnosia and visual associative agnosia during the initial 2 years is incompatible with his definition of PPA, although he recognizes that, in clinical practice, SD often is a diagnosis given to patients with fluent aphasia but without visual agnosia. He feels that such patients without visual agnosia should be labeled as having PPA, not SD. Obviously, this diversity in the use of the term “semantic dementia” is a considerable source of confusion that, at the least, requires careful definition in clinical and research communications.

Going beyond subclassifications of PPA, PPA itself now often is considered to be a subtype of FTD, a degenerative dementia that is second in prevalence only to AD, accounting for 10% to 15% of untreatable dementias (Boeve, 2003). Pathologic substrates of FTD include Pick’s disease, CBD, and dementia lacking distinctive histology. Clinically, FTD is characterized by personality-behavioral changes, PPA, or both (Boeve, 2003). Patients with early prominent personality-behavioral changes are considered to represent the frontal

phenotype of FTD, whereas those with early prominent language changes (PPA and, for some, SD) are considered to represent the temporal phenotype.

In a similar conceptual approach, PPA is considered to be one (or two) of three distinct manifestations of a broad category of disorders known as frontotemporal lobar degeneration (FTLD) (Neary et al., 1998). Included under this broad heading are (1) FTD, which is characterized by behavioral/personality changes (e.g., disinhibition, impulsivity, poor insight, perseveration, and inflexibility); (2) SD, which is characterized by loss of word or object meaning with preservation of language fluency and syntax; and (3) PNFA, characterized by “labored speech,” anomia, and/or agrammatism. It has been suggested that PPA accounts for approximately 10% of FTLDs, and SD accounts for about 15% (Snowden, Neary, & Mann, 2002). Thus, in this scheme, PPA is not considered to be a subtype of FTD but, rather, a subtype of FTLD. Within this approach, patients with SD and PNFA could meet the criteria for a diagnosis of PPA (ignoring the issue of whether SD would capture all patients with fluent PPA).

Finally, Kertesz and Munoz (1997) have argued that several disorders, including PPA, FTD, Pick’s disease, and CBD, should be classified as part of “Pick complex” because of shared histopathologic features (discussed later). At this point, however, imaging, neuropathology, genetics, and biochemistry have not provided an absolute answer to the problem of classification (Petersen, 2001). It may be that PPA is linked to multiple diseases sharing a common anatomic locus (i.e., the left hemisphere perisylvian language area). An alternative explanation is that it results from an as-yet-incompletely understood unitary disease (e.g., Pick complex, lobar atrophy-Pick’s disease-tauopathy, or frontotemporal degeneration) that includes a spectrum of anatomically and behaviorally distinct degenerative brain disorders. This latter explanation receives some support from genetic analyses of so-called FTLD syndromes that include PPA and FTD (Mesulam, 2001; Mesulam, Grossman, Hillis, Kertesz, & Weintraub, 2003). Petersen (2001) points out that “it is incumbent on the clinician to classify persons with these disorders as accurately as possible to allow for diagnostic, treatment, counseling and prognostic advice for patients and families. In the final analysis there may be no gold standard” (p. 422) on which all of these disorders can be uniquely characterized.

Clinical Presentation

How do people with PPA present clinically? What is their history, and how do they behave? Initial diagnosis hinges strongly on the answers to these questions, so it is important to recognize typical presenting features.

People with PPA often present clinically many months or even a year or more after the onset of language difficulty.

Occasionally, they associate the onset with a specific event, giving the onset a superficially acute appearance; in such cases, more often than not, the event was one with significant language demands or psychological stress (e.g., a public speech). Most frequently, however, the onset is insidious, and the patient and family often are vague or even disagree about when symptoms first appeared. Unlike people with AD, however, those with PPA often are aware of the problem before their family, friends, or work colleagues.

Presenting speech and language complaints can be strikingly similar to those of people with stroke-induced aphasia. The classic refrain of the person with aphasia that “I know what I want to say but I can’t find the words!” is commonly heard. Word finding difficulty seems to be the most frequent presenting complaint among people with PPA (Westbury & Bub, 1997).⁴

People with PPA rarely deny their deficits. In fact, they, rather than their families, usually initiate the search for diagnosis and treatment. They do not complain of memory disturbances outside the verbal domain, and they are not disoriented. They and their significant others do not report significant personality changes, although expressions or frank evidence of frustration and reactive depression are common. If work demands are not language-based, job performance can be unchanged. Daily routine activities (e.g., grooming, driving, shopping, and exercising) typically are unaffected. Conversely, if language demands for job performance or daily routine activities (e.g., reading, writing, and calculations for record keeping) are high, especially those involving rapid or large-capacity language processing and extemporaneous production and comprehension, then difficulty with job performance or routine daily activities can be the initial situations that reveal early signs or symptoms.

To summarize, the initial clinical presentation of people with PPA can be strikingly different from those of people with AD or other degenerative diseases that induce diffuse impairments of memory, thinking, organization, self-awareness, personality, and ability to succeed in routine social, self-care, and work activities. Conversely, they can be strikingly similar to stroke-induced and other static etiologies for aphasia.

Character of the Aphasia

It appears that any type of aphasia (as it traditionally has been classified) is possible. The types reported in the not-so-recent literature include fluent and nonfluent, Broca’s,

Wernicke’s, anomic, and transcortical (e.g., Karbe, Kertesz, & Polk, 1993; Kertesz, Davidson, & McCabe, 1998; Turner, Kenyon, Trojanowski, Gonatas, & Grossman, 1996); even pure word deafness has been reported (Mesulam, 1982; Otsuki, Soma, Sato, Homma, & Tsuji, 1998; Philbrick, Rummans, Duffy, Kokmen, & Jack, 1994).

Because of changing trends in the classification of PPA (see previous discussion), the recent neurologic literature tends to classify patients as having nonfluent or fluent PPA, or SD. Some investigators have also described a logopenic form, in which significant word finding difficulty is present, there is a slowing and decrease of verbal output, but syntax, phonology, and motor speech production are relatively preserved (e.g., Gorno-Tempini, Dronkers et al., 2004; Kertesz, Davidson, & McCabe, 2003; Weintraub et al., 1990).

It is important to note that the subclassification of PPA along a “fluency” dimension is not without problems, and that these problems are similar to those associated with classifying aphasia resulting from stroke or other acute-onset causes (Darley, 1982; McNeil, 1988; Schwartz, 1984). Specifically, the problem with using fluency or nonfluency as valid adjectives for aphasia is that they (1) are without theoretic motivation as a descriptor of language pathology, (2) are not assigned by a set of uniform criteria across users or standardized tests and are unreliably assigned to patients (Trupe, 1984), and (3) as typically applied, are more likely the result of concomitant sensorimotor speech pathologies (dysarthria or AOS) than of a language-specific impairment.⁵

With the above caveats, PPA with nonfluent verbal output characteristics (i.e., Broca’s aphasia, agrammatism or telegraphic speech, brief and unelaborated verbal expression, and hesitant and/or dysprosodic speech) deserves some special comment, because it generally is unexpected during the earlier stages of probable AD. It thus contributes to neurologic differential diagnosis. In addition, its demographics, localization, etiology, prognosis, and responsiveness to medical and behavioral management may differ from those PPA without nonfluent language characteristics, which by default are usually termed “fluent” (see the subsequent discussion of neuroimaging correlates and histopathology). In fact, several studies and reviews support the distinction among several PPA subtypes (and SD) on behavioral, anatomical, or pathologic grounds (e.g., Gorno-Tempini, Dronkers et al., 2004; Grossman & Ash, 2004; Josephs et al., 2006a; Kertesz et al., 2003). Operational definitions for PPA types and the reliability of placement of patients into each type, however, are not reported in many studies. It is essential that the characterization of PPA be made on the basis of careful definitions and

⁴This complaint alone may not assist differential diagnosis, however, because it also is a common presenting complaint in patients with probable AD.

⁵See the case report of McNeil, Small, Masterson, & Fossett (1995) for a clinical example and discussion of the importance of accurate differential diagnosis of the speech production impairments that often are used to classify the “nonfluency.”

descriptions of what constitutes fluent, nonfluent, and other types of aphasia, and with the recognition that many patients may not fit neatly into any single category. As will be discussed in following sections, it also is important to distinguish among aphasia, AOS, and dysarthria in studies of PPA. Only when large series of patients are reported, using strict diagnostic criteria, will the true characterization and distribution of the “type” of aphasia in PPA be clearly understood.

Basic Demographics

Gender Ratio and Age of Onset

Table 20-1 summarizes reviews by Duffy and Petersen (1992), Westbury and Bub (1997), and Rogers and Alarcon (1999). Although these reviews suggest that more men than women are affected, with an approximately 2:1 male:female ratio (Duffy & Petersen, 1992; Westbury & Bub, 1997), it should be noted that recent series of 30 or more patients have not found significant gender differences (e.g., Gorno-Tempini, Dronkers et al., 2004; Kertesz et al., 2003), or they have found male predominance in patients with fluent PPA and female predominance in those with nonfluent PPA (Clark, Charuvastra, Miller, Shapira, & Mendez, 2005). The age of onset is quite variable, covering nearly all adult decades, but onset most often is between 40 and 75 years, with average age of onset across reviews converging on 60.5 years (Duffy & Petersen, 1992; Rogers & Alarcon, 1999; Westbury & Bub, 1997). On average, therefore, PPA develops in the presenium (before age 65).

Time until Onset of Other Cognitive Deficits

Among the cases reported in the literature, the duration from onset of aphasia to the emergence of more widespread impairment of cognitive functions, when they emerge, has varied from 1 to more than 15 years,⁶ with an average duration across reviews of about 5 years. Duffy and Petersen's (1992) review found that approximately 50% of persons with PPA eventually developed nonaphasic cognitive impairments. Rogers and Alarcon's (1999) review reported that an overall average of 45.7% (46.8% averaged across reviews) progressed to nonaphasic cognitive impairments. Sentiment is growing, however, that, although many patients have isolated language symptoms for an average of about 5 years

after onset and for as long as 15 years, the great majority eventually will experience symptoms in areas such as memory, personality, or mood (Green, Morris, Sandson, McKeel, & Miller, 1990; Krefft, Graff-Radford, Dickson, Baker, & Castellani, 2003; Thompson, 1997). Many of the exceptions, especially when onset is later in life, may be those who succumb to unrelated, acute, or more rapidly progressive conditions (e.g., heart attack, carcinoma, and stroke) before the PPA advances to affect other cognitive functions.

Life Expectancy

Although relatively few cases have been reported, the evidence summarized by Rogers and Alarcon (1999) suggests that the average age of death for persons with PPA is 67.4 years, with a 7.6-year standard deviation and a range from 48 to 84 years; the average duration from PPA symptom onset to death was 7.4 years, with a range of 3 to 17 years. These figures are in rough agreement with data from more recent studies of small to relatively large groups of patients with PPA (e.g., Josephs et al., 2005, 2006a,b; Kertesz et al., 2003; Knibb et al., 2006; Krefft et al., 2003). The difference between the number of years of isolated language deficits preceding the onset of non-linguistic cognitive deficits and the average time from symptom onset to death (i.e., the average time from onset of general cognitive deficits to death) was 2.4 years in the Rogers and Alarcon (1999) review; however, this duration spans the considerable range of 1 to 17 years.

Accompanying Deficits

Other neurologic signs and symptoms can accompany PPA. Dysarthria, dysphagia, right-central facial weakness, AOS, nonverbal oral apraxia, limb apraxia, right-extremity weakness or clumsiness, and extrapyramidal deficits (e.g., rigidity) have been reported (e.g., Duffy & Petersen, 1992; Fuh, Liao, Wang, & Lin, 1994; Krefft et al., 2003; McNeil, 1998).

Mesulam et al. (2003) consider dysarthria, ideomotor apraxia, dyscalculia, construction deficits, impaired executive functions, visual recognition deficits, extrapyramidal deficits, and decreased learning of word lists to be “boundary features” of PPA that usually arise later in the disease course and are less prominent than the aphasia. They also note that some patients with PPA develop personality changes characteristic of frontal lobe dementia, extrapyramidal deficits characteristic of CBD (typically characterized by cortical and extrapyramidal signs, including asymmetric limb rigidity and apraxia), or signs of motor neuron disease after 2 years. They suggest that such patients can be said to have a “PPA-plus” syndrome or, alternatively, frontal lobe dementia with aphasia, CBD with aphasia, and so on. It is well-documented that aphasia can be the initial sign (or a prominent early sign) of CBD (Frattali, Grafman, Patronas, Makhlof, & Litvan, 2000; Gorno-Tempini, Murray et al.,

⁶Cases with a duration of less than 2 years would not meet Mesulam and colleagues' criteria for a diagnosis of PPA and, if embraced, might be labeled on initial evaluation as having “possible PPA.” As stated, however, the diagnosis of PPA is best made on the coherence of both inclusionary criteria for aphasia of any type and exclusionary criteria for the disorders with which it is most likely to be confused (e.g., dementia and conversion disorder).

2004; Kertesz et al., 2003; Lehman Blake, Duffy, Boeve, Ahlskog, & Maraganore, 2003); aphasia was present in more than 50% of patients with CBD who were carefully studied by Frattali et al. (2000) and by Lehman Blake et al. (2003). In addition, PPA has been associated with atypical PSP (Boeve et al., 2003; Josephs et al., 2005) and, rarely, with dementia with Lewy bodies (Caselli, Beach, & Sue, 2002). These interrelationships support the contention that these conditions may belong to a common family of focal diseases and that the individual clinical syndromes reflect a different anatomy of disease onset and progression.

Neuroimaging Correlates

The results of neuroimaging studies that are conducted as part of clinical workups for suspected PPA sometimes are normal, supporting conclusions that the disorder does not stem from stroke, tumor, or other nondegenerative causes of focal lesions. In other cases, neuroimaging identifies abnormalities that contribute to understanding the anatomical bases of the aphasia. The methods most frequently reported include electroencephalography (EEG), magnetic resonance imaging (MRI), positron-emission tomography (PET; measuring glucose use), single-photon-emission computed tomography (SPECT; measuring blood flow), and voxel-based morphometry (VBM; an MRI-based measure of regional brain atrophy using voxel-based comparisons of gray matter volumes between groups of subjects). Abnormalities in blood flow (SPECT) and metabolism (PET) may emerge before evidence of atrophy (MRI and VBM) (Mesulam, 2001).

In a general summary of neuroimaging in PPA, Mesulam (2003) indicated that many patients with PPA have atrophy, EEG slowing, decreased blood flow, and decreased glucose use in left hemisphere language areas. The right hemisphere may be normal, especially early in the course of disease; when right-hemisphere abnormalities are present, they generally are less pronounced than abnormalities in the left hemisphere (Kertesz et al., 2003). Those with nonfluent PPA tend to have metabolic dysfunction and atrophy in the left inferior frontal cortex, whereas those who are fluent and have comprehension deficits have abnormalities in the left temporal lobe. Mesulam's generalizations are supported by previous literature reviews (Duffy & Petersen, 1992; Westbury & Bub, 1997). For example, Westbury and Bub (1997) found that 56% of patients with abnormalities on MRI had left hemisphere abnormalities only, with the remainder having bilateral abnormalities; the left hemisphere abnormalities most often were in the region of the sylvian fissure or temporal lobe. They also found that 97% of patients with PPA who underwent PET or SPECT had abnormalities and that 69% of the abnormalities were in the left hemisphere only (the remaining 31% were bilateral). Most of the left hemisphere abnormalities were in the temporal and/or frontal lobe.

More recent neuroimaging studies generally have identified left perisylvian and anterior temporal and inferior parietal lobe atrophy, without regard to PPA type. Some have found significant overlap and nonsignificant differences in the distribution of anatomic abnormalities between patients with fluent and nonfluent PPA (Clark et al., 2005; Sonty et al., 2003). In general, however, studies of patients classified as nonfluent find evidence of left frontal and perisylvian atrophy (e.g., Abe, Ukita, & Yanagihara, 1997; Josephs et al., 2006a), sometimes more narrowly localized to the left inferior frontal and insular areas (Gorno-Tempini, Dronkers et al., 2004; Nestor et al., 2003). In contrast, studies of fluent PPA or SD find more posterior abnormalities, such as left anterior temporal and inferior parietal lobe atrophy (Gorno-Tempini, Dronkers et al., 2004; Mummery et al., 1999) or superior, middle, and inferior temporal gyri, hippocampal, and parahippocampal gyrus atrophy (Abe et al., 1997); patients with SD tend to have bilateral abnormalities (e.g., Mummery et al., 1999). Findings on VBM of patients classified as logopenic have been localized to the inferior parietal lobe (Gorno-Tempini, Dronkers et al., 2004).

In summary, when patients with PPA have abnormal neuroimaging findings, they tend to show left hemisphere or more left than right hemisphere abnormalities. The fact that some patients with PPA have bilateral abnormalities suggests that their underlying disease is not confined to the left hemisphere, even if their current clinical syndrome is. This supports the contention that PPA and related syndromes may best be thought of as asymmetric rather than focal diseases. It will be important in future research to determine whether patients with PPA and neuroimaging evidence of bilateral disease progress more rapidly to diffuse cognitive deficits than those with neuroimaging evidence of left hemisphere disease only.

Histologic Pathology

Autopsy results for people with PPA are few, but increasing. In general, the pathologic changes in PPA (and SD, when analyzed separately) tend to be consistent with neuroimaging findings regarding the location of the brunt of pathologic changes. That is, they are more pronounced in the frontal lobes, perisylvian regions, and frontal and temporal lobes, in contrast to changes in AD, which typically are most pronounced in hippocampal areas (Davies et al., 2005; Mesulam, 2003).

Histopathologic findings identify a variety of pathologic diagnoses. In a sense, this is not surprising, because anatomical localization, not histopathology, determines the clinical manifestations of neuropathologic processes. The pathologic heterogeneity associated with PPA suggests that it can be caused by several entities whose initial or prominent effects happen to be, for unexplained reasons, located in those areas of the brain that, when affected, result in deficits of language processing consistent with those of aphasia.

Perhaps the most frequent autopsy findings in PPA are of cellular changes that do not correspond to well-known specific clinical or pathologic conditions. It is estimated that about 60% of patients with PPA have microscopic findings commonly called “dementia lacking distinctive histopathology” or “nonspecific focal atrophy,” in which there is focal neuronal loss, gliosis, and mild spongiform changes in superficial cortical layers (Krefft et al., 2003; Mesulam, 2001, 2003; Mesulam et al., 2003).

In addition, PPA has been associated with the histopathology of Pick’s disease (e.g., Craenhals, Raison-Van Ruymbeke, Rectem, Seron, & Laterre, 1990; Fukui, Sugita, Kawamura, Shiota, & Nakano, 1996; Graff-Radford et al., 1990; Holland, Mcburney, Moossy, & Reinmuth, 1985), which typically manifests clinically as significant cognitive, memory, or personality disturbances. It has been estimated that about 20% of patients with PPA have Pick’s disease pathology (i.e., Pick bodies or tau-positive spherical neuronal inclusions) (e.g., Krefft et al., 2003; Mesulam, 2003; Mesulam et al., 2003).

In people with autopsy-confirmed pathologic diagnoses of AD, PPA can occur as well (e.g., Engel & Fleming, 1997; Green, Patterson, Xuereb, & Hodges, 1996; Kempler et al., 1990), but this is not the pathology in a majority of autopsied cases. Some have found AD pathology in about one-third of patients with PPA (split about evenly between those with PNFA and those with SD), although often with an atypical anatomic distribution (Knibb et al., 2006); however, some suggest that pathologic features of AD may not emerge until long after the onset of disease (Mesulam, 2003; Mesulam et al., 2003). Others estimate that less than 20% of people with PPA have AD pathology (e.g., Krefft et al., 2003; Mesulam, 2001, 2003; Mesulam et al., 2003; Mesulam, Johnson, Grujic, & Weintraub, 1997; Westbury & Bub, 1997). Mesulam (2001) points out that none of the genetically caused forms of AD leads to early or prominent language deficits, an observation that supports the distinction between PPA and AD.

Of interest, PPA also has been associated with autopsy-confirmed pathologic diagnoses of CBD, PSP, amyotrophic lateral sclerosis (ALS), Creutzfeldt-Jakob (CJD) disease,⁷ and even motor neuron disease⁸ (e.g., Arima et al., 1994;

Josephs et al., 2005, 2006b; Mandell, Alexander, & Carpenter, 1989; Sakurai et al., 1996; Shuttelworth, Yates, & Paltan-Ortiz, 1985; Yamanouchi, Budka, & Vass, 1986), the common clinical characteristics of which all include motor disturbances. For example, PSP and CBD pathology accounted for nearly 70% of the pathologic findings in 13 patients with nonfluent PPA studied by Josephs et al. (2006a). In general, although the descriptions of the speech- and language characteristics of these cases are quite variable, patients with nonfluent verbal output characteristics and/or AOS seem to be over-represented. In some instances, the aphasia or AOS was the first symptom of disease. For example, the first symptom for all four of the patients with pathologically “atypical PSP” described by Josephs et al. (2005) was speech or language difficulty that, on initial examination, reflected AOS (4/4 patients) and aphasia (3/4 patients).

It may be that this plethora of pathologies share histologic or biochemical features that unite many of them and, in fact, tie PPA to other neurodegenerative diseases. As noted previously, this suggests that PPA and FTLT/FTD may represent anatomically distinct manifestations of a unitary histologic process (Josephs et al., 2006b; Mesulam, 2003; Mesulam et al., 2003; Snowden, Neary, & Mann, 2002), possibly captured by the concept of the Pick complex (Kertesz, 1997; Kertesz, Hudson, MacKenzie, & Munoz, 1994; Kertesz & Munoz, 1997). This generic concept includes several neurodegenerative diseases associated with focal cortical degeneration, such as PPA, FTD, Pick’s disease, and CBD. Support for this is exemplified in a recent clinicopathologic study of 60 patients with FTD/Pick complex, 22 of whom had PPA (Kertesz et al., 2005). Findings revealed clinical and pathologic overlap between FTD and PPA and suggested that patients clinically described as having CBD belong within the entity of Pick complex. The study found that patients within the Pick complex had a range of underlying pathologies that, on immunohistochemical analysis, primarily divided between tau-negative and tau-positive (often called “tauopathy”⁹) biochemistry, as well as differences in the cortical and subcortical distribution of lesions. Both PPA and CBD presented more frequently with tau-positive pathology, whereas the behavioral variety of FTD more frequently was tau-negative and associated with motor neuron disease pathology or dementia lacking distinctive histopathology. Kertesz et al. (2005) acknowledged that there may be many exceptions to this dichotomy, and that it may be premature to split the Pick

⁷ Because most patients with CJD die within 2 years, they would not meet the Mesulam and Weintraub (1992) criteria for PPA diagnosis. Regardless, it is important to recognize that a progressive aphasia can announce the presence of CJD.

⁸ A recent study (Davies et al., 2005) examined 18 consecutive cases with SD pathologically. “Motor neuron inclusion dementia” (motor neuron disease-type inclusions) was the most common pathology (13/18 patients); three cases had Pick’s disease and two AD. It is noteworthy that only one patient had evidence of motor neuron disease during life, an observation that highlights the fact that clinical diagnosis does not always correspond to histopathologic diagnosis.

⁹ Tauopathies are non-Alzheimer’s dementias that are associated with abnormal accumulations of hypophosphorylated tau (a protein) in neurons or glia. Mutations in the tau gene (chromosome 17) can be associated with dementia and parkinsonism (Mesulam, 2000).

complex either clinically or pathologically. The tauopathy-nontauopathy distinction, however, seems to be a useful one. Among patients with PPA, it appears that tauopathy (tau-positive) is overrepresented in patients classified as nonfluent (Josephs et al., 2006a; Knibb et al., 2006) and that tau-negative findings are more common in those classified as fluent (Knibb et al., 2006). It thus appears that histopathologic/biochemical support is emerging for the distinction between fluent and nonfluent PPA (although the distinction may have more to do with the presence or absence of AOS than with differences in the aphasia).

What is known about the possible genetic basis of or risk factors for PPA? Very little at this time, although Neary et al. (1993) found that 42% of their patients with PPA had a first-degree relative with a “similar condition” (Neary et al., 1993). Apolipoprotein E genotyping (the E4 allele is a risk factor for AD) found that the pattern of allele distribution for 12 patients with PPA was similar to that of controls and different than of patients with a clinical diagnosis of probable AD or a histologic diagnosis of AD (Mesulam et al., 1997). This provides support for distinguishing between PPA and probable AD clinically, and it is in agreement with evidence that most patients with PPA do not have the histopathology of AD. Finally, Mesulam (2001) notes that frontal lobe dementia, PPA, lobar atrophy without distinctive histopathology, and Pick-like inclusions can result from mutations within chromosome 17, some of which have been traced to the tau gene. Within a kindred, some patients may develop prominent aphasia and others display a frontal lobe dementia; this suggests that chromosome 17 mutations are prone to marked phenotypic divergence. These observations also raise the possibility that sporadic FTDs (presenting as PPA or frontal lobe dementia) may have a unitary pathogenesis, perhaps related to tauopathy or to impairment of some other function of chromosome 17 (Mesulam, 2001).

PRIMARY PROGRESSIVE APRAXIA OF SPEECH

Because AOS very often is a component of the syndrome of Broca’s (or nonfluent) aphasia (McNeil & Kent, 1990), it is reasonable to ask if its presence in PPA is important to variables such as emergence of non-language cognitive impairments, survival, etiology, or management. In addition, AOS is of interest because progressive AOS, in the absence of aphasia and nonaphasic cognitive impairment, has been reported in the literature and encountered by us frequently enough to tentatively label such occurrences as PPAOS.

Similar to PPA, PPAOS may herald more specific neurologic diseases but likely not any single neurologic disease. It has been our observation that when it is prominent and accompanied by dysarthria, it tends to progress in a direction that leads to clinical diagnoses with prominent motor

manifestations (e.g., PSP, CBD, and ALS). Whether these clinical diagnoses reliably predict ultimate histologic diagnosis remains to be determined, although emerging evidence suggests that it may have predictive value in this regard (Josephs et al., 2006a).

The distinction between PPAOS and PPA may be relevant to prognosis and, possibly, medical management, especially if it is found to have predictive value relative to underlying histopathology. That is, decisions about medical/pharmacological management often depend on predictions about the ultimate clinical or pathologic diagnosis. As a result, for example, existing or future pharmacologic treatments for probable AD likely will be different than those for PSP, ALS, and other degenerative sensorimotor disorders. The degree to which PPA and PPAOS eventually may be linked to different specific clinical neurologic diagnoses or to underlying histopathology may mean that they will be treated in medically as well as behaviorally different ways.

Basic Definition and Terminology

Primary progressive AOS can be defined as AOS of insidious onset, gradual progression, and prolonged course, in the absence of non-language cognitive impairments and, sometimes, in the absence of aphasia, for a substantial period of time or perpetually resulting from a degenerative condition that, presumably, involves the left hemisphere’s apparatus for translating the phonologic aspects of language into the learned kinematic parameters necessary for their expression through speech.¹⁰ When AOS occurs with PPA, its presence should be explicitly recognized (e.g., “PPA with AOS”). When the AOS is more prominent than the aphasia, the appropriate diagnostic label in our opinion should be “PPAOS with aphasia.” When observed in the absence of aphasia, it should be labeled as PPAOS.

Historical Perspective

The existence of AOS as a problem distinct from aphasia often is neglected in the neurology literature, and when its characteristics are recognized, they tend to be subsumed under diagnoses of aphasia or dysarthria. This almost certainly has been the case within the literature on PPA. It is very likely that many patients said to have PPA, particularly PNFA, have had AOS, and it is very possible that some unknown percentage of them have had AOS and little or no

¹⁰ The reader is referred to McNeil, Doyle, and Wambaugh (2000) or to McNeil, Robin, and Schmidt (1997) for a detailed definition and discussion of the nature of AOS.

aphasia. If true, this is unfortunate, because it will have distorted our understanding of PPA and limited our understanding of degenerative AOS.

The literature on neurodegenerative disease—and on PPA in particular—has begun to recognize problems of speech motor planning or programming as a problem separable from aphasia and, sometimes, as *the* predominant or only communication problem. During the last 10 to 15 years, a small but increasing number of case reports or relatively small case series have documented progressive AOS, sometimes in the absence of any aphasia and often as the predominant communication disorder (e.g., Broussolle et al., 1996; Chapman, Rosenberg, Weiner, & Shobe, 1997; Cohen, Benoit, Van Eekhout, Ducarne, & Brunet, 1993; Fukui et al., 1996; Hart, Beach, & Taylor, 1997; Josephs et al., 2005, 2006a; Tyrrell, Kartsounis, Frackowiak, Findley, & Rosser, 1991). Others have explicitly included AOS as a component of PPA, although not necessarily as the predominant communication disorder (e.g., Craenahls et al., 1990; Gorno-Tempini, Dronkers, et al., 2004; Hart et al., 1997). In general, the presence or possible influence of AOS in patients diagnosed as having PPA is increasingly recognized. For example, Clark and colleagues (2005), discussing findings for their subjects with PNFA, wondered if “the nonfluency of PPA results more from articulatory disturbances, such as apraxia of speech...” (p. 58). Kertesz and colleagues (2003) recently noted an “aphemic variety” of PPA. Mesulam et al. (2003) recommend that PPA be distinguished from “pure progressive dysarthria or phonological disintegration,” a designation that probably is equivalent to AOS.

Recently, Duffy (2006) summarized data for 80 patients with progressive AOS that represented either the only or the most prominent communication disorder associated with degenerative neurologic disease. The findings support a conclusion that AOS can be the first and/or most prominent manifestation of neurodegenerative disease, and they highlight several reasons for distinguishing between progressive AOS and PPA. The data from this study will be relied on heavily in subsequent description of progressive AOS and PPAOS.

Diagnostic Criteria and Character of the AOS

The defining characteristics of AOS associated with degenerative neurologic disease appear to be very similar to those associated with AOS in general. The most common deviant perceptual features among the 80 patients with AOS associated with degenerative neurologic disease described by Duffy (2006) included slow rate (79%), distorted substitutions (78%), syllable segmentation and/or excess and equal stress (75%), poorly sequenced sequential motion rates (i.e., rapid repetition of “puhtuhkuh”) (66%), increased off-target errors with increased utterance length (62%), and sound

sequencing errors (50%).¹¹ A minority of patients also exhibited false starts/restarts, distorted sound additions, reduced words per breath group despite adequate maximum vowel duration, effortful orofacial movements during speech, sound repetitions, inaccurate speech alternating motion rates (i.e., rapid repetition of “puhpuhpuh,” “tuh-tuhtuh,” or “kuhkuhkuh”), and sound prolongations. Many of these features correspond to those felt to be consistent with a diagnosis of AOS in general (Duffy, 2006; McNeil et al., 1997, 2000). The finding of reduced words per breath group despite adequate maximum vowel duration in 26% of the sample is noteworthy, because it is not typically reported in AOS from non-degenerative causes and is not usually associated with dysarthria. Duffy (2006) suggests that it may turn out to be a distinguishing feature of degenerative AOS (i.e., distinctive relative to features of AOS resulting from nondegenerative causes).

Issues of Classification and Nomenclature

The heart of the issue here is the distinction between AOS and aphasia. As already noted, within the literature, progressive AOS often is embedded with the designation of PPA or PNFA, but often without recognizing its distinctiveness from aphasia. This appears to be changing, although slowly. For example, Grossman and Ash (2004) suggest that some findings in studies of PNFA suggest that, fundamentally, it is a modality-specific disorder of speech and articulation, known by some as “dysarthria.” If so, the problem would not meet our definition of aphasia but could meet the definition of AOS. Others explicitly recognize that patients with PNFA caused by FTD can have AOS as part of the syndrome (Boeve, 2003). Nestor and colleagues (2003) have suggested that the breakdown of “fluency” in patients with PNFA “is due to a motor articulatory planning deficit (speech apraxia) combined with a variable degree of agrammatism” (p. 2406). Gorno-Tempini, Dronkers and colleagues (2004) noted that 9/11 subjects in their PNFA group had AOS. And, as already noted, Kertesz and colleagues (2003) have recognized an “aphemic” variety of PPA, with “predominantly phonological, articulatory errors and stuttering or verbal apraxia” (p. 715). In our opinion, PPAOS (i.e., in the absence of aphasia or when the AOS is the predominant

¹¹ We recognize that poorly sequenced sequential motion rates and sound sequencing errors, although clearly helpful in distinguishing aphasia and AOS from dysarthria, may not be helpful in distinguishing aphasic phonemic errors from AOS and, arguably, are more consistent with aphasia than with AOS (e.g., McNeil et al., 1997, 2000). Thus, the sequencing errors in these affected individuals may have reflected the influence of aphasia on their speech output. Nonetheless, the other prominent characteristics in the group are not expected in aphasia and are consistent with the diagnosis of AOS.

problem) should not be considered as a subcategory of PPA, because, simply, AOS is not aphasia.

In the larger picture of neurodegenerative diseases, PPAOS could be considered as another variant of the asymmetric cortical degeneration syndromes (Broussolle et al., 1996) and, possibly, as a member of disorders within the Pick complex.

Clinical Presentation

The clinical presentation of PPAOS is very similar to that of PPA in many respects (see previous discussion for a summary of what typically is *not* part of the presentation). The differences lie in the specifics of the complaints that are offered. In the absence of any aphasia, the person with PPAOS will deny difficulties with listening or reading comprehension and with writing. Instead of complaining about word retrieval problems or semantic or grammatical errors, they complain that “the right words don’t come out the right way” and, often, that lengthy or complex words create more problems than simpler ones.

Basic Demographics

Gender Ratio and Age of Onset

Duffy (2006) provides the most comprehensive data to date. Sixty-one percent of his patients were men. Average age at onset was about 67 years, with a range of 36 to 86 years. The data on gender should be interpreted cautiously, however, because single-case reports and smaller case series reported in the literature (Broussolle et al., 1996; Chapman et al., 1997; Cohen et al., 1993; Didic, Ceccaldi, & Poncet, 1998; Fukui et al., 1996; Hart et al., 1997; Josephs et al., 2005, 1996; Sakurai et al., 1998), in which degenerative AOS has been explicitly identified, have reported more women than men. The average age at onset in those reports is a few years younger (about 63 years) than those reported by Duffy.

Time until Onset of Other Deficits

Data regarding this are limited. Fifty-six percent of the 75 patients reported by Duffy (2006), for whom data on non-language cognitive functioning were available, had no evidence of nonaphasic cognitive impairment at the time of initial assessment (on average, about 2.5 years post-onset); only 3% of them complained of such deficits. Only 9% had non-speech motor complaints as an initial symptom. In general, many patients eventually develop nonspeech motor deficits, but often not until several years after the AOS has emerged.

Life Expectancy Following Onset of PPAOS

The seven patients reported by Josephs et al. (2006a) who had a progressive AOS as their sole or predominant commu-

nication disorder died an average of 8.7 years after initial symptom onset (range, 4–16 years). Three of the patients with AOS reported by Broussolle et al. (1996) died at 6, 6, and 10 years post-onset. Other cases in the literature that were followed to death seem to fall within this distribution of survival duration.

Accompanying Deficits

Other neurologic symptoms and signs can accompany progressive AOS and PPAOS. Among the 80 patients with progressive AOS summarized by Duffy (2006), aphasia was unequivocally present in 49% and most often was nonfluent or Broca-like in character. Fifty percent of the cases were dysarthric, most often spastic and/or hypokinetic in type. Eleven percent of the cases had neither aphasia nor dysarthria.

Deficits beyond the speech and language domain can include dystonia, limb apraxia, nonverbal oral apraxia, and alien limb phenomena (Duffy, 2006; Gorno-Tempini, Murray et al., 2004). A majority of Duffy’s patients with AOS for whom information about nonaphasic cognitive impairment was available did not have such impairment; in those who did, the cognitive deficits were never clearly worse than the AOS.

Deficits beyond the speech-language domain can lead to more specific clinical diagnoses. Twenty-nine percent of Duffy’s patients received neurologic diagnoses tied to prominent motor signs, most frequently including CBD or PSP (16%) and ALS (7–9%). The association between AOS and CBD and PSP is now well-established. For example, in each of two separate studies, one that described 13 patients with autopsy-confirmed CBD (Lehman Blake et al., 2003) and the other 14 patients with a clinical diagnosis of CBD (Frattali & Sonies, 2000), 38% had AOS; in those studies as well as a case reported by Gorno-Tempini, Murray et al. (2004), AOS (and, often, aphasia) preceded the emergence of other signs that permitted the diagnosis of CBD in several instances. In addition, in a recent autopsy study, Josephs et al. (2006a) found that PSP was the pathologic diagnosis for five of seven patients whose predominant speech-language disorder was AOS (one had CBD, and one had Pick’s disease). An additional three patients who had PPA and AOS that were of comparable severity had pathologic diagnoses of CBD.

Neuroimaging Correlates

Neuroimaging abnormalities are similar to those documented for PPA. Duffy (2006) concluded that neuroimaging can be normal but that, when abnormal, left or left-greater-than-right hemisphere abnormalities are common. SPECT was more sensitive to abnormalities than EEG, CT, or MRI, with 14% of patients having abnormalities confined to the

left hemisphere and 48% having left-greater-than-right hemisphere abnormalities. Other studies, mostly focused on PNFA (but in which at least some subjects were identified as “aphemic” or having AOS), generally concur and add some anatomical specificity. They generally point to the left perisylvian region, most often in the frontal lobe and usually in the region of the inferior frontal lobe/frontal operculum and anterior insula (Gorno-Tempini, Dronkers et al., 2004; Kertesz et al., 2003; Nestor et al., 2003)

Histologic Pathology

Recently, Josephs et al. (2006a) studied 17 patients with degenerative aphasia or AOS for whom pathologic diagnoses were available. Seven patients were classified as “AOS” (those in whom AOS was more prominent than any aphasia, if present), and three patients were classified as “PNFA-AOS” (those with PNFA and AOS in which neither aphasia nor AOS clearly predominated). Among the seven patients classified as AOS, the pathologic diagnoses were PSP (five patients), CBD (one patient), and Pick’s disease (one patient). The three patients classified as PNFA-AOS had pathologic diagnoses of CBD. The pathologic diagnosis for the remaining seven patients in the study (in whom aphasia could not be classified as SD or PNFA and in whom AOS or dysarthria, if present, nonetheless was dominated by the aphasia) was classified as “frontotemporal lobar degeneration with ubiquitin-only-immunoreactive changes” in five patients, PSP in one patient, and CBD in one patient. In addition, within the 11 cases that had evidence of AOS, all had underlying tau biochemistry. Among them, the pathologic diagnoses were PSP (six patients), CBD (four patients), and Pick’s disease (one patient). Thus, a clinical diagnosis of predominant AOS was strongly predictive of tauopathy histology and a pathologic diagnosis of PSP. When PNFA and AOS were roughly equivalent, tauopathy also was predicted, but with a predominance of CBD pathology. Less prominent or absent AOS suggested non-tauopathy. Although these results require replication, they highlight the potential value of distinguishing between AOS and aphasia. Not only are AOS and aphasia managed differently from a behavioral standpoint, it appears that the distinction may be helpful in predicting pathologic diagnosis and specific biochemical findings. Thus, the identification of AOS (and its predominance relative to aphasia) seems to have implications for clinical, histological, and biochemical levels of inquiry.

The results of the Josephs et al. (2006a) study are supported by other pathologic findings, if it can be assumed that many patients classified as PNFA also had AOS. Thus, for example, Knibb et al. (2006) characterized, both clinically and pathologically, 38 patients with PPA, 23 of whom had PNFA. Seventy-four percent of their patients with PNFA were said to have “phonetic paraphasia,” and 26% had

“dysprosody”—features that might reflect AOS. The most frequent pathology in the PNFA group was non-Alzheimer’s tauopathy (10/23 patients). In their 15 cases with fluent PPA, FTLT with ubiquitin-positive, tau-negative inclusions was the most frequent pathology (8/15 patients). They concluded that tauopathies were over-represented in their PNFA group and that their findings provide pathologic support for the existence of two distinct PPA syndromes. Obviously, one might argue that the two syndromes do not really reflect fluent and nonfluent aphasia but, rather, aphasia and AOS, or fluent aphasia versus nonfluent aphasia and AOS.

MANAGEMENT OF PPA AND PROGRESSIVE AOS

As with all interventions for aphasia, the consideration of therapy for PPA and progressive AOS requires both philosophical and scientific inspection. This inspection has taken the form of a number of frequently asked questions. Duffy (1987) asked:

1. Should persons with PPA or progressive AOS receive speech-language services at all?
2. If the answer to the first question is affirmative, under what conditions should treatment be given?
3. What should be the nature of the management efforts?
4. What are the criteria for success?

To these queries, we might ask what about PPA or progressive AOS is similar to or different from other forms of therapy for aphasia or AOS and what about it would require different criteria for intervention initiation, treatment type, and expected or acceptable consequences to the treatment.

Once the theoretic/philosophical definitions of what aphasia and AOS are and are not have been answered, we can begin to address the questions raised above that make the progressive form different from a static or non-progressive form of aphasia or AOS. If the fundamental definitions of aphasia and AOS are the same (as we have argued that they must be, or the diagnosis is incorrect), then it is only the progressive nature of the disorder that demands our differential consideration for treatment implementation. That is, does the progressive nature of the disorder obviate the consideration of treatment? If so, this would be a rare exception among progressive disorders of speech and language that is not considered for intervention simply because of its degenerative nature. Likewise, the life expectancy of the individual has been raised as an issue in the decision to initiate treatment, especially for degenerative disorders. It seems to us that a decision to initiate or withhold treatment based only on the duration of life expectancy is ethically indefensible. On these bases alone, the question of whether PPA or PPAOS should be exempt from treatment consideration can

be dismissed. Therefore, the question becomes whether the patient under consideration has the motivation, financial and other (e.g., transportation) resources, level of linguistic and other cognitive resources (e.g., attention and memory), and the potential for language or motor and communication learning and maintenance necessary to support a recommended treatment. When these determinations have been made, secondary questions can be asked about the potential to benefit from specific intervention procedures.

To our knowledge, the treatment data (administered under experimental conditions that allow the examination of its efficacy) for only three patients with PPA have been published (McNeil et al., 1995; Rapp, Glucroft & Urrutia, 2005; Schneider, Thompson & Luring, 1996).¹² One other uncontrolled case study (Murray, 1998) describes a sequence of treatments administered to one person with PPA, and a book chapter (Rogers, King, & Alarcon, 2000) describes the rationale and a detailed plan for the treatment of persons with PPA. The experimental data are, of course, too limited to provide guidance for the treatment of subsequent patients. What has become apparent from these experiments and from the treatment pundits, however, is that the same array of treatment options remains available to persons with PPA as to those persons with non-progressive aphasia. To the degree that this is true, it also is apparent that these options are governed, in large measure, by the same clinical and theoretic considerations and biases. That is, whether treatment potential is determined by an assessment of the patient's activity limitations and restrictions in social participatory roles alone or is based on the evaluation of the presumed underlying mechanisms for the communication disorder (impairment-level assessment) represents a major clinical/theoretic bias. Likewise, the type of intervention selected is determined, in great measure, by this bias. Other issues involve the commitment to treat areas of deficit to improve them temporarily or maintain them as long as possible, or, alternatively, to direct intervention toward the expected decline in abilities with augmentative/alternative communication as the goal and the method. Each of these considerations and biases can be found among the publications reviewed below.

McNeil et al. (1995) published the first experimental attempt to assess the efficacy of treatment for a person with PPA. They evaluated the effects of treatment directed to

dysnomia, the primary sign and symptom in a patient with PPA of recent onset. The patient presented with very mild spastic dysarthria, nonverbal oral apraxia, aphasia that crossed all modalities and levels of language, and no AOS. In the context of a single-subject, multiple-baseline design, data were derived that demonstrated improved word finding ability when that was the focus of treatment (Lexical-Semantic Activation Inhibition Treatment [L-SAIT]), declines in language abilities that were not treated, and stable non-language cognitive performance. The most effective treatment for the patient was a combination of behavioral treatment plus dextroamphetamine. Although this particular patient's course of degeneration was atypically short and was dominated toward its end by severe spastic dysarthria and dysphagia, the impairment-focused treatment was efficacious and bolstered the patient's interpersonal and intrapersonal communication for some time. Generalization to untreated and progressively deteriorating areas of language performance was evidenced to some degree, but secondary benefits of treatment were observed. During the periods in which the patient was receiving treatment, he had an additional purpose and goal for his life and his otherwise unfilled time. Although of no obvious consequence to his life expectancy, his demonstrated improvements in language and communication gave him a sense of control that was not available to him in other areas of his life. This benefit was acquired with full knowledge that his treatment would not retard progression of the underlying disease. Augmentative communication was not an acceptable modality to this patient, and other potential forms of treatment became unreasonable because of the rapid progression of his underlying disease.

Also in the context of a single-subject, experimental multiple-baseline design, Schneider and colleagues (1996) presented data for a person with PPA demonstrating that oral and oral plus gestural training of verb tense was learned and generalized to untreated verbs within tense, but not across tenses. This impairment-directed treatment for agrammatism using gestural plus oral responding resulted in higher levels of correct oral sentence production than verbal responding alone. Although generalization to untreated areas of language and communication was not robust, the gestural responding generalized and was maintained for a 3-month period following the withdrawal of treatment. This maintenance was achieved in the context of declines in other language functions.

Murray (1998) presented a detailed case study (without experimental control) describing a series of treatments administered to a single subject with nonfluent PPA. The patient presented 1 year post-onset of self-described "stuttering," with the complaint of increased "slurring" of speech and word finding difficulties. Although impaired across all modalities, the patient's progressing deficits during the course of treatment were characterized by agrammatism,

¹² A small number of studies have reported the results of treatment for "naming" or "forgotten" vocabulary in individuals with SD (Graham, Patterson, Pratt, & Hodges, 2001; Jokel, Rochon, & Leonard, 2002; Snowden & Neary, 2002). We have elected not to review them here because of our uncertainty about whether the study participants would meet the criteria for the diagnosis of aphasia as presented in this chapter.

anomia, phonemic paraphasia, AOS, and auditory comprehension deficits. Treatment was first administered over an 11-month period and was directed at her auditory and reading comprehension. It was described as consisting of “traditional stimulus-response activities which were designed to stimulate and facilitate . . .” (p. 658). The second treatment involved 24 one-hour sessions over a 4-month period and used the “back to the drawing board” program (Morgan & Helm-Estabrooks, 1987), a treatment that involves drawing pictures for communicative purposes and claims to be both an alternative communication method and a deblocker of speaking and writing. The third treatment involved both individual and aphasia support group therapy. Individual treatment in this phase “focused on improving communication interactions between D.D. and her spouse” and involved identifying turn-taking and repair skills. The patient also was trained and appeared to use an augmentative communication device (Dyna Vox), although with poor situational generalization.

Although the lack of experimental control in this case study obviates the attribution of any change to the treatments that were administered, it clearly describes the change of treatment focus and technique as the patient’s signs and symptoms changed over the course of her decline. This changing sequence of treatment goals and methods may represent the most common practice in the treatment of aphasia of any etiology. For this to represent a generalizable model for best practice in the planning and implementation of intervention for PPA, it will require the same level of evidence as for the treatment of aphasia of any etiology. It does, however, illustrate the apparent frequently used and perhaps necessary adaptations of treatment goals and methods that follow careful observation of patient change that accompanies any efficacious treatment.

In the context of a single-subject, multiple-baseline design (with a single averaged data point reported for each baseline, treatment, and follow-up for each trained and untrained list of stimuli), Rapp and colleagues (2005) reported positive acquisition effects of a writing intervention focused on spelling to dictation. This 63-year-old individual had an 8-year history from first-noticed dysgraphic symptoms to treatment. She was diagnosed with fluent PPA 4 months before the initiation of the experimental treatment. During the 4-month course of therapy, the individual demonstrated normal and stable performance on a number of non-linguistic tasks (e.g., Rey Figures, delayed verbal recall, and verbal recognition memory) while demonstrating a substantive decline in language (Rey auditory verbal learning; word fluency for the letters F, A, and S; spoken picture naming). In addition, a systematic and substantive decline in the untrained spelling lists occurred over the course of the treatment and at the 6- and 12-month post-treatment evaluations.

The treatment involved having the participant spell each word to dictation, study the word, and then attempt to spell it again if it had been spelled incorrectly. This sequence was

repeated as many as three times or until the stimulus word was spelled correctly. A control condition also was administered whereby a matched list of stimuli were presented but without feedback regarding accuracy. A list of words also was given as homework and self-assessed at home. Finally, as mentioned above, a list of control words was presented only at the pre- and post-tests. Treatment effects were determined by the number of correct letters divided by the number of target letters. Repeated and treated lists were identical at pre-treatment (about 68% correct). The treated list improved to 76%, however, and the repeated list dropped to 67% accuracy. The untreated control list dropped from 65% pre-treatment to 60% post-treatment and then to about 52% at 6-month follow-up. Interestingly, the repeated words and the homework remained relatively stable during the treatment period but dropped substantially during the 6-month follow-up, as did the treated spelling list. The treated list, however, remained higher than either untreated list at this 6-month maintenance phase. Only the treated list improved, and with the withdrawal of treatment, performance on all spelling lists diminished to roughly equivalent levels.

This study adds to findings that intervention can provide short-term, positive consequences for communicative function in PPA and intermediate-term, protective consequences as well. They also underscore the important conclusion that behavioral treatment does not reverse or prevent progression of the underlying disease; however, it can provide meaningful relief to the burden of the unrelenting march of the disease and the limitation it imposes on communicative functions.

In an uncontrolled case study, Koenig-Bruhin, Studer-Eichenberger, Donati, Zwahlen, and Hohl (2005) reported improvement on the sentence repetition subtest of the Aachen Aphasia Test over a 5-month, once-per-week regimen in areas targeted for treatment (phonologic aspects of repetition and short-term memory). The other subtests of this test remained unchanged over this time period. These changes cannot be attributed to the intervention, but the targets of treatment chosen for this individual reflect the predominant impairment-based approach to remediation of PPA.

Impairment-based treatment is not, however, the only approach advocated for the treatment of PPA. Rogers and colleagues (2000) presented a detailed description of proactive management for PPA that they believe will minimize activity limitations and participation restrictions as well as maximize communication competence as speech and language decline. This is accomplished by “early intervention focused on the development and training of augmentative and alternative communication (AAC)” (p. 306). In addition to the early training in AAC, patient and family education and family/partner intervention is advocated, with particular attention being paid to activity and participation limitations in both patient assessment and treatment planning and

implementation. It is the inherent assumption of this approach that AAC is both an efficacious method of therapy for aphasia and the inevitable treatment modality in persons with PPA. In terms of evidence-based practice, neither of these assumptions stands on firm ground. Treatment efficacy and effectiveness data for aphasia are essentially nonexistent concerning AAC. In addition, compliance data for patients with aphasia, an issue in AAC training for all communication disorders, is in need of verification and, perhaps, improvement.

It seems clear to us that the call by Rogers and colleagues (2000) for assessment of PPA that deemphasizes the understanding of the nature of the impairment (for treatment planning purposes) and shifts it toward the individual's communication needs, partners, and environments, and that prescribes the early initiation of AAC as the target of treatment, is potentially problematic—or at the least premature. One problem is that it may be destined for nonacceptance from a substantial segment of the PPA patient population. A second problem is that this approach neglects the potential to improve and/or maintain specific language processing functions that underlie both the interpersonal and intrapersonal communication deficits (and, consequently, communicative and other activities and participatory limitations) for a meaningful period of time. That is, it neglects the fact that many, if not most, patients with PPA decline at a rate and a level sufficient to support and maintain independent language and communication skills, supporting communicative activity and social participation for many years. It may be that planning for AAC is on firmer ground when the progressive disorder is motor in nature (e.g., PPAOS or dysarthria) or when PPA is accompanied by progressive motor speech impairment. It seems to us that a much more rational and palatable approach, depending on the rate of decline and the impairment level of the patient, is to direct treatment at the hypothesized deficits, at compensatory strategies, at psychosocial concomitants of the disorder, at environmental influences (e.g., significant others and caregivers), and when communicatively appropriate, accepted by the patient, and trained before their use is necessary, at AAC systems. One difference in the treatment of persons with PPA compared to treatment of those of aphasia and a more static course is the need for clear patient and family education and counseling that emphasizes the progressive nature of this disorder. As with other etiologies, counseling that spans the course of the treatment as well as the accompanying patient and family changes is essential.

Similar to these treatment recommendations, Thompson (1997) provided the following useful guidelines for the treatment of PPA:

1. Early speech-language-cognitive evaluation is important, as are frequent follow-ups to establish the pattern of decline.
2. Early treatment may focus on impaired functions but should be adjusted as decline occurs.
3. AAC should be introduced early, when it is most easily learned, so that it can be used as the need arises.
4. Family members/significant others must be involved to enhance awareness of successful strategies and to practice with patient.
5. Treatment will not reverse progression of the disease but may enhance communication ability.

In the absence of reported and documented attempts to treat PPAOS, it seems altogether reasonable that the same principles for structuring intervention for PPA would apply. The single addition to these general treatment strategies would be to reiterate the potential for AAC intervention in persons with PPAOS over that of individuals whose access to language is impaired.

In summary, no *a priori* theoretic or philosophical reason exists to withhold language and communication treatment from persons with PPA or PPAOS if the usual criteria for treatment candidacy are met. It is, however, too early in the accumulation of evidence to determine whether treatment for persons with PPA or PPAOS is predictably efficacious and whether it will follow the same principles of management as aphasia and AOS resulting from other etiologies and of other natural courses. It has been demonstrated that persons with PPA can improve on language and communication tasks with impairment-directed treatments that are typical of and efficacious for persons with static aphasia. It is reasonable to assume that—but currently untested whether—persons with PPA can learn, will use if learned, and will benefit from AAC devices. Patient and family counseling and communication training are likely to be integral parts to any successful aphasia or AOS regimen.

KEY POINTS

1. Aphasia of insidious onset, gradual progression, and prolonged course, without evidence of non-language computational impairments, and resulting from a degenerative condition that, presumably and predominantly, involves the language-dominant perisylvian region of the brain, is known as PPA. The criteria for the diagnosis of aphasia of any etiology or type are the same as those required for establishing the diagnosis of PPA. The disorder does not include patients in whom language impairment is just a prominent manifestation of dementia. PPA is a clinical syndrome, not a reflection of particular underlying brain pathology.
2. Currently applied criteria for the diagnosis of PPA include (a) a minimum of a 2-year history of language decline; (b) prominent language deficits, with relative

preservation of other mental functions; (c) independence in ADLs; (d) a full neurologic workup that has excluded other causes of aphasia; and (e) a comprehensive speech-language and neuropsychological evaluation that yields results consistent with the complaint and clinical neurologic examination. It should be noted that the 2-year history criterion is somewhat arbitrary—a working diagnosis of PPA may be justified without regard to duration of the aphasia. In addition, reduced ADLs that can be explained by the aphasia should not preclude a diagnosis of PPA.

3. The initial clinical presentation of people with PPA can be very different from that of people with AD or other degenerative diseases that induce diffuse cognitive impairments. It can be strikingly similar to stroke-induced and other static etiologies for aphasia, with the exception of its temporal course.
4. More men than women have PPA. Age of onset is highly variable but averages about 60 years. The duration from onset of aphasia symptoms to the emergence of more widespread impairment of cognitive functions also is highly variable but averages about 5 years. About 45% of reported cases have eventually developed non-aphasic cognitive impairments, but an emerging general consensus is that the great majority eventually experience symptoms in areas such as memory, personality, or mood, if they live long enough.
5. Apraxia of speech, nonverbal oral apraxia, dysarthria, dysphagia, right-central facial droop or weakness, right-extremity weakness or clumsiness, rigidity, agnosia, and depression have been reported in persons with PPA.
6. MRI and SPECT are commonly used for the neuro-radiologic evaluation of people with PPA. When abnormal, these modalities tend to show left hemisphere abnormalities or left-greater-than-right hemisphere abnormalities.
7. PPA can be associated with a variety of specific histopathologic diagnoses, including AD, corticobasal degeneration, PSP, motor neuron disease, and CBD. The most frequent autopsy findings are perhaps, however, of cellular changes that do not correspond to well-known, specific clinical or pathologic conditions (e.g., nonspecific focal degeneration with spongiform changes and gliosis, nonspecific cortical degeneration). Most patients with PPA will not have a histologic diagnosis of AD.
8. Apraxia of speech (AOS) may be the initial, only, or prominent manifestation of degenerative neurologic disease. Similar to PPA, it may herald more specific neurologic diseases and is unlikely to represent a sin-

gle neurologic disease. Distinguishing between a progressive AOS and PPA may be relevant to prognosis, management, and perhaps, underlying histopathology.

9. Efficacy and outcome data regarding management of PPA and progressive AOS are very limited, but no *a priori* theoretic or philosophical reasons exist to withhold language, speech, or communication treatment from persons with either disorder if the usual criteria for treatment candidacy are met.
10. It is premature to draw conclusions about whether treatment of persons with PPA or PPAOS is generally effective, but it has been demonstrated that some affected persons with PPA can improve on language and communication tasks with impairment-directed treatments that are typical of, and efficacious for, persons with static aphasia. It is reasonable to assume that—but is currently untested whether—persons with PPA or progressive AOS can learn, will use if learned, or will benefit from AAC devices and strategies.
11. For persons with PPA or PPAOS and their families, a need exists for education and counseling that emphasizes the progressive nature of the disorder and that behavioral treatment to maximize communication ability cannot be expected to retard or reverse progression of the disease.
12. In general, it appears that the most rational approach to management of PPA or PPAOS is to gauge the rate of decline and the level of impairment, and then to direct treatment at the hypothesized deficits, at compensatory strategies, at psychosocial concomitants of the disorder, and at environmental influences (e.g., significant others and caregivers). When communicatively appropriate, accepted by the patient, and trained before their use is necessary, AAC systems may be used, particularly if substantive motor speech deficits accompany the PPA or if PPAOS is substantially greater in severity than aphasia.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Discuss the unique features of PPA, other than its slow onset, that differentiate it from non-progressive courses of aphasia.
2. Discuss the criteria for diagnosing PPA.
3. List the neurogenic language disorders with which PPA is most likely to be confused or misdiagnosed, and identify the diagnostic features that differentiate each from PPA.
4. Discuss the evidence for and against the classification of PPA as a subtype of FTD.
5. What percentage of individuals with PPA can be expected to develop non-aphasic cognitive impairment?

6. What are the theoretic objections and clinical implications of classifying all persons with adult-onset language disorders as “aphasic”?
7. Discuss the neurologic degenerative diseases in which progressive AOS can be an accompanying or presenting sign or symptom.
8. Discuss the demographic and etiologic similarities and differences between PPA and PPAOS.
9. What are the two most significant theoretic biases governing the selection and implementation of treatment for progressive aphasia and AOS?
10. Discuss the amount and quality of the evidence supporting each theoretic bias governing the selection and implementation of treatment for progressive aphasia and AOS.

Chapter 21

Global Aphasia: Identification and Management

Richard K. Peach

OBJECTIVES

Following the completion of this chapter, the reader will be able to identify the features of global aphasia, its etiology, the patterns of evolution and outcome in global aphasia, and some factors that are related to recovery from this syndrome. The reader also will be able to provide a rationale for early intervention with these patients, describe contemporary goals for assessment, and develop treatment plans that exploit the residual language capacity and/or other functional abilities of patients with global aphasia. Finally, the reader will be able to identify current testing measures and both impairment-based and socially oriented treatment programs that emphasize improved language and functional communication and are appropriate for assessing and treating patients with global aphasia.

Positive developments regarding the rehabilitation of persons with global aphasia have continued to appear in the literature since publication of the last version of this chapter. Clinicians and families therefore have reasons to be guardedly optimistic concerning the communication outcomes from this condition. Among these developments are an improved understanding of the cerebral mechanisms underlying recovery of auditory comprehension following global aphasia (Zahn et al., 2004); novel approaches to treating naming, including phonologic treatment (Biedermann, Blancken, & Nickels, 2002) and transcranial magnetic stimulation (Naeser et al., 2005); and extended application of computer-based communication systems to produce sentences of varying syntactic complexity (Koul, Corwin, & Hayes, 2005; McCall, Shelton, Weinrich, & Cox, 2000). The emergence of social approaches for language and communication treatment, some of which have demonstrated efficacy, also provides an important dimension to rehabilitation for global aphasia (Kagan, Black, Duchan, Simmons-

Mackie, & Square, 2001). The prognosis for recovery of premorbid speech-language abilities is, indeed, poor following global aphasia, but these individuals do make significant improvements in communication skills with treatment during the first year post-onset (Nicholas, Helm-Estabrooks, Ward-Lonergan, & Morgan, 1993) and beyond (Naeser et al., 2005). Those improvements also occasionally exceed the outcomes observed in patients with other types of aphasia (i.e., Broca's and Wernicke's aphasia) that are associated with better prognoses for improvement (Basso & Farabola, 1997; Kertesz & McCabe, 1977). Identification of new treatments yielding limited but nonetheless positive communication benefits for these individuals is therefore an important advance, particularly when considered in the context of the historically pessimistic views associated with this clinical group.

The central questions regarding outcomes following global aphasia concern discovering the patient characteristics that can be associated with various prognoses and applying these in treatment planning (Peach, 1992). Some recent studies have attempted to do this by examining outcomes with regard to the patterns of lesion sites producing global aphasia (Basso & Farabola, 1997; Kumar, Masih, & Pardo, 1996; Naeser, 1994; Okuda, Tanaka, Tachibana, Kawabata, & Sugita, 1994). Others have investigated the role of an accompanying hemiplegia (Keyserlingk, Naujokat, Niemann, Huber, & Thron, 1997; Nagaratnam, Barnes, & Nagaratnam, 1996). Still others have employed positron-emission tomography to identify predictors that might account for the large amount of variability observed in recovery from aphasia generally and from global aphasia specifically (Heiss, Kessler, Karbe, Fink, & Pawlik, 1993; Okuda et al., 1994).

These developments are encouraging especially, because the largest percentage of patients with aphasia referred for speech-language services is composed of those presenting with global aphasia (Sarno & Levita, 1981). Despite the poor prognosis for recovery of oral language skills following global aphasia, clinicians now have more tools than ever to make informed decisions regarding both whether and how to treat individuals with global aphasia and the impact that this treatment will have on the patients' communication skills.

FEATURES

Incidence

Global aphasia may be one of the most frequently occurring types of aphasia. Previously, incidence rates of between 10% and 40.6% have been reported for global aphasia (Basso, Della Sala, & Farabola, 1987; Brust, Shafer, Richter, & Bruun, 1976; Collins, 1986; De Renzi, Faglioni, & Ferrari, 1980; Eslinger & Damasio, 1981; Kertesz, 1979; Kertesz & Sheppard, 1981). Some recent reports, however, suggest that the incidence rate during the acute stage may be even higher. Scarpa, Colombo, Sorgato, and De Renzi (1987) reported an incidence of 55.1% in an acute sample. All of the 108 patients with aphasia included in the study by Scarpa and colleagues (1987) were assessed between 15 and 30 days post-onset and were right-handed with a single, left hemisphere lesion. When these data are combined, they provide evidence indicating that patients with global aphasia are prominent among patients with aphasia as a whole. As a result, they constitute a significant demand on the resources of clinical aphasiologists from the acute stages of illness through the time of maximal recovery.

Characteristics

Age and Sex

Discrepancies appear in the literature with regard to age and global aphasia. Some studies suggest no effect of age on global aphasia (Habib, Ali-Cherif, Poncet, & Salamon, 1987; Scarpa et al., 1987; Sorgato, Colombo, Scarpa, & Faglioni, 1990), whereas others report differences only with patients demonstrating Broca's aphasia (i.e., patients with Broca's aphasia tend to be significantly younger than those with global aphasia). This difference appears to hold true not only for Western patients with stroke but also for Indian patients with stroke (Bhatnagar et al., 2002). The older patients in the sample of Sorgato and colleagues (1990), however, did tend to show atypical aphasias, including global aphasia from brain damage that was restricted to either anterior or posterior areas.

With regard to sex, there appears to be no observable difference in the distribution of global aphasia (Habib et al., 1987). Davis (1983) suggested a general bias toward males in the data generated among the VA Medical Centers because of the nature of the population seen at these hospitals. Further studies, including more representative patient distributions, may be necessary for reliable data regarding the influence of sex on global aphasia. Nonetheless, age and sex may not be considered to have a differential effect on the incidence of global aphasia.

Site of Lesion

Cerebrovascular lesions producing global aphasia have been described as involving Broca's (posterofrontal) and Wernicke's

(superotemporal) areas (Kertesz, 1979) or, alternatively, both the prerolandic and postrolandic speech zones (Goodglass & Kaplan, 1983). The subjects with global aphasia described by Murdoch, Afford, Ling, and Ganguley (1986) exhibited large lesions extending from the cortical surface inferiorly to subcortical areas, including the basal ganglia, internal capsule, and thalamus. Basso and Farabola's (1997) subject with global aphasia had damage to the left frontal operculum, Wernicke's area, the premotor area, the supramarginal gyrus, inferior and superior parietal lobules, angular gyrus, and Heschl's gyri. All of these global aphasia-producing lesions involved the cortex and were extensive, dominating the left hemisphere. Numerous exceptions have been reported in the literature, however, suggesting that such an extensive lesion may not be necessary to produce a global aphasia.

Mazzocchi and Vignolo (1979) found global aphasia in 3 of 11 cases following lesions that were confined to anterior regions. In four additional cases, the lesions were deep and confined to the insula, the lenticular nucleus, and the internal capsule. Varying lesion effects also were described by Cappa and Vignolo (1983). Basso, Lecours, Moraschini, and Vanier (1985) observed global aphasia following discrete lesions confined to anterior (sparing of postrolandic centers) or posterior cortical sites. Alexander (2000) suggests that the comprehension deficit in patients with lesions limited to the frontal lobe may be the result of inattention, underactivation, unconcern, poor problem solving, or perseveration interacting with modest phonologic and/or semantic deficits to produce more profound functional comprehension deficits. Lüders and colleagues (1991) produced global aphasia during electrical stimulation of the basal temporal region. This region has its white matter in contact with the white matter deep to Wernicke's area, thereby favoring close interaction between these two areas. Sugiu, Katsumata, Ono, Tamiya, and Ohmoto (2003) observed global aphasia in a patient with a subarachnoid hemorrhage of the interhemispheric fissure identified by computed tomography (CT) and a small ischemic lesion in the territory of the distal left anterior cerebral artery identified by magnetic resonance imaging (MRI). Angiography demonstrated an anterior communicating artery aneurysm and severe vasospasm of the A1 segment of the anterior cerebral artery, the M1 segment of the middle cerebral artery, and the distal internal carotid artery. Conversely, Basso and colleagues (1985) reported other forms of aphasia following lesions that would have been suggestive of global aphasia.

Global aphasia also has been described in patients with lesions restricted to subcortical regions. Alexander, Naeser, and Palumbo (1987) found global aphasia in association with one lesion or with a series of primarily subcortical lesions that collectively damaged the striatum-anterior limb of the internal capsule; the anterior, superior, anterosuperior, and extraanterior periventricular white matter; and the temporal

isthmus. Yang, Yang, Pan, Lai, and Yang (1989) also identified global aphasia in patients with lesions involving the internal capsule, basal ganglia, thalamus, and anteroposterior periventricular white matter. Okuda and colleagues (1994) described four patients with global aphasia who had lesions in the putamen, posterointernal capsule, temporal isthmus, and periventricular white matter of the left hemisphere. Kumar and colleagues (1996) observed global aphasia in their patient following a left thalamic hemorrhage.

Ferro (1992) as well as Basso and Farabola (1997) investigated the influence of lesion site on recovery from global aphasia. Ferro initially examined 54 subjects during either the first month (34 subjects), third month (7 subjects), or sixth month post onset (13 subjects). He then followed-up each patient at 3, 6, and 12 months and then yearly thereafter when possible. The lesions in his group of subjects with global aphasia were grouped into five types with differing outcomes. Type 1 included patients with large pre- and postrolandic middle cerebral artery infarcts; these patients had a very poor prognosis. The remaining four groups were classified as follows: type 2 = prerolandic; type 3 = subcortical; type 4 = parietal, and type 5 = double frontal and parietal lesion. Patients in these latter groups demonstrated variable outcomes, improving generally to Broca's or transcortical aphasia. Complete recovery was observed in some cases with type 2 and type 3 infarcts. In contrast to these findings, Basso and Farabola investigated recovery in three cases of aphasia based on the patients' lesion patterns. One patient had global aphasia from a large lesion involving both the anterior and posterior language areas, whereas two other patients had Broca's and Wernicke's aphasia from lesions restricted to either the anterior or posterior language areas, respectively. The patient with global aphasia was found to recover better than his two aphasic counterparts, but his overall outcome was considered to be outstanding. Based on these observations, Basso and Farabola concluded that group recovery patterns based on aphasia severity and site of lesion may not be able to account for the improvement that occasionally is observed in individual patients.

Language

The hallmark of global aphasia is impaired language comprehension (up to the 30th percentile on the Boston Diagnostic Aphasia Examination [Alexander, 2000]) with concomitant deficits in expressive abilities (Damasio, 1991; Davis, 1983; Kertesz, 1979) in the context of almost universal buccofacial and limb apraxia (Alexander, 2000). Wallace and Stapleton (1991) suggested that, traditionally, the linguistic deficit in global aphasia has been interpreted as a loss of language competency (i.e., the knowledge of linguistic rules and operations). According to these authors as well as others (Rosenbek, LaPointe, & Wertz, 1989), the recent clinical evidence demonstrating preserved areas of language

functioning in global aphasia suggests that the loss for these patients may be viewed more appropriately as a variable mix of competence and performance deficits.

Comprehension

Patients with global aphasia may have considerable single-word comprehension (Alexander, 2000). Several isolated areas of relatively preserved comprehension following global aphasia also have been identified in the literature. These include recognition of specific word categories (McKenna & Warrington, 1978; Wapner & Gardner, 1979), familiar environmental sounds (Spinnler & Vignolo, 1966), and famous personal names (Van Lancker & Klein, 1990; Yasuda & Ono, 1998; but see also Forde & Humphreys, 1995, for a report of relatively impaired access to personal names following global aphasia). In the case of famous personal names, Yasuda and Ono (1998) found a distinct advantage for comprehending these items when reading versus listening. They attributed this finding to the nonsemantic, referential nature of personal names and to the probable processing of these stimuli in the patients' intact right hemispheres. Subjects with global aphasia also show relatively better comprehension for personally relevant information (Wallace & Canter, 1985; Van Lancker & Nicklay, 1992).

Wallace and Stapleton (1991) analyzed the responses of subjects with global aphasia on the auditory comprehension portion of the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983), or BDAE, to identify patterns of preserved and impaired performance. Their results generally supported previous claims that distinct patterns of preserved components are absent in global aphasia; nonetheless, two or three of their subjects did show evidence of differential performance both within and across tasks. Interestingly, the scores for each of these subjects were collected during the acute stage of their recovery. The authors speculate that differential auditory comprehension performance during acute aphasia may be a useful prognostic indicator.

Expression

It has been suggested that patients with global aphasia may be most severely impaired in their expressive abilities. This may be a result of the greater contributions of the right hemisphere for comprehension than for expressive behaviors (Collins, 1986). The verbal output of many patients with global aphasia primarily consists of stereotypic recurring utterances or speech automatisms (Kertesz, 1979). Some authors have concluded that stereotypic recurring utterances are unique to global aphasia (Poeck, De Bleser, & Keyserlingk, 1984). Because of this and complementary evidence, Selnes and Hillis (2000) speculate that Tan, a patient with Broca's aphasia whose speech was limited to repetitions of the syllable "tan," actually may have presented with an

atypical global aphasia rather than the historically accepted diagnosis of Broca's aphasia.

Stereotypes have been described as being either nondictionary verbal forms (unrecognizable) or dictionary forms (word or sentence) (Alajouanine, 1956). Blanken, Wallesch, and Papagno (1990) examined 26 patients demonstrating the nondictionary forms of speech automatisms. Of these cases, 24 were classified as having global aphasia. The other patients demonstrated signs more closely associated with Broca's and Wernicke's aphasia. Although speech automatisms frequently were associated with comprehension disturbances, the observed variability in language comprehension among these patients suggests that speech automatisms cannot be used to infer the presence of severe comprehension deficits. Blanken and colleagues (1990) proposed that speech automatisms relate only to speech output and do not necessarily indicate the presence of severe comprehension deficits.

Cognition

The cognitive abilities of patients with brain damage often are assessed by administration of the Raven's Colored Progressive Matrices (Raven, 1965), or RCPM, a nonverbal test of analogical reasoning. Conflicting results have been reported regarding the performance of subjects with aphasia relative to that of patients with left brain damage but without aphasia. Some studies have found that subjects with aphasia perform at lower levels (Basso, Capitani, Luzzati, & Spinnler, 1981; Basso, De Renzi, Faglioni, Scotti, & Spinnler, 1973; Colonna & Faglioni, 1966), but others have failed to show any significant difference between these two groups (Arrigoni & De Renzi, 1964; Piercy & Smith, 1962). Collins (1986) has reported significant positive correlations between the language ability of subjects with global aphasia and their performance on the RCPM. The subjects in the Collins study were in the early stages of recovery, and eventually, these subjects achieved RCPM scores similar to those of subjects with less severe aphasia.

Using a modified version of the RCPM to minimize the potential effect of unilateral spatial neglect, Gainotti, D'Erme, Villa, and Caltagirone (1986) compared acute and chronic subjects with varying types of aphasia to normal controls, subjects with right hemisphere damage, and subjects with left hemisphere damage but without aphasia. In this study, the subjects with aphasia performed worse than the subjects in the other groups. Further, the patients with global aphasia and with Wernicke's aphasia scored the poorest in comparison to those in the other aphasic groups (anomic, Broca's, and conduction). These results were similar to those obtained by Kertesz and McCabe (1975). Gainotti and colleagues (1986) did not obtain differences relative to the severity of aphasia, but they did link poor performance on the RCPM to the presence of receptive semantic-lexical disturbances. Gainotti colleagues conclude that "a

specific relationship exists in aphasia between cognitive non-verbal impairment and breakdown of the semantic-lexical level of integration of language" (p. 48).

Rossor, Warrington, and Cipolotti (1995) demonstrated relatively preserved calculation skills in a patient with global aphasia secondary to progressive atrophy of the left temporal lobe. Together with previous reports of selective impairment of calculation in patients with intact language skills, the authors posited that this double dissociation reflects a functional independence between the two domains of behavior (i.e., that calculation skills are not dependent on the language processing system). Because selective impairment of calculation skills has been associated with left parietal lesions, the authors also suggested that lesions producing language disturbances that spare the parietal lobe may be associated with preserved calculation skills.

Communication

Recurring utterances among individuals with global aphasia was addressed previously. Those who exhibit only recurring consonant-vowel syllables (e.g., "do-do-do" or "ma-ma-ma") often give the impression of somewhat preserved communicative abilities in that they may make use of the suprasegmental aspects of speech (Collins, 1986). The use of suprasegmentals in conversational turn taking may appear to indicate that the patient with aphasia is producing utterances with some communicative intent. deBlesser and Poeck (1984) studied a group of patients with global aphasia and found that they did not exhibit prosodic variability to the extent necessary for conveying communicative intent. The utterances used for analysis, however, were limited to those elicited during formal testing, and they may not have reflected the spontaneous use of inflection to convey intent (Collins, 1986). deBlesser and Poeck (1985) subsequently analyzed the spontaneous utterances of a group of subjects with global aphasia and output limited to consonant-vowel recurrences. Utterances were sampled during interviews in which the examiner asked a series of open-ended questions, and the length of the utterances and their pitch contours were analyzed for variability. The authors concluded that both length and pitch appeared to be stereotypic and that the prosody of these patients did not seem to reflect communicative intent. The appropriateness of these consonant-vowel recurring utterances with regard to turn taking remains questionable. These findings highlight the marked discrepancy that exists between research outcomes and clinical reports. deBlesser and Poeck (1985) suggest that the contributions to conversation for which these patients are credited may, in fact, be the result of the communicative partner's need for informative communication rather than the patient's use of prosodic elements to convey intent.

In a study by Herrmann, Koch, Johannsen-Horbach, and Wallesch (1989), a group of patients with chronic and severe

nonfluent aphasia were described in terms of their communication strategies and communicative efficiency. The patients presented with either severe Broca's or global aphasia (50%). The results showed that the efficiency of the patients' communication depended on the type of question to which they were asked to respond. As might be expected, superior performance was observed for responses to yes/no questions (e.g., "Did your illness occur suddenly?") when compared to interrogative pronoun questions (e.g., "How long have you had language problems now?") and narrative requests (e.g., "Tell me what happened to you after you took ill."). Herrmann and colleagues (1989) reported that the patients used mostly gesture in their responses to the yes/no questions. The other types of questioning require increased verbal output and, thus, created the need for more complex communicative responses from the patients.

In examining the communication strategies utilized, Herrmann and colleagues (1989) found that patients rarely took the initiative or expanded on topics. The most frequent strategies reported by these authors were those enabling the patients to secure comprehension (e.g., indicating comprehension problems or requesting support for establishing comprehension). Herrmann and colleagues concluded that patients with global aphasia rely most heavily on nonverbal communication.

Marshall and colleagues (1997) also investigated the efficiency of different communication strategies used by three patients with severe aphasia: A patient with Broca's aphasia communicated primarily through writing and drawing; a patient with Wernicke's aphasia communicated primarily through speaking; and a patient with global aphasia and apraxia of speech communicated primarily through gesturing with a few single words. Marshall and colleagues assessed each patient's communicative efficiency and the degree of communicative burden assumed by a partner during a declarative message exchange task that was evaluated using a visual analogue scale. The investigators also analyzed the effects of context and shared knowledge on efficiency in communicative interactions by varying the extent of the raters' awareness of the message contents (e.g., no knowledge or partial or full knowledge). Their results demonstrated that the efficiency of communication by the patient with global aphasia approximated that of the most efficient patient (i.e., the patient with Broca's aphasia). Also, the burden imposed by his gestural strategy was nearly as low as the writing and drawing of the patient with Broca's aphasia. These findings support the effectiveness of the nonverbal strategies used by patients with global aphasia and further reinforce their training as a target of rehabilitation.

Affect

Depression following aphasia has been "underrecognized and undertreated" (Masand & Chaudhary, 1994). Masand

and Chaudhary suggest this might be the result of heavy reliance on verbal responses for establishing a diagnosis of depression. Also, patients with global aphasia tend to be excluded from treatment studies because of their severe comprehension deficits. In a case report of a patient with chronic global aphasia hospitalized for deteriorating mental status, these authors describe positive benefits from administration of the psychostimulant methylphenidate for treatment of his major depression. From a pre-treatment state characterized by drowsiness and lethargy, sad affect, and an inability to participate in his care, the patient improved within 72 hours of achieving a therapeutic dose (15 mg/day) to become more alert, smiling, attentive, and actively involved in his care. These changes resulted in his improved candidacy for rehabilitation, and on referral, he reportedly made significant gains in speech-language treatment that included producing single words, following simple commands, and imitating gestures. Discontinuation of his medications, including the methylphenidate, secondary to two generalized tonic-clonic seizures resulted in a return to his previous apathetic state within a week.

ETIOLOGY

As described, the majority of lesions producing global aphasia are extensive and involve both pre- and postrolandic areas. The blood supply for these areas is via the middle cerebral artery, which is the largest branch of the internal carotid artery, branching at the point of the sylvian fissure. Because of the extent of the lesion, global aphasia most commonly results from a cerebrovascular event, the locus of which is in the middle cerebral artery at a level inferior to the point of branching. When accompanied by hemiplegia, the event causing global aphasia tends to be thrombotic more than embolic (Collins, 1986). The stroke mechanism causing global aphasia without hemiparesis, however, is heterogeneous (Bang et al., 2004; Hanlon, Lux, & Dromerick, 1999). Greater late recovery may be associated with large hemorrhages (Alexander, 2000).

Not all occurrences of global aphasia are the result of a cerebrovascular event in the middle cerebral artery. Interestingly, Wells, Labar, and Solomon (1992) reported a temporary case of global aphasia because of simple partial status epilepticus. The aphasia lasted during a period in which periodic lateralized epileptiform discharges occur. Wells and colleagues reported that the patient's language returned to near normal during the 24 hours following the seizures. A case of rapidly developing global aphasia and personality change in a young woman secondary to demyelinating disease also is described in the case records of the Massachusetts General Hospital (Anonymous, 1996). An MRI scan of the brain with gadolinium showed multiple enhancing white matter lesions predominating in the subcortical and periventricular white matter, the posterior limb

of the left internal capsule, and the corona radiata and centrum semiovale bilaterally. Treatment with corticosteroids resulted in minimal improvements; administration of cyclophosphamide, an anti-inflammatory/immunologic agent, produced steady improvement. No other information was provided regarding her speech-language outcome. Katz, Shetty, Gobin, and Segal (2003) reported a case of transient global aphasia resulting from a giant dural arteriovenous fistula of the superior sagittal sinus that resolved after fistula embolization. Global aphasia also was reported following a ruptured anterior communicating artery aneurysm and vasospasm (Sugiu, Katsumata, Ono, Tamiya, & Ohmoto, 2003). His symptoms improved following endovascular treatment of the aneurysm.

RECOVERY

The outlook for recovery from global aphasia tends to be bleak. For this reason, the term “global aphasia” may be more prognostic than descriptive (Peach, 2004). Kertesz and McCabe (1977) reported that the group of subjects with global aphasia in their study generally demonstrated limited language recovery, a pattern similar to that reported by Wapner and Gardner (1979). When assessing the language recovery that does occur, better improvement is demonstrated in comprehension than in expression (Lomas & Kertesz, 1978; Prins, Snow, & Wagenaar, 1978). With regard to recovery of nonverbal cognitive abilities, Kertesz and McCabe (1975) found a precipitous and parallel rate of improvement for RCPM and language performance during the first 3 months post-onset. During the next 3 months, performance on the RCPM continued to increase substantially, surpassing language performance that was only mildly improved from levels attained at the end of the first 3 months. Patients appeared to reach a plateau in both RCPM and language performance during the period between 6 and 12 months post-onset. Overall, performance on the RCPM by the patients with global aphasia did not exceed approximately 50% of the maximum attainable score.

In relation to the recovery observed in other types of aphasia, Kertesz and McCabe (1977) described patients with global aphasia as having the lowest recovery rate. With regard to the temporal aspects of recovery in global aphasia, differences have been reported depending on whether the subjects were receiving speech and language treatment. For patients with global aphasia not receiving treatment, improvement appears to be greatest during the first months post-onset (Kertesz & McCabe, 1977; Pashek & Holland, 1988). Siirtola and Siirtola (1984) observed the greatest improvement in their untreated subjects during the first 6 months post onset.

Patients with global aphasia receiving treatment, however, demonstrate substantial improvements during the first 3 to 6 months but also continued improvement during the

period between 6 and 12 months or more post-onset (Kertesz & McCabe, 1977; Nicholas et al., 1993; Sarno & Levita, 1979, 1981). In the study by Kertesz and McCabe (1977), significantly greater improvement was noted in treated versus untreated patients with global aphasia during this period, although the authors attributed this gain at least partially to subject heterogeneity. In the studies by Sarno and Levita (1979, 1981), improvement was most accelerated between 6 and 12 months poststroke. Nicholas and colleagues (1993) found different patterns of recovery for language and non-language skills following longitudinal administration of the Boston Assessment of Severe Aphasia (Helm-Estabrooks, Ramsberger, Morgan, & Nicholas, 1989), or BASA, an instrument developed specifically to evaluate communication performance in patients with severe aphasia. Substantial improvements in praxis and oral-gestural expression were noted only during the first 6 months post-onset, whereas similar improvements in auditory and reading comprehension were observed only between 6 and 12 months post-onset. Based on these findings, the authors stressed the need for analyzing subsets of communication skills rather than overall scores to evaluate recovery from global aphasia.

Evolution

The majority of patients with global aphasia will not recover to less severe forms of the disorder. Some patients, however, will improve to the extent that they evolve into other aphasic syndromes. A number of studies have documented these changes using a variety of assessment instruments and testing schedules.

Six studies used the Western Aphasia Battery (Kertesz, 1982), or WAB, to assess language performance during the acute period of recovery and at regular intervals for up to 1 year (or more) post-onset. Kertesz and McCabe (1977) tested 93 subjects with aphasia between 0 and 6 weeks post-onset and found that 5 of their 22 subjects with global aphasia progressed to other syndromes, including Broca's, transcortical motor, conduction, and anomic aphasia after 1 year or more. Siirtola and Siirtola (1984) classified subjects with aphasia within the first 2 weeks after hospitalization. At 1 year post-onset, 6 from among 14 subjects with global aphasia had evolved to other syndromes, including Broca's, conduction, anomic, and Wernicke's aphasia, or, in the case of one subject, had recovered completely. For 1 year, Holland, Swindell, and Forbes (1985) followed 15 patients who had been classified as having global aphasia immediately after stroke. In this study, classifications were based on results obtained from the WAB as well as from clinical impressions. Several patterns were observed at the end of the first year: Two patients (in their 30s) returned to normal language functioning, two (in their 40s) evolved to Broca's aphasia, two (59 and 61 years of age) evolved to anomic

aphasia, two (in their 70s) evolved to Wernicke's aphasia, and two (in their 80s) remained global aphasic. The five remaining subjects died during the course of the study. Pashek and Holland (1988) described the evolution of 11 subjects with global aphasia from among a larger group of 32 subjects who were followed for at least 6 months. Language performance was assessed by repeated administration of the WAB, these subjects with aphasia were classified on the basis of descriptive criteria rather than WAB typology. All subjects were evaluated within the first 5 days after stroke. Four of these patients evolved to less severe syndromes, including Broca's, Wernicke's, and anomic aphasia. Two patients evolved to a less severe but unclassifiable aphasic syndrome. One subject recovered normal language, and two subjects demonstrated symptoms of dementia. Mark, Thomas, and Berndt (1992) reported the 1-year outcomes of 13 patients initially classified as having global aphasia at 7 to 10 days post-onset. One patient was no longer aphasic, whereas seven patients recovered to a less severe form of aphasia. Among the latter, two patients recovered to Wernicke's aphasia, two recovered to conduction aphasia, and three recovered to anomic, Broca's, and transcortical motor aphasia, respectively. Finally, 9 of 13 patients with global aphasia followed by McDermott, Horner, and DeLong (1996) evolved to other forms of aphasia. Seven of these patients evolved to Broca's aphasia, and two evolved to Wernicke's aphasia.

Nicholas and colleagues (1993) assessed 17 patients with global aphasia as well as seven other patients with severe aphasia for 2 years after the onset of their aphasia to describe the patterns of recovery. Patients were scheduled for testing with the BASA at 1 to 2 months after the onset of their aphasia and at every 6-month anniversary of their strokes thereafter up to 24 months. Of the patients with global aphasia initially, four changed classification during this period, and the remaining 13 continued to be classified as having global aphasia. For the patients who did evolve, one changed to a mild Wernicke's aphasia and changed to mixed nonfluent aphasia.

Sarno and Levita (1979) investigated recovery from global aphasia using selected subtests of the Neurosensory Center Comprehensive Examination for Aphasia (Spreen & Benton, 1977) and the Functional Communication Profile (Sarno, 1969), or FCP. Classification of aphasia was based on clinical impressions as well as language test scores. In the study by Sarno and Levita (1979), the earliest language observations were collected at 4-weeks post-onset, with a variation of no greater than plus or minus 1 week. Repeated testing was continued until 1 year after the stroke. In contrast to the above studies, none of these 14 subjects with global aphasia evolved to another type of aphasia by the end of the year. Similar results were observed in a follow-up study of seven subjects with global aphasia (Sarno & Levita, 1981).

Laska, Hellblom, Murray, Kahan, and Von Arbin (2001) studied the natural course of aphasia during the acute phase and at 3, 6, and 18 months after stroke onset in 119 consecutive, unselected patients. The median time for acute testing was 5 days (range, 0–30 days); 90% of all patients were tested within 11 days. Clinical tests included the "Grunntest for aphasi" (Reinvang, 1985, as cited in Laska et al., 2001), a test that the authors described as being similar to the WAB; the Amsterdam-Nijmegen-Everyday-Language-Test, or ANELT, which is a measure of functional verbal communication; and the Token Test. A subjective ranking of aphasia severity also was obtained. Recovery was determined by the degree of change in ANELT scores. A vast majority of the patients had either global, Wernicke's, or conduction aphasia. Improvements were observed in all types of aphasia, including global aphasia. A positive correlation was found for initial severity and degree of recovery. Of six patients who were diagnosed initially with global aphasia and were available at least three times during 18 months, four evolved to mixed nonfluent aphasia, one to conduction aphasia, and one to mixed fluent aphasia (the category of mixed aphasias on the Reinvang test includes the presence of two or more aphasic syndromes).

One apparent explanation for the discrepancies among these studies might be the greater instability of language scores and, therefore, aphasia classifications obtained during the first 4 weeks after stroke versus those obtained after the first month post-onset. McDermott and colleagues (1996) found greater magnitude-of-change scores and frequencies of aphasia type evolution in subjects tested during the first 30 days post-onset versus those tested during the second 30 days post-onset. Aphasia tends to be more severe during the acute stage, giving observers an initial impression of global aphasia. This symptomatology may be fleeting, however, and result in a seemingly greater potential for patients to evolve to a less severe aphasic syndrome following this early period (Table 21–1).

Holland and colleagues (1985) as well as Pashek and Holland (1988), however, found that patients with global aphasia who do progress to some other form of aphasia demonstrate changes that extend into the first months post-onset. In some cases, the global aphasia may not begin to evolve until after the first month has passed. In addition, Reinvang and Engvik (1980) initially assessed their subjects with aphasia between 2 and 5 months after their injuries (mean, 3 months) and found that four of the seven subjects with global aphasia had evolved to a less severe Broca's, conduction, or unclassifiable syndrome at retesting. The retesting was completed no sooner than 1 month after initial testing, with a mean time of 7.5 months after injury and a range of 3 to 30 months. Based on these findings, the discrepancies in recovery from global aphasia reported in these studies do not appear to be the result simply of the time at which the initial language observations were recorded. Apparently,

TABLE 21-1

Proportion of Subjects with Global Aphasia Evolving to Less Severe Aphasic Syndromes or Normal Language with Time of Initial Testing after Cerebral Injury

Study	Subjects (<i>n</i>)	Initial Testing	% Evolved ^a
Holland, Swindell, & Forbes (1985)	10	Immediately	80
Pashek & Holland (1988)	11	0–5 days	64
Laska, Hellblom, Murray, Kahan, & Von Arbin (2001)	6	0–30 days	100
Mark, Thomas, & Berndt (1992)	13	7–10 days	62
Siirtola & Siirtola (1984)	14	0–2 weeks	43
Kertesz & McCabe (1977)	22	0–6 weeks	23
McDermott, Horner, & DeLong (1996)	13	0–6 weeks	69
Sarno & Levita (1979)	11	4 weeks	0
Sarno & Levita (1981)	7	4 weeks	0
Nicholas, Helm-Estabrooks, Ward-Loneragan, & Morgan (1993)	17	1–2 months	24
Reinvang & Engvik (1980)	7	2–5 months	57

^aEnd-stage assessments were completed between 6 to 12 months post-injury in all studies except Kertesz & McCabe (1977), Reinvang & Engvik (1980), Nicholas et al. (1993), McDermott and colleagues (1996), and Laska and colleagues (2001). Only 10 of the subjects with global aphasia studied by Kertesz and McCabe (1977) were assessed at 1 year or more post-onset. Specific data for the subjects with global aphasia of Reinvang & Engvik (1980) were not reported; the mean time post-onset for the end-stage observations of all subjects with aphasia in their study was 7.5 months, with a minimum time of 3 months post-onset. Fifteen of the 17 subjects with global aphasia followed by Nicholas and colleagues (1993) were assessed at 24 months post-onset; final testing for the remaining two subjects was completed at 18 months post-onset. Re-evaluation for the 13 subjects with global aphasia tested by McDermott and colleagues (1996) occurred approximately between 1 and 6 months post-onset, with a minimum intervening period of at least 30 days. The patients of Laska and colleagues (2001) received follow-up at 18 months post-onset of their aphasia.

evolution from global aphasia is the result of a complex interaction among a number of heretofore incompletely understood factors.

Prognostic Factors

Age

Following global aphasia, a patient's age appears to have an impact on recovery: The younger the patient, the better the prognosis (Holland et al., 1985; Pashek & Holland, 1988). Age also may relate to the type of aphasia at 1 year post-stroke. For example, in the study reported by Holland and colleagues (1985), younger patients with global aphasia evolved to a nonfluent Broca's aphasia, whereas older patients evolved to increasingly severe fluent aphasias with advancing age. The oldest patients remained global aphasic (see above).

Whether age can be considered a prognostic indicator has yielded differing conclusions. Advanced age has been found to have a negative influence on recovery (Holland & Bartlett, 1985; Holland, Greenhouse, Fromm, & Swindell, 1989; Marshall & Phillips, 1971; Sasanuma, 1988) and to be an insignificant predictor of recovery (Hartman, 1981; Kertesz & McCabe, 1977; Sarno, 1981; Sarno & Levita, 1971). Pashek and Holland (1988) noted specifically that age appeared to predict a poor prognosis for change in global aphasia but also identified a number of exceptions to this rule. Thus, age cannot be considered an absolute predictor.

The variability in evolution patterns and age effects identified by these authors is intriguing and suggests the need for further large-scale research studies in this area.

Hemiplegia

Occasionally, global aphasia occurs without an accompanying hemiparesis (Bogousslavsky, 1988; Ferro, 1983; Van Horn & Hawes, 1982). Motor abilities may be preserved following dual discrete lesions occurring in the frontal and temporoparietal regions, a single frontotemporoparietal lesion, or a single temporoparietal lesion. Absence of a hemiparesis in global aphasia may be a positive indicator for recovery (Legatt, Rubin, Kaplan, Healton, & Brust, 1987; Tranel, Biller, Damasio, Adams, & Cornell, 1987). Tranel and colleagues (1987) described patients with global aphasia with dual discrete lesions (anterior and posterior cerebral) that spared the primary motor area. The global aphasia of these patients improved significantly within the first 10 months post-onset. Deleval, Leonard, Mavrouidakis, and Rodesch (1989) reported two cases of global aphasia without hemiparesis following discrete prerolandic lesions. Although both of these patients exhibited mild right arm weakness initially, this motor disturbance cleared within 48 hours of onset. The patients reported by Deleval and colleagues (1989) showed rapid recovery yet continued to exhibit what the authors referred to as a residual motor aphasia. The patient described by Basso and Farabola (1997) experienced global aphasia and a right hemiparesis that

cleared within a few days following a single, left frontotemporal lesion. Although severely aphasic at the initiation of treatment 40 days post-onset, the patient's language outcome 2.5 years later was described as "outstanding." Nagaratnam and colleagues (1996) examined language recovery at 3 months poststroke in 12 patients diagnosed with global aphasia without hemiparesis 4 to 8 days post-onset. Eight patients with single lesions in either anterior language cortex or posterior language cortex recovered to no more than mild levels of impairment. Four patients with lesions in both anterior and posterior language areas continued to have severe language impairments.

Global aphasia without hemiparesis does not necessarily result in extensive language recovery. Keyserlingk and colleagues (1997) found that chronic patients with global aphasia and no history of hemiparesis secondary to a single, large lesion of the left perisylvian region did not fare any better with regard to language outcome than did their counterparts with global aphasia and hemiparesis from the time of onset. The critical difference between the two groups for motor, but not language, function depended on the degree to which the patients' lesions extended into the subcortical white matter and nuclei. Eight of the 11 patients studied by Bang and colleagues (2004) showed minimal improvement 8 weeks after stroke onset. Three patients demonstrated the classical pattern of dual lesions in the left inferior frontal gyrus and the superior temporal gyrus, five patients exhibited single lesions of either the left inferior frontal gyrus or the superior temporal gyrus, and three patients had a subcortical or cortical lesion outside the perisylvian area. Language recovery could not be predicted by lesion location.

Hanlon, Brown, and Gerstman (1999) found three distinct subtypes of global aphasia in 10 patients without hemiparesis. The subtypes were associated with different patterns of language outcome 10 to 12 weeks after their strokes. The auditory-verbal subtest scores and the aphasia quotient (AQ) from the WAB were entered into a cluster analysis to define the groups. Lesion patterns also were identified. Four patients with a mean AQ of 2.3 comprised cluster 1; these were the most severely impaired patients and were characterized by dense, nonfluent speech with severe initiation deficits, marked comprehension impairment, no repetition, and grossly defective naming. Their lesions primarily involved the left superior temporal gyrus. Patients in this cluster showed minimal or no change in language scores at follow-up and remained globally aphasic. Cluster 2 consisted of two patients with a mean AQ of 34.9 who were characterized by dense, nonfluent spontaneous speech; moderate comprehension impairment; minimal capacity for naming monosyllabic, high-frequency nouns; and limited repetition. The left inferior frontal gyrus and adjacent subcortical white matter, primarily involving the territory of the precentral, central, lenticulostriate, and insular branches of the middle cerebral artery, were lesioned. These patients

recovered to a pattern most like transcortical motor aphasia, with relative preservation of repetition and improved comprehension and naming. Cluster 3 included four patients with a mean AQ of 13.9. These patients demonstrated low-level, dysfluent speech; marked comprehension impairment; minimal or no repetition; and severely defective naming characterized by perseverative monosyllabic utterances. Lesioning of the left pre- and postcentral gyri involving the central and posterior parietal vascular territories was found. At follow-up, increased speech fluency and improved comprehension were observed, accompanied by inconsistent changes in repetition and naming. All members of this group evolved to a pattern of Wernicke's aphasia. Degree of recovery was related to group subtype.

Neuroimaging Patterns

Both CT and functional MRI (fMRI) have been used to estimate outcome from global aphasia. In a two-part study, Pieniadz, Naeser, Koff, and Levine (1983) investigated the relationship between hemispheric asymmetries and recovery from aphasia. The first part of the study involved the analysis of hemispheric asymmetry in a large group of subjects with aphasia and in a group of control subjects without aphasia. The results demonstrated significant similarity and consistency in hemispheric asymmetry for both groups. The most frequent asymmetry involved left-greater-than-right occipital width. Frontal width was greater in the right hemisphere than in the left hemisphere. Length also was greater in the left occipital region. For frontal length, the hemispheres were typically equal.

In the second part of the study by Pieniadz and colleagues (1983), recovery patterns were examined in a group of subjects with global aphasia. These researchers found larger right occipital widths and lengths on CT scans for subjects demonstrating superior recovery of single-word comprehension, repetition, and naming. Pieniadz and colleagues suggested that these atypical asymmetries may indicate right hemisphere dominance for language. Evaluation of hemispheric asymmetries may be used, therefore, to predict recovery of single-word functions, with atypical patterns suggesting superior long-term gains.

Naeser, Gaddie, Palumbo, and Stiassny-Eder (1990) used CT to compare lesion location and language recovery in a group of subjects with global aphasia. The primary foci in their study were recovery of comprehension abilities and differentiation between temporal lobe lesions involving Wernicke's area and those restricted to the subcortical temporal isthmus. The subjects had either frontal, parietal, and temporal lobe lesions or lesions involving the frontal and parietal lobes with temporal lobe lesions restricted to the subcortical temporal isthmus. The results of this study showed significantly better recovery of auditory comprehension for the group without damage to Wernicke's area

(lesions limited to subcortical temporal isthmus). Over the course of 1 to 2 years, the majority of these subjects reportedly obtained auditory comprehension scores on the BDAE (Goodglass & Kaplan, 1983) that were consistent with only mild to moderate comprehension deficits (Naeser et al., 1990). None of the subjects in this study made significant gains in speech output.

A group of patients with severe global aphasia and extreme loss of both verbal and nonverbal communication (including comprehension) was studied by De Renzi, Colombo, and Scarpa (1991). These authors found a variety of lesion patterns, only 35% of which involved the entire language area. Attempts to correlate specific types of lesions with some recovery of language abilities were unsuccessful. For the patients who showed some comprehension improvement, no common lesion pattern was found.

Mark and colleagues (1992) evaluated CT scans of patients with global aphasia in a routine acute-care setting to assess their viability of such scans for predicting language performance at 1-year post-onset. The scans were measured for lesion volume, total occipital asymmetry, and the cerebral volume occupied by the lateral ventricles and correlated with WAB (Kertesz, 1982) AQ and auditory comprehension scores. No clear relationship was found between acute imaging of the patients' lesions and their aphasia outcomes.

Zahn and colleagues (2004) used fMRI to investigate the underlying mechanism for recovery of auditory comprehension following global aphasia. Seven patients with large lesions following left middle cerebral artery infarction were identified using the Aachen Aphasia Test or the Aachen Aphasia Bedside Test during the acute or subacute stages of their illnesses. Different degrees of auditory comprehension recovery were demonstrated among these patients at follow-up 6 to 12 months later. A functional activation paradigm was used that allowed differentiation of anatomical patterns associated with processing of auditory word form versus meaning. When compared to normal subjects, no differences were observed in the patients having global aphasia with regard to the lateralization or the general regions of activations. The left extrasylvian temporal cortex and right posterior parietal cortex were the most consistently activated regions. The extrasylvian temporal activations were thought to represent correlates of recovery of lexical-semantic processing. The authors concluded that comprehension recovery occurs via functional compensation by spared parts of the partially damaged semantic word processing system (redundancy recovery). The results did not support other mechanisms for recovery that have been proposed, such as reactivation of functionally connected areas, substitution of previously nonactive areas, or transfer of function to right hemisphere homologues. Right hemisphere contributions, however, may be substantial for lexical-semantic processing of words presented visually, particularly when phonologic processing is severely impaired (Gold & Kertesz, 2000).

Language Scores

Collins (1986) has used scores obtained from patients with global aphasia on the Porch Index of Communicative Ability (Porch, 1981), or PICA, to predict recovery. According to Collins (1986), patients with global aphasia invariably obtain scores below the 25th percentile. High intra- and intersubtest variability, however, suggest at least the potential for recovery. Variability in this instance is defined as the difference between the mean score for a PICA subtest and the highest score within that subtest. A total variability score is derived by adding the variability scores for all PICA subtests. Variability scores of greater than 400 suggest excellent potential for recovery, whereas scores of less than 200 suggest poor potential for recovery.

Using medical and PICA data, Collins (1986) suggests that patients with global aphasia demonstrating some variability within subtests and variability scores of around 100, but relatively flat scores across all modalities, have a poor prognosis for recovery. Imitation, copying, and matching may be better than other test behaviors. Patients with variability scores of much greater than 100 and with greater divergence among modality scores have a fair prognosis for recovery. Performance generally is characterized by mostly correct object matching, good copying skills, the ability to name one or two of the objects, and production of some differentiated responses on the verbal subtests. Significant increases in overall variability relative to the previous two categories and occasionally higher scores (seven or above) on auditory comprehension, reading, and naming subtests are consistent with a good prognosis for recovery. One patient described by Collins (1986) achieved a variability score of greater than 400 while still performing at the 9th percentile.

The recommendations of Collins should be tempered by subsequent work. Wertz, Dronkers, and Hume (1993) tested the influence of PICA intrasubtest variability on prognosis for improvement in aphasia. Negative and nonsignificant correlations were obtained between variability scores at 1 month post-onset and improvement in PICA overall performance at 6 and 12 months post-onset. In addition, no significant differences in improvement were found at 6 and 12 months post-onset between two groups with high variability (score greater than 350) and low variability (score less than 300) at 1 month post-onset. Wertz and colleagues concluded that intrasubtest variability has no influence on prognosis. For other measures of aphasia, it generally appears that a lack of variability between auditory comprehension scores and other language scores may be viewed as a negative indicator. The more performance differs among tasks, the better the outlook. Further, higher test scores (i.e., less severe impairment) are consistent with a better prognosis. Within auditory comprehension scores, patients with global aphasia who provide yes/no responses to simple questions, regardless of their accuracy, seem to have a better outcome

at 1 year post-onset compared with those who cannot grasp the yes/no format (Mark et al., 1992).

INTERVENTION

Before discussing clinical intervention for global aphasia, a few introductory remarks are provided in support of the management strategies that follow. The issues addressed here include some influences regarding the timing of intervention for global aphasia, the nature of the language assessment, and the behavioral targets of treatment.

Influences Regarding the Timing of Intervention

As described previously, the prognosis for recovery from global aphasia generally is poor (Kertesz & McCabe, 1977). Nonetheless, approximately one-fourth to three-fourths or more of these patients with global aphasia will recover to a less severe aphasia or even to a normal condition by the end of the first year after their stroke. Do these findings argue against early intervention for global aphasia? Should practitioners withhold assessment and treatment for these patients until a stable language profile is achieved? Clinicians have opposed withholding early treatment (Collins, 1986; Peach, 2001), and a number of reasons exist to continue to do so.

Prognostic Limitations

Primary among the reasons for advocating early intervention is the inability to identify accurately those patients with global aphasia who will evolve to less severe syndromes and those who will not. Even if it could be established that withholding early treatment from patients who have a high or low probability for good recovery is an acceptable clinical practice, current methodologies prevent clinicians from accurately identifying the recovery potential for these patients to make such decisions. Global aphasia cannot be reliably discriminated in the early stage (Wallesch, Bak, & Schulte-Monting, 1992), and any general conclusions about recovery in individual patients are “premature” (Basso & Farabola, 1997). Conflicting findings with regard to many of the factors identified above continue to present problems for estimating clinical prognosis.

Information derived from technologic applications may assist with this problem. In one study, the potential for recovery of auditory comprehension following global aphasia was estimated by examining the lesion site patterns on CT scans for these patients. As described earlier, better recovery was predicted at 1 to 2 years post-onset in patients whose temporal lesions spared Wernicke’s area and involved only the subcortical temporal isthmus. Patients with temporal lesions that included more than half of Wernicke’s cortical area, however, were expected to demonstrate moderate to severe comprehension deficits at 1 to 2 years after their injuries

(Naeser et al., 1990). Recent evidence derived from fMRI studies of patients initially diagnosed with global aphasia has demonstrated that activation of regions associated with lexical-semantic processing in normal subjects (left extratemporal and right posterior parietal cortex) is associated with good recovery of auditory comprehension at 6 months or greater following global aphasia (Zahn et al., 2004).

Recovery of spontaneous speech in severely nonfluent patients with stroke and left middle cerebral artery infarction can be estimated from the extent of lesion in two subcortical white matter areas: the medial subcallosal fasciculus (initiation of spontaneous speech), and the middle third of the periventricular white matter (motor/sensory aspects of spontaneous speech) (Naeser, Palumbo, Helm-Estabrooks, Stiassny-Eder, & Albert, 1989). For patients with lesions outside the left middle cerebral artery, Naeser and colleagues (1989) suggest examining other specific structures as well (e.g., supplementary motor area and cingulate gyrus).

These findings provide a promising approach to prognosis for global aphasia, but their application appears to warrant discretion on several accounts when making decisions regarding early intervention for global aphasia. For example, the findings of Naeser and colleagues (1989) are limited, because many of the patients in their most severe subject groups were not global aphasic. In addition, exceptions to expected patterns of recovery exist even in patients who meet the suggested neuroanatomical profiles (Naeser et al., 1989). Finally, the lack of clear patterns on CT scans that could be associated with recovery from global aphasia in other studies (De Renzi et al., 1991; Mark et al., 1992) suggests that these approaches are in need of further data before they can be applied rigorously.

Besides CT, a patient’s levels of alertness or attention at the outset of global aphasia also might be assessed to predict superior recovery. Patients who initially are more alert or have better attention appear to show greater recovery from their global aphasia (Kertesz & McCabe 1977; Sarno & Levita, 1981). Because the evidence for these latter findings is primarily anecdotal, however, its application as a clinical guideline is tenuous until additional information becomes available. These observations, along with differing profiles in the evolution of global aphasia, underscore the fact that patients with global aphasia are a heterogeneous group. It is evident that research is needed to identify the particular factors and the way that they interact to account for better recovery. Clinicians might then more accurately identify the subgroups of patients with global aphasia who will demonstrate substantial language recovery and those who will not. This information can then be applied in management decisions regarding treatment (Ferro, 1992; Sarno, Silverman & Sands, 1970).

In the absence of accurate techniques for predicting recovery from global aphasia, the most powerful reasons for providing early treatment are (1) the latent recovery

observed in those patients who receive acute speech and language treatment and (2) the greater effects generally observed in patients with aphasia when treated during the acute period of recovery. As a group, patients with global aphasia receiving early treatment show continued language improvement during the period between 6 and 12 months post-onset (Kertesz & McCabe, 1977; Nicholas et al., 1993; Sarno & Levita, 1979, 1981) that is not observed in untreated patients (Pashek & Holland, 1988; Siirtola & Siirtola, 1984). In addition, meta-analyses of the aphasia treatment literature have provided convincing evidence that outcomes for patients with severe aphasia are much greater when treatment is begun immediately after onset rather than during the post-acute period (Robey, 1998). Until more is known about the individual patient with global aphasia, these data suggest that clinicians should continue to intervene at the earliest opportunity to assist these patients at a time when such treatments may be most crucial to long-term recovery.

Treatment Objectives

A second reason for early intervention in global aphasia concerns the purpose of treatment. In deliberating this issue, consider a scenario in which the clinical limitations described above no longer applied in predicting recovery from global aphasia. With full awareness of whether a patient will experience a good versus a minimal recovery, which outcome would suggest the need for early treatment? For patients who are expected to evolve to a less severe aphasia, might treatment be deferred to obtain the more stable language profile that might subserve a more effective long-term management plan, or might treatment be initiated immediately to accelerate the patient's anticipated recovery? For patients who are not expected to demonstrate substantial recovery, might treatment be withheld because of the poor prognosis to allocate clinical and financial resources more effectively, or might these patients become primary candidates for treatment to develop a functional communication system from the outset of their aphasia that will provide the primary means through which they subsequently will communicate? When considering the purpose of treatment in either case, the arguments for early intervention with patients who have global aphasia, no matter their outcome, are more compelling than otherwise. The recovery patterns per se following global aphasia therefore do not provide an adequate rationale for postponing treatment of aphasia for these patients.

Global aphasia will be greatest during the acute phase of recovery. Often, as alluded to above, treatment during this phase focuses on the remediation of language deficits via stimulation of disrupted cognitive processes. Depending on the degree to which the condition renders the patient unable to communicate even the most basic of needs, however, the

first goals of treatment also focus on establishing some means of communication, no matter how simple. Some methods to accomplish this would include establishing reliable yes/no responding or a basic vocabulary of functional items through oral or gestural means, such as head nodding, eye blinking, and pointing to pictures or specific icons. Interestingly, the activities associated with establishing these communication systems may, in and of themselves, be considered stimulatory for language. Clinicians also provide information to family, friends, and health-care staff during this phase regarding the patient's particular language profile (i.e., preserved versus deficient areas), prognosis, and suitable ways to improve communication with the patient. Early intervention in global aphasia therefore has the multiple purposes of language stimulation directed toward cerebral reorganization and recovery, identification of successful communication strategies, and patient, family, and staff counseling. None of these activities can—or should—be deferred until a stable language profile is achieved.

Goal Revisions

Patients with global aphasia do demonstrate varying improvements in linguistic, extralinguistic, and nonverbal communicative functioning (Kenin & Swisher, 1972; Mohr, Sidman, Stoddard, Leicester, & Rosenberger, 1973; Prins, Snow, & Wagenaar, 1978; Sarno & Levita, 1979, 1981; Wapner & Gardner, 1979). As discussed, these improvements may result in recovery to a less severe form of aphasia in some cases, whereas in others, the changes may be insufficient even at 1 year post-onset to suggest reclassification to another form of aphasia (Sarno & Levita, 1979, 1981). For this latter group, improvement can be anticipated in at least one of these categories, especially that of functional communication.

Most, if not all, clinical aphasiologists recognize the dynamic nature of aphasia. Early testing therefore is viewed only as a measure of the patient's language functioning at a single point in time that will be used to establish a baseline for intervention during the acute period. Because of recovery, frequent probes for improvement in treated and untreated behaviors during this early period as well as re-evaluation using formal instruments is not only encouraged, it is expected.

Withholding early treatment while awaiting more stable language profiles to improve treatment planning does not acknowledge that establishing and revising short-term treatment goals are inherent principles of aphasia rehabilitation. Whether treatment is provided before or after the first month post-onset, this process will be repeated regularly throughout the term of the patient's rehabilitation, regardless of the type of aphasia. There is little sense, therefore, in declaring this process to be less valid in global aphasia when treatment is initiated before the first month after injury.

Clinicians have much to offer patients with global aphasia and their families during the acute period of recovery. When patients improve, the treatment objectives reflect this change; when they fail to change, concerted rehabilitative efforts continue in the areas of the patients' greatest functional communicative needs.

Nature of the Assessment

Assessment of individuals with aphasia encompasses more than simple diagnosis. Ideally, assessment provides a profile not only of the patient's areas of weakness but also of his or her strengths. Reasonable treatment plans require both types of data. Formal tests provide one method for gathering such data and, in addition, facilitate discussion of patient findings among colleagues. To that end, Collins (1986, p. 62) provides a summary of the severity ratings for a number of these tests that are suggestive of global aphasia. Sometimes, however, formal tests may be inadequate for treatment planning (Rosenbek et al., 1989), especially in the case of severely impaired patients, such as those with global aphasia. Little can be gained about patients' preserved areas of communicative functioning from scores that are consistently near the floor for a given test. For these patients, information regarding their residual communicative capacities may be more readily available from a variety of informal (i.e., nonstandardized) measures. Such measures consist of patient observation to determine functional communication and the diverse methods for cueing behaviors that, when logically varied, allow a practical test of approaches that result in the most favorable responses. Methods that are successful in eliciting target behaviors are incorporated into treatment and provide an initial approach for developing subsequent behaviors.

Contemporary approaches include both formal and informal measures of assessment to establish a communication profile for the patient with global aphasia. From a practical point of view, initial contact with the patient should be preceded by a review of medical records and interviews with knowledgeable others to glean information about the patient's communicative status. To the degree possible, a formal language assessment should be completed using a standardized aphasia battery, sampling behaviors across tasks at least minimally in each language domain (i.e., speaking, listening, reading, and writing), and describing the patient's responses to each item. Given this baseline, assessment continues through what might be viewed as diagnostic treatment to identify the conditions that further promote successful language performance. Included here would be an analysis of patient responses during interviews focusing on familiar topics or in selected situations and the evaluation of hierarchical cues within language tasks.

In this "qualitative" approach, as described by Helm-Estabrooks (1986), neither type of language assessment (for-

mal or informal) is seen as simply augmenting the other. For the patient with global aphasia, both types are deemed mandatory for adequately describing communication functioning. A host of procedures are available to accomplish these objectives. These will be reviewed in the following sections.

Behavioral Targets for Treatment

Because the impairment in aphasia is, first and foremost, a linguistic one, the primary target for treatment traditionally has been that of language performance. As a result, the success of intervention most often has been evaluated by the extent of changes occurring exclusively in the patient with aphasia's grammatical and lexical behaviors. In such an approach, the potential for these changes is diminished with increases in the initial severity of the language impairment. Too often, this approach has resulted in underestimation of what has been accomplished regarding recovery of communication skills.

Nowhere might this problem be more prevalent than in the case of the patient with global aphasia. From the time that Sarno and colleagues (1970) suggested that patients with stroke and severe aphasia do not benefit from speech and language treatment, many health-care providers have taken a rather pessimistic view with regard to rehabilitation outcomes in this group of patients. The conclusions of Sarno and colleagues, however, and of others like them, were based solely on statistical comparisons of pre- and post-treatment language scores and failed to account for positive changes that may have occurred in other communication behaviors. In a subsequent study involving patients with global aphasia, Sarno and Levita (1981) examined the changes occurring not only in language scores but also in communication performance as assessed by the FCP. Clinically significant improvements in the patients' language scores were observed that, nonetheless, were insufficient to warrant reclassification to another aphasic syndrome. Inspection of nonverbal communication abilities revealed recovery of alternate skills (e.g., gesture, pantomime, and other extralinguistic behaviors) that exceeded the reported language changes. According to Sarno and Levita (1981), these improvements resulted in limited but effective communication by the end of the first year after stroke. Nicholas and colleagues (1993) also found significant improvements in the communication skills of their patients with global aphasia during the first year poststroke, even though the majority of those patients did not change classification.

These findings have given way in many instances to social approaches that exploit the residual language capacity and/or other functional abilities of these patients as well as the skills of conversation partners to improve communication and the patient's quality of life. Clinicians no longer

attend exclusively to improving propositional speech in patients with global aphasia during or after the acute period of recovery. Such an emphasis is apparent in many of the treatment methods that have been developed recently for such patients.

ASSESSMENT

Assessment of communication functioning in patients with global aphasia is best achieved using both formal and informal measures. These measures are summarized in Table 21-2.

Formal Test Measures

General Language

The language features of global aphasia were described in a previous section. Some standardized aphasia test batteries that specifically address global aphasia in their classification schemes include Aphasia Diagnostic Profiles (Helm-Estabrooks, 1992), the BDAE (Goodglass, Kaplan, & Barresi, 2001), the Language Modalities Test for Aphasia (Wepman & Jones, 1961), the Minnesota Test for Differential Diagnosis of Aphasia (irreversible aphasia syndrome) (Schuell, 1974), the Sklar Aphasia Scale (Sklar, 1983), and the WAB (Kertesz, 1982). Additional batteries that comprehensively assess language performance to provide the clinical data for establishing a diagnosis of global aphasia include the Aphasia Language Performance Scales (Keenan & Brassell, 1975), Examining for Aphasia-Third Edition (Eisenenson, 1994), the Neurosensory Center Comprehensive Examination for Aphasia (Spreeen & Benton, 1977), the PICA (Porch, 1981), and Psycholinguistic Assessments of Language Processing in Aphasia (Kay, Lesser, & Coltheart, 1992). For Spanish speakers, the Multilingual Aphasia Examination-Spanish (Rey, Sivan, & Benton, 1991) can be used. The performance pattern for patients with global aphasia on any of the tests identified above generally is one of severe impairment in all language abilities.

Some modality-specific assessment instruments also might be appropriate in the evaluation of patients with global aphasia. These tests include the following: for auditory comprehension, the Token Test (De Renzi & Vignolo, 1962), the Auditory Comprehension Test for Sentences (Shewan, 1979; Shewan & Canter, 1971), the Revised Token Test (McNeil & Prescott, 1978), and the Functional Auditory Comprehension Task (LaPointe & Horner, 1978; LaPointe, Holtzapple, & Graham, 1985); for reading comprehension, the Reading Comprehension Battery for Aphasia-Second Edition (LaPointe & Horner, 1998) and the Gray Oral Reading Tests-Fourth Edition (Wiederholt & Bryant, 2001); and for naming, the Boston Naming Test (Kaplan, Goodglass, & Weintraub, 2001), the Object and

Action Naming Battery (Druks & Masterson, 2000), and the Test of Adolescent/Adult Word Finding (German, 1990).

Unlike the foregoing instruments, the BASA (Helm-Estabrooks, Ramsberger, Morgan, & Nicholas, 1989) was developed "for the specific purpose of identifying and quantifying preserved abilities that might form the beginning

steps of rehabilitation programs for severely aphasic patients” (p. 1). The BASA assesses performance on 61 items in 15 areas: social greetings and simple conversation; personally relevant yes/no question pairs; orientation to time and place; buccofacial praxis; sustained phonation and singing; repetition; limb praxis; comprehension of number symbols; object naming; action picture items; comprehension of coin names; famous faces; emotional words, phrases, and symbols; visuospatial items; and signature. Responses are scored for response modality (verbal, gestural, or both), communicative quality (fully communicative, partially communicative, noncommunicative, unintelligible, irrelevant, incorrect, unreliable, or task refused or rejected), affective quality, and perseveration. Raw scores are summed according to seven clusters of items: auditory comprehension, praxis, oral-gestural expression, reading comprehension, gesture recognition, writing, and visuospatial tasks. Norms are provided to convert the total raw score and item cluster raw scores to standard scores and percentile ranks. “Because an important goal of the BASA is to help determine whether a severe case of aphasia may be classified as global,” (p. 42) two separate sets of norms are provided, one for cases of severe aphasia and one for global aphasia.

Functional Communication

Measures for the formal assessment of functional communication include the FCP (Sarno, 1969); Communication Activities of Daily Living–Second Edition (Holland, Fratalli, & Fromm, 1998), or CADL-2; the American Speech-Language-Hearing Association Functional Assessment of Communication Skills for Adults (Fratalli, Holland, & Thompson, 1995), or ASHA FACS; and the Assessment of Language-Related Functional Activities (Baines, Martin, & Heeringa, 1999), or ALFA. The FCP assesses 45 communication behaviors in a conversational situation that are considered to be common functions of everyday life. Behaviors are rated as normal, good, fair, or poor and are transformed to raw scores within five dimensions: movement, speaking, understanding, reading, and other behaviors. The raw scores are converted to a percentage and a weighted score representing the patient’s performance relative to normal behavior for that dimension. An overall score is obtained by summing the weighted scores to represent the patient’s percentage of normal communication.

The CADL-2 includes 50 items that assess communication skills in structured, simulated daily activities. It includes a series of context-dependent items that evoke a variety of speech acts and verbal interchanges as well as other items that assess functional reading, writing, and math. Responses can be communicated by a variety of verbal and nonverbal means and are scored as correct, adequate, or wrong. The CADL-2 has high inter- and intrarater reliability and includes standard scores and performance norms.

The ASHA FACS contains 43 items that assess functional communication in four areas: social communication; communication of basic needs; reading, writing, and number concepts; and daily planning. A seven-point quantitative scale rates the frequency of behaviors. A five-point qualitative scale rates the adequacy, appropriateness, and promptness of an individual’s responses as well as the relative sharing of communication burden with the partner. The ASHA FACS has been found to be reliable and valid for use with adult aphasia resulting from left hemisphere stroke and adult cognitive communication disorders resulting from traumatic brain injury. It is available in both a paper-and-pencil version and a computerized version.

The ALFA consists of 10 subtests, including telling time, counting money, addressing an envelope, solving daily math problems, writing a check/balancing a checkbook, understanding medicine labels, using a calendar, reading instructions, using the telephone, and writing a phone message. The subtests probe auditory comprehension, verbal expression, reading and writing, as well as cognitive and motor skills. The test yields a raw score for each subtest that is associated with a rating of independent functioning levels for two populations (below and above 65 years of age). The ALFA was standardized on 495 patients between the ages of 20 and 96 years with neurological histories as well as a group of 150 normal adults.

Informal Measures

General Language

As described previously, informal measures of language assessment are conducted following formal assessment with a standardized battery to identify the conditions that further promote successful language performance. Such measures aim to identify isolated areas of preserved performance, such as those listed above as features of comprehension. Hierarchical cues are used to evaluate such residual areas within language tasks.

Salvatore and Thompson (1986) provide an example of informal assessment procedures designed to assess verbal and nonverbal communication systems in patients with global aphasia. The model used in their approach employs one stimulus to evoke a variety of responses. When stimuli are presented to evoke all levels of responding, stimulus-response relations that are preserved and those that are impaired are identifiable. For example, patients may be asked to provide several responses to a pictured stimulus, including matching it to an identical picture and both writing and saying its name. Responses are analyzed in different modes, including gesturing, drawing, reading, writing, and verbalizing. A matrix is developed to categorize the various relations that are tested. The results of the assessment provide important information that provides a basis for treatment.

Edelman (1984) provides an outline for the assessment of comprehension in global aphasia that specifically takes into account research findings identifying areas of residual function in global aphasia and factors that facilitate understanding. The suggested framework permits a systematic evaluation of understanding, both contextually and acontextually, while manipulating variables found to be facilitative. Performance is assessed using commands and questions at simple linguistic levels. Commands are divided into two sections. Those relating to the self involve whole-body movements, limb movements, and orofacial movements, and those relating to objects in the environment are divided into object recognition and object manipulation. These tasks are assessed respectively in a natural verbal context (e.g., "Have you any water?"; "Can you pass the tissues?") and acontextually (e.g., "Show me the comb"; "Pick up the comb"). Questions require affirmation or negation only, and they include those relating to self as well as those of less personal saliency. Responses are accepted when communicated either verbally or nonverbally. In addition, hierarchical cueing, consisting of repetition, utterance expansion, and gestural accompaniment, is incorporated and scored using a modified PICA system.

Functional Communication

A number of informal procedures that can be used to systematically evaluate the functional communication of patients with global aphasia also have appeared in the literature. Holland (1982) developed a procedure to score observations of natural communication in normal family interactions. The categories of behaviors included verbal and nonverbal output, reading, writing, math, and other communicative behaviors, such as talking on the phone and singing. The verbal behaviors were further subcategorized to capture the form, style, conversational dominance, correctional strategies, and metalinguistics of the production. Holland's procedure is "primarily concerned with the frequency and form of successful and failed verbal and nonverbal communicative acts" (p. 52).

Lomas and colleagues (1989) constructed the Communicative Effectiveness Index, or CETI, using communicative situations provided by patients with aphasia and their families that were thought to be important in day-to-day life. The CETI quantitatively assesses the performance of those with aphasia over time in 16 situations using judgments provided by spouses or significant others. Performance is rated relative to the person with aphasia's premorbid abilities using a visual analogue scale. The situations range from getting somebody's attention to describing or discussing something in depth. The index was found to be internally consistent, to have acceptable test-retest and interrater reliability, and to be a valid measure of functional communication when compared with other measures. The authors

conclude that the CETI is an instrument that is capable of measuring the functional changes occurring during the recovery of patients with aphasia that have been difficult to measure previously.

Cunningham, Farrow, Davies, and Lincoln (1995) developed the Assessment of Communicative Effectiveness in Severe Aphasia, or ACESA. It consists of two sections: a structured conversation, and an assessment of the patient's ability to convey information about objects and pictures. Gesture, facial expression, speech, symbolic noise, and intonation are accepted ways for conveying information. Communicative effectiveness is rated using separate scales of recognizability for verbal and nonverbal responses. In an initial study to test the reliability of the instrument, test-retest reliability and intrarater reliability were found to be good. The authors therefore suggested that the tool can be useful for assessing change in communicative effectiveness when it is scored by the same person. Low interrater reliability, however, suggested that the tool needs further modifications before it can be used confidently for other clinical and/or research purposes.

Finally, a less systematic—but often effective—assessment of functional communication can be derived from patient interviews or questionnaires completed by individuals who are familiar with the patient who has global aphasia. Collins (1986) reviews several of these questionnaires and provides one such example, an adaptation of the FCP called the Functional Rating Scale.

TREATMENT

Given the generally poor outcome in chronic global aphasia (Kertesz & McCabe, 1977; Sarno & Levita, 1981) and the negative results that have been reported for treatment programs aimed specifically at remediating verbal skills (Sarno et al., 1970), treatment for these patients may emphasize functional and/or social approaches that attempt to improve participation in communication activities as well as impairment-based approaches that attempt to reduce the severity of the language impairment (Peach, 1993). Functional (patient-oriented) and social (partner-oriented) approaches use strategies that exploit the patient's residual linguistic and non-linguistic cognitive skills to increase successful communication (Herbert, Best, Hickin, Howard, & Osborne, 2003). Impairment-based approaches use structured methods that are carefully controlled for levels of difficulty to provide a context that will facilitate successful language responses and shape succeeding language behaviors of increasing complexity. Functional and social approaches tend to predominate during the chronic phase of the condition, but all approaches may—and should—be used during the course of recovery from global aphasia (Peach, 2001). Table 21-3 provides a summary of these approaches.

Impairment-Based Approaches**Auditory Comprehension**

Collins (1986, 1997) suggests that a realistic goal for treatment with the patient who has global aphasia consists of improving auditory comprehension, supplemented with contextual cues, to permit consistent comprehension of one-step commands in well-controlled situations. For the most severe comprehension deficits, picture matching, accompanied by the clinician's production of the name of the items to be matched, may provide the most basic level of auditory stimulation. Even in those cases when the patient has no understanding of the auditory stimulus accompanying the pictures, the response elicited by the matching task is assumed to evoke auditory representations of the visual stimuli that

may underlie subsequent association of meaning with the name of the pictures (Peach, 1993). Complexity may be increased within this task by (a) increasing the size of the response field; (b) moving from pairing real objects to realistic pictures of objects to line drawings of the objects; (c) matching objects to pictures and pictures to objects, a technique incorporated in Visual Action Therapy (Helm-Estabrooks, Fitzpatrick, & Barresi, 1982); and (d) using sets of pictures that represent nouns with decreasing frequency of occurrence in language usage. As performance improves, these tasks may be followed by word recognition for objects, pictures, or body parts and responding to simple questions.

Marshall (1986) provides an approach to treating auditory comprehension in patients with global aphasia that is presented in four phases: (a) eliciting responses, (b) eliciting differentiated responses, (c) eliciting appropriate responses, and (d) eliciting accurate responses. In the first phase, clinicians focus on attending, pointing, and yes/no responding; at a minimum, the clinician should help patients to express themselves through head nods, smiles, or frowns. Patients who cannot respond to spoken messages may engage in visual matching or orientation tasks. They also may be provided spoken messages accompanied by gestures. Questions and statements about personally relevant topics may comprise one of the best ways to elicit responses during this phase. In the second phase, the materials and techniques to elicit responses are not unlike those used in the first phase. At this time, however, the clinician accepts and reinforces any response that is different from the previous response given for those stimuli (e.g., varied facial expressions, head nods, gestures, and stereotypic utterances). To do this, the clinician records the patient's responses to a standard set of simple questions, looking for a variety of responses both between stimuli and from session to session. With progress, patients will move into the third phase, demonstrating appropriate responses with occasional accurate responses, such as pointing to a calendar when asked to show the date, saying "yes" instead of "no," and shrugging the shoulders when asked how they are feeling. Other appropriate responses consist of performing one command for another or production of jargon in response to a question or request for information. Marshall suggests that, for some patients, appropriate responses may represent their best performance and, therefore, should be encouraged by clinicians and others in the patient's environment. Finally, in the fourth phase, clinicians seek accurate responses to such tasks as object and picture identification, following commands, and responding to yes/no and "wh-" questions. Nonverbal responses may be facilitated with accompanying props, including pages with words and numbers written on them; a clock with movable hands; a calendar; a road atlas; lists of families, relatives, and friends; and a communication notebook.

Collins (1986, 1997) has designed a program to treat auditory comprehension using playing cards. This approach

is based on the observation that patients with global aphasia often can recognize names that contain two salient features (e.g., “queen of hearts”), differentiate cards by suit, and place cards in a sequence when they are unable to perform similarly with other stimuli. Although not all patients achieve the highest levels of performance, Collins suggests that portions of the program are useful at some stage for most patients.

Verbal Expression

Despite conclusions that traditional treatment focused on verbal communication skills may be ineffective for global aphasia (Salvatore & Thompson, 1986; Sarno & Levita, 1981), short-term attempts to establish or expand verbal expression in patients with global aphasia may be a legitimate therapeutic activity during both the acute and chronic phases of recovery (Rosenbek et al., 1989). Rosenbek and colleagues (1989) do this by first attempting to associate meaning with speech movements. To do this, patients use available methods (e.g., showing fingers, pointing, gesturing, writing, matching, and selecting objects) to confirm the meaning of any successfully elicited verbalizations. Included among these may be serial productions, imitated words and phrases, or automatic, meaningful responses to conversations relating to a variety of topics. As described previously, conversational topics that are personally relevant will improve performance (Van Lancker & Klein, 1990; Van Lancker & Nicklay, 1992; Wallace & Canter, 1985). Patients who succeed in these tasks are taught to produce at least a small repertoire of useful spoken or spoken plus gestured responses. They suggest that these items include at least one greeting, the words “yes” and “no,” a few proper names, single words that express important needs, and perhaps, one or more phrases, especially if they appear in the patient’s spontaneous verbal productions. Imitation, either alone or supplemented by gestures and reading, is used to establish these responses (for a detailed approach to establishing an unequivocal yes/no response, see Collins, 1986, 1997). Imitated responses are then practiced in more functional contexts using questions or practical situations to facilitate response generalization.

Conversational prompting, a method reported by Cochran and Milton (1984), uses modeling, expansion, and feedback to develop the verbal responses of patients with severe aphasia in conversational contexts. Props and written cues are provided to facilitate verbal expression. Ten conversational levels are identified, ranging from concrete, structured contexts (e.g., manipulating objects or acting out and describing sequences) to more open contexts (e.g., structured interview or structured discussion). A cueing hierarchy is described to promote language retrieval. With its emphasis on conversational interaction, this technique may be particularly useful in developing contextually appropriate

communication for patients with global aphasia. It also may provide a suitable means for overcoming some of the problems traditionally associated with the generalization of trained responses to conversational contexts.

The verbal output of many patients with global aphasia consists primarily of stereotypic recurring utterances or speech automatisms. For many of these patients, productive usage of single words or phrases may not be a realistic goal. The treatment program Voluntary Control of Involuntary Utterances (Helm & Barresi, 1980; Helm-Estabrooks & Albert, 2004), or VCIU, can be used with these patients to bring these stereotypies into more productive usage. In this program, words that are involuntarily and inappropriately produced in the contexts of testing and treatment are identified and used as later targets in treatment. The words are trained in a sequence of activities, including oral reading, confrontation naming, and finally, conversational usage, until a vocabulary of between 200 and 300 words is established.

Two studies have investigated treatments for improving naming ability in patients with global aphasia. To test theories regarding the psycholinguistic representation of homophones as well as the effectiveness and generalization of phonologic treatment, Biedermann and colleagues (2002) treated naming to confrontation using phonologic cues in a 59-year-old man with global aphasia 13 years poststroke. The cuing hierarchy consisted of (a) an initial cue (consonant + schwa or vowel), (b) tapping the syllable number of the word, and (c) repetition. The design included four conditions: homophones, semantically related words, phonologically related words, and unrelated words. Item-specific, short-term improvements were observed for treated items; no generalization to untreated items, except for homophones, occurred. These results were consistent with previous studies of aphasia that have found poor generalization to untreated items following phonologic treatment.

Naeser and colleagues (2005) used transcranial magnetic stimulation (TMS) to treat the naming abilities of a 51-year-old woman with severe nonfluent/global aphasia who was 6.5 poststroke. TMS is a noninvasive procedure that uses magnetic fields to generate electrical currents over discrete brain regions. These lead to neuronal depolarization that can excite or inhibit the cortex. Functional imaging studies have suggested an anomalous right frontal response in patients with left frontal damage that is thought to interfere with language recovery. Naeser and colleagues therefore applied repetitive TMS (rTMS) to reduce the cortical excitability of right pars triangularis in this patient and effect improvements in language functioning. She received ten 20-minute, 1-Hz rTMS treatments 5 days a week for 2 weeks. Language testing at 2 and 8 months post-treatment demonstrated modest improvements in naming on the Boston Naming Test and the BDAE. Improvements at 1 year post-treatment were considered to be substantial enough to warrant referral for further speech-language treatment. This

patient continued to improve, especially in auditory comprehension and in the voluntary use of words and phrases appropriate to her environment.

Functional (Patient-Oriented) Approaches

Gestural Programs

American-Indian Code

Gestural programs constitute a sizeable portion of the functional treatment approaches for global aphasia. Probably the best known of the gestural programs is American-Indian (Amer-Ind) Code (Rao, 2001; Skelly, 1979). Amer-Ind Code is adapted from Amer-Ind sign, a gestural system based on the concepts underlying words rather than on the word themselves (Skelly, Schinsky, Smith, Donaldson & Griffin, 1975). According to Rao and Horner (1980), Amer-Ind Code is concrete, pictographic, highly transmissible, easily learned, agrammatical, and generative. The system can be applied in aphasia rehabilitation as an alternative means of communication, as a facilitator of verbalization, and as a deblocker of other language modalities (Rao, 2001). A few reports have demonstrated the usefulness of Amer-Ind Code as an alternative means of communication (Rao 1995; Rao et al., 1980; Tonkovich & Loverso, 1982). The approach also might be combined with other nonverbal means of communication (e.g., drawing) (see below) to increase a severely affected patient's communicative effectiveness (Rao, 1995). The greatest utility of the technique, however, appears to be as a facilitator of verbalization, though reports of its effectiveness vary (Hanlon et al., 1990; Hoodin & Thompson, 1983; Kearns, Simmons, & Sisterhen, 1982; Rao & Horner, 1978; Raymer & Thompson, 1991; Skelly, Schinsky, Smith, Donaldson, & Griffin, 1974). Rosenbek and colleagues (1989) describe a treatment program for gestural reorganization that uses Amer-Ind Code as the primary system of gestures and has, as its end goal, verbalization without gestural accompaniment.

Visual Action Therapy

Visual Action Therapy (Helm-Estabrooks & Albert, 2004; Helm-Estabrooks et al., 1982; Helm-Estabrooks, Ramsberger, Brownell, & Albert, 1989; Ramsberger & Helm-Estabrooks, 1989), or VAT, uses gestures to reduce apraxia and improve the patient's verbal expression or ability to use symbolic gestures as a means of communication. Three programs constitute the approach: proximal limb, distal limb, and buccofacial VAT. A hierarchical procedure is used in each program to "move the patient along a performance continuum from the basic task of matching pictures and objects to the communicative task of representing hidden items with self-initiated gestures" (Helm-Estabrooks & Albert, 2004, p. 255). The authors suggest that the method produces improve-

ments not only in the area of pantomime, as indicated by formal assessments, but also in the areas of auditory and reading comprehension, verbal repetition, and graphic copying.

Conlon and McNeil (1991) proposed that the efficacy of VAT has not been established because of experimental limitations in the original work of Helm-Estabrooks and colleagues (1982). Therefore, they investigated the effects of VAT on the communication abilities of two patients with global aphasia. Using a modified program for experimental purposes, positive treatment effects were observed on most steps of the program for their first subject and on about half the steps for their second subject. These results generally were consistent with those of Helm-Estabrooks and colleagues (1982), but generalization of these effects to untreated items was not observed. This lack of generalization suggested that the learned behaviors did not influence performance on untreated but similar behaviors. Conlon and McNeil (1991) determined that VAT is not effective in achieving the program's stated purpose of establishing "symbolic representation" as defined by Helm-Estabrooks and colleagues (1982). Conlon and McNeil concluded that further research is needed before VAT can be confidently recommended for the treatment of patients with global aphasia.

Some other gestural programs include pantomime; limited manual sign systems for hospitals and nursing homes, such as manual shorthand, manual self-care signals, or a hand-talking chart; gestures for "yes" and "no"; eye-blink encoding; and pointing (Silverman, 1989). Silverman (1989) offers a number of suggestions for the selective use of each of these approaches. For example, pantomime may be appropriate for the patient with aphasia who cannot use Amer-Ind Code. Limited manual sign systems may be used initially, on an interim basis, until other communication systems can be developed, but ultimately, these limited systems may provide the only means of communication in the most severely impaired patients (see, e.g., Coelho, 1990, 1991). Pointing is desirable for the patient who is going to use a communication board.

Non-Speech Communication Aids

Non-speech aids include those that assist communication by both non-electronic and electronic means. Strategies using non-electronic assistance include transmission of messages by communication boards, manipulation of symbol sequences, and drawing. One of the most prominent strategies in the rehabilitation of patients with global aphasia using electronic means is computer-aided visual communication (C-ViC) (Weinrich, Steele, Carlson, et al., 1989).

Preparatory Training

Alexander and Loverso (1993) developed a specific program for the treatment of global aphasia that supports the capacity

to make categorical and associational semantic discriminations while being sufficiently easy to allow an understanding of the nature and purpose of the tasks. Those authors contend that therapy of this sort establishes a necessary precondition for subsequent treatment with communication programs using iconic/substitutional language (e.g., communication boards or C-ViC). Twenty-four common everyday objects, realistic pictures of those objects, and realistic pictures of the locations in which those objects would be found were used as treatment stimuli. The stimuli were described as being representationally similar to those adopted for communication boards or C-ViC. Eight hierarchically-arranged treatment levels were identified, beginning with object-to-object matching in a field of one and increasing to picture sorting into locatively related groups. Two of five patients with global aphasia who were studied reached the proposed goal of treatment—namely, demonstration of semantic capacity across categorical and associational boundaries. The remaining patients with global aphasia were unable to recognize the nature of the response required at more complex levels. The authors concluded that, even if only 40% of the cases respond successfully to the program, these patients constitute the appropriate group for substituted language systems.

Salvatore and Nelson (1995) described a training model for establishing equivalence relationships among visual stimuli that may have potential for use with gestural-assisted programs like those described below. In their study, four subjects with severe aphasia learned novel symbolic relationships and generalized these to untrained relationships. The authors suggested that demonstrations of such generalization may be used as an indicator of the patient's ability to benefit from further treatment efforts.

Communication Boards

Communication boards vary in type and complexity. For severely impaired patients, a typical board will contain personally relevant words and pictures, numbers, and the alphabet. Specific treatment is required for effective use of the board. Collins (1986, 1997) suggests a training procedure in which target items are identified in isolation, then after an imposed delay, and finally, from among increasing numbers of foils until a temporary ceiling is obtained for the number of items contained on one board. Alternative boards containing pictures within only one domain (e.g., family or familiar objects) may be used to increase the number of items available to the patient.

Bellaire, Georges, and Thompson (1991) investigated the acquisition, generalization, and maintenance effects of picture communication board training. Although their two subjects did not have global aphasia, their findings have potential application to the treatment of this population.

Treatment and acquisition probes were administered in a traditional treatment room, whereas generalization probes

and training occurred during a coffee hour in a nursing home care unit. Pictures were divided into three sets for communicating social responses, requests for food and other items, and personal information. Stimulus presentations were followed by a 5-second response interval. If an accurate response was not observed, cues consisting of a verbal cue, a model, and a physical assist were provided. Subjects received response-contingent verbal feedback. Generalization training was conducted using a role-playing procedure in the treatment room with a script employed during the coffee-hour probes or within the coffee-hour setting. Maintenance data were collected for up to 6 months.

Following treatment, requesting and personal information responses were acquired, but not social responses. No response generalization to untrained responses was observed, nor was generalization of board use seen during the coffee hour. Of the two procedures for training generalization, only training within the actual coffee-hour setting resulted in generalized use of all responses except for social responses. Based on these results, the authors recommended that (a) communication boards include primarily pictures that communicate specific content items and (b) treatment for the use of picture communication boards take place in the natural environments where the board is to be used.

Ho, Weiss, Garrett, and Lloyd (2005) speculated that the failure of symbol use to generalize to functional communication following global aphasia might be a result of (a) the difficulty individuals with global aphasia have extracting meaning from symbols referring to abstract concepts, (b) a correlation between the severity of the language impairment and the ability to use symbols, and (c) the absence of the cognitive ability to initiate symbol use without the support of conversational partners. To overcome these challenges, they suggested using remnants (actual objects or photographs depicting recent or past events) that have personalized value in conversational interactions with persons who have global aphasia. In a study using a combination ABA and alternating treatment single-subject design with two patients who had global aphasia, the authors demonstrated that the participants initiated more topics and had fewer unrepaired communication breakdowns during conversation when either remnants or pictographs were used versus when no symbols were available. Participants demonstrated more pointing behavior, however, with remnants than with pictographic symbols. The subjective evaluations of the communication partners also favored the remnants over the pictographs. The authors concluded that their results support the use of communication books with individuals who have aphasia.

Blissymbols

Johannsen-Horbach, Cegla, Mager, Schempp, and Wallesch (1985) assessed the benefits of treating four patients with

global aphasia using Blissymbols, a visual symbol system of pictograms and ideograms. All patients had previously received at least 6 months of traditional therapy for aphasia without significant improvement in expressive language. For the procedures using Blissymbols, patients received individual treatment twice per week for a period of at least 2 months. The program was designed (a) to provide a basic lexicon of nouns, verbs, adverbs, and function words; (b) teach the production and comprehension of simple sentence in the symbol language; and (c) acquaint relatives with the symbol system to use in communicating with the patients. Symbols were introduced verbally along with simultaneous presentation of pictures or objects or the pantomime of the therapist. Training consisted of associating symbols and pictures for nouns, verbs, and function words in multiple-choice arrays and, subsequently, incorporating these items into Blissymbol sentences.

All patients acquired a symbol lexicon; three patients produced Blissyntactically correct sentences in response to pictures. Two of the patients successfully used the symbols in their communication with their relatives. In an important related finding, three patients evidenced the ability to articulate the correct words while pointing to the corresponding symbols, and one patient articulated grammatical sentences. Variable outcomes with regard to continued use of the symbols by these four patients were reported.

The success of some patients with severe aphasia in communicating using novel visual symbol systems has been interpreted as evidence for the superiority of such systems relative to the surface forms of natural language. To test this assumption, Funnell and Allport (1989) investigated the ability of two patients with severe aphasia (neither of whom appeared to have global aphasia) to use Blissymbols to communicate in conversational situations. By performing detailed analyses of the patients' abilities to process isolated words during listening, speaking, reading, and writing, the authors were able to compare the patients' use of Blissymbols to their processing of similar forms in natural language. Funnell and Allport found that the performance of the patients with aphasia using Blissymbols was entirely consistent with their processing of spoken and written words, and that the use of Blissymbols did not provide a channel for communication that was independent of natural language processes. Further inquiry will be necessary to determine whether these findings can be applied to patients with global aphasia who have more severely impaired natural language abilities than those of the subjects participating in the study by Funnell and Allport.

Drawing

Drawing has received considerable attention both as a communicative medium and as a means to deblock verbal and written communication. Morgan and Helm-Estabrooks (1987; see also Helm-Estabrooks & Albert, 2004) designed a

program entitled Back to the Drawing Board (BDB) to teach patients to communicate messages through sequential drawings. Patients are trained to draw cartoons from memory using verbal instruction, demonstration, and practice through copying. The cartoons range from one to three panels. Criterion performance consists of reproducing a recognizable drawing that contains the critical details relevant to the humorous aspects of the cartoon. Treatment outcome is evaluated by increased accuracy in the patients' drawings of nine "accidents of living." Morgan and Helm-Estabrooks (1987) provide an operational definition of accuracy to facilitate comparison and interpretation of the drawings. Their post-treatment results for two patients indicated an improved ability to convey information through the use of drawing alone.

Lyon and Sims (1989) undertook a study to determine the degree to which patients with severe aphasia can communicate through drawing and to evaluate the effectiveness of a treatment program emphasizing drawing-aided communication. Eight patients with aphasia and eight comparable, normal adults participated in the study. The eight subjects with aphasia were enrolled in a treatment program focused on refining primary drawing skills (form, visual organization, detail, and perspective) within defined communicative contexts. Verbal and graphic cueing and requests for enlargement of distorted parts were used to improve the recognizability of the drawings. The drawings were then placed in a communicative interaction between the patient and a trained interactant who used specific strategies to optimize communicative effectiveness.

Communicative effectiveness was assessed using a 40-item drawing outcome measure to evaluate pre- and post-treatment performance both with and without the use of drawings. A scale of communicative effectiveness was designed to rate performance on the outcome measure, and a second scale was designed to rate the recognition of drawings. Pre- and post-treatment performance on the PICA also was used to measure communicative effectiveness.

Following drawing treatment, substantial gains were observed in the communicative effectiveness of subjects with aphasia compared to their pretreatment levels. Performance further improved following treatment to 88% of the communicative effectiveness score attained by the normal adults. The subjects with aphasia also improved in the recognizability of their drawings following treatment, achieving 65% of the normal adults' scaled value. Based on these data, the authors concluded that drawing serves as an important facilitator of communication by providing to patients with aphasia a fixed representation of a concept that is readily available for subsequent modification.

Kearns and Yedor (1992) have pointed out that specific programming may be needed in some cases to establish spontaneous use of drawing for communicative purposes. Ward-Lonergan and Nicholas (1995) described such a program for their patient with global aphasia. The program

began with BDB (Morgan & Helm-Estabrooks, 1987), progressed to the less structured conversational framework employed in Promoting Aphasics' Conversational Effectiveness (Davis & Wilcox, 1981) (see below), and concluded with an unstructured, interactive approach they identified as Functional Drawing Training. The patient made substantial progress during the course of the program, and although spontaneous initiation of communicative drawing was still lacking at the end of the treatment, the patient was able to communicate effectively through drawing when given limited encouragement.

Computer-Aided Visual Communication

Computer-aided visual communication (Steele, Kleczewska, Carlson, & Weinrich, 1992; Steele, Weinrich, Kleczewska, Carlson, & Wertz, 1987; Steele, Weinrich, Wertz, Kleczewska, & Carlson, 1989; Weinrich, Steele, Kleczewska, et al., 1989) provides another approach to establishing alternative communication in severely impaired patients. Using procedures similar to those of visual communication (Gardner, Zurif, Berry, & Baker, 1976) but in a microcomputer environment, C-ViC is an iconographic system in which patients construct communications by selecting symbols from six "card decks" and arranging them according to certain syntactic conventions. The card decks contain interjections, animate nouns, verbs, prepositions, modifiers, and common nouns. The program has been used successfully to train comprehension of a variety of lexical categories (e.g., verbs and prepositions), although generalization to oral production of these items has been limited (Weinrich, Steele, Kleczewska et al., 1989; Weinrich et al., 1993). Formal procedures have been developed that extend training from introductory phases which teach the patient to follow simple commands to later phases designed to transfer C-ViC communication skills to use in a home setting (Baker & Nicholas, 1992). One patient with global aphasia was able to accurately select the lexical items for a message as well as apply simple syntactic rules to produce basic constructions (subject-verb, irreversible and reversible subject-verb-object) (McCall et al., 2000). This patient demonstrated great difficulty in multi-sentence production, however, and positive gains that were observed over the protracted period required for this training did not generalize to standardized assessment measures.

Naeser and colleagues (1998) investigated the lesion site patterns for 17 patients with severe aphasia who had undergone C-ViC training to determine whether these patterns were predictive of communication outcomes following C-ViC treatment. Although some of their patients did not have global aphasia, all of the patients did present with little or no spontaneous speech and impaired auditory comprehension. Before treatment, all patients were tested with the BASA (Helm-Estabrooks, Ramsberger, Morgan, & Nicholas, 1989) and underwent non-contrast enhanced CT at 3 months

or later poststroke. The C-ViC training was initiated no earlier than 3 months after aphasia onset and was continued twice weekly for 6 months to 1 year. Outcomes were based on a rating scale that was developed to assess the quality of C-ViC-generated sentences.

The findings from this study suggested that the lesion site pattern associated with the best response (i.e., initiates communication) using C-ViC spares large portions of either posterior systems that include Wernicke's area and the temporal isthmus or anterior systems that include the supplementary motor area and the cingulate gyrus. Moderate responses (i.e., responds to questions but does not initiate interactions) were found following lesions that spared posterior systems but involved anterior systems. Patients who demonstrated no response to the program had bilateral lesions that included variable lesions in either left posterior or posterior and anterior systems. The authors also found, however, that prediction of outcome was optimized when these lesion site patterns were combined with behavioral results obtained from pre-treatment testing with the BASA (Naeser et al., 1998).

Similar to that reported with gestural strategies, verbal facilitation has been noted (personal observation) during C-ViC training that produces successful naming that is not seen in these same patients in other communicative contexts (e.g., conversation or formal testing). The ultimate goal of C-ViC is not verbalization without computer assistance (as might be the case with some of the foregoing gestural strategies), but these observations suggest that C-ViC is a powerful verbal reorganizer that may enhance the language production of patients using this tool.

Lingraphica

The Lingraphica is a speech-generating device combining images, animation, text, and spoken words to provide computer-based communication. It contains a large number of words represented by icons and can be customized with a user's special words and pictures. The user selects icons to express a thought or need, which the device then turns into audible words or sentences. The Lingraphica also is loaded with a wide range of practice materials that can be used in the clinic under the direction of a speech-language pathologist or independently at home.

Three studies have demonstrated positive effects for chronic patients with a wide range of types and severities of aphasia following treatment using the Lingraphica System. Aftonomos, Steele, and Wertz (1997) studied the responses to computer-based treatment of 23 patients with aphasia who were 6 months to more than 15 years post-onset and who had been discharged from previous courses of speech-language treatment. All patients received 1-hour treatment sessions with a speech-language pathologist using the Lingraphica System and, with the exception of one patient, used the

system at home for practice between clinical treatment sessions. Comparison of pre- and post-treatment scores on a variety of formal language instruments demonstrated significantly improved performance in multiple modalities.

Aftonomos, Appelbaum, and Steele (1999) extended the previous work by assessing the outcomes of computer-based treatment on functional communication as well as formal language tests. Sixty subjects, consisting of 14 patients less than 6 months post-onset and 46 patients more than 6 months post-onset, were administered the WAB and CETI before the initiation of treatment. Treatment consisted of 1-hour sessions using the Lingraphica clinical exercises but with a focus on improving the patients' functional communication outside the clinic. The number of treatment sessions ranged from 10 to 132. Post-treatment group results demonstrated significant improvements for all subtests of the WAB and for the CETI. The acute and chronic aphasic groups each made significant improvements on both of the test measures, and all of the patients grouped by aphasia category, except for patients with Wernicke's and transcortical motor aphasia, made significant improvements. Eleven patients with global aphasia included in this group had a mean AQ improvement of 6.2 points.

Finally, Aftonomos, Steele, Applebaum, and Harris (2001) reported outcome data for both the impairment and functional levels following treatment with the Lingraphica System. Fifty patients, including six with global aphasia, completed at least 1 month of treatment, after which pre- and post-treatment scores on all items of the WAB and CETI were compared. Participants were found to have improved significantly on all language subtests of the WAB, on the WAB AQ, and for all items of the CETI following treatment. Patients with global aphasia made the second least gains (behind patients with anomic aphasia) at the impairment level and the third least gains in functional communication. When analyzed by patient severity, those with the most and least severe aphasias made the smallest, although still statistically significant, gains at the impairment level, whereas those with the most severe aphasias made the greatest gains in functional communication. The authors attributed the latter outcome to commonly observed "ceiling effects" in less impaired patients following treatment.

Gus Multimedia Speech System

Gus is a computer-based graphic symbol communication system that offers graphic and orthographic symbols along with synthetic speech output (Koul et al., 2005). The program presents symbols in a dynamic display format that allow the symbols to be presented across screens logically (e.g., superordinate categories in a first screen that explode into subordinate categories in a second screen, followed by specific items in that category in a third screen). The patient's cognitive, linguistic, motor, and visuoperceptual

skills determine the number of symbols that are displayed in each screen, and each symbol can be programmed to produce a spoken message.

Koul and colleagues (2005) investigated the effect of Gus intervention on the production and generalization of graphic symbol sentences of varying grammatical complexity in 10 patients with severe aphasia, 2 of whom had global aphasia. The motivation for the study was to evaluate the extent to which patients with severe aphasia can use electronic communication aids to support or replace spoken language. The first patient with global aphasia was unable to produce even the most syntactically simple sentences (two word agent + action or action + object constructions). The second patient was able to achieve criterion for two out of six Level I constructions and one Level II construction (morphologic inflections [e.g., boy reading]); he did not achieve the criteria for any of the more complex constructions. No generalization was observed for any of the sentences that were probed. That even one of the two patients with global aphasia was able to use the computer-based system to produce sentences of varying syntactic complexity was viewed by the authors as evidence for the effectiveness of this approach following global aphasia when compared to the patients' natural language.

Promoting Aphasics' Communicative Effectiveness

The last functional approach to be considered here is Promoting Aphasics' Communicative Effectiveness, or PACE, treatment (Davis, 1980, 1986, 2005; Davis & Wilcox, 1981, 1985; Wilcox & Davis, 1978). Despite having attributes such as direct language stimulation and real-life conversation (Davis, 2005), its inclusion here (as in previous versions of this chapter) is based on the limited language of persons with global aphasia and the potential for using this procedure as a means to promote nonverbal, functional options for communication.

Because PACE procedures allow patients to freely choose the channels through which they will communicate, the technique provides opportunities for patients to use either a verbal strategy or any of the nonverbal strategies described above, with or without verbal accompaniment, to convey messages. In this way, the approach emulates natural conversation by allowing participants to exchange information through multiple modalities.

In addition to free selection, some of the other characteristics of natural conversation that provide guiding principles for PACE treatment include the following: (a) Clinician and patient participate equally as senders and receivers of messages, (b) the interaction incorporates the exchange of new information between clinician and patient, and (c) the clinician's feedback is based on the patient's success in communicating a message (Davis & Wilcox, 1985). PACE treatment also uses a multidimensional scoring system to better

capture the full range of behaviors that may be observed in this interactive approach. Generalization of language gains observed following PACE treatment has been demonstrated on formal language assessment instruments. Given its emphasis on the pragmatic aspects of language, PACE is well suited as a means to incorporate compensatory strategies into communication treatment. An additional strength of the approach, however, lies in its use as a framework for incorporating traditional language stimulation techniques into a communicatively dynamic context.

Social (Partner-Oriented) Approaches

Social approaches (covered in greater detail elsewhere in this volume) target communication partners or other ways to reduce communication barriers in addition to improving language or compensatory functional language (LPAA Project Group, 2001; Simmons-Mackie, 2001). As such, they may be particularly appropriate for individuals with global aphasia, given their poor prognosis for language recovery. One particularly good example of this approach is Supported Conversation for Adults with Aphasia (Kagan, 1998; Kagan et al., 2001), or SCA. Others have included conversational coaching (Hopper, Holland & Rowega, 2002), reciprocal scaffolding (Avent & Austermann, 2003), partner training (Simmons-Mackie, 2004), and the use of autobiographical reports (Pound, Parr, & Duchan, 2001).

The SCA program teaches techniques to conversation partners that will help them better reveal the competence of people with aphasia (Kagan, 1998). It builds on the assumption that many adults with aphasia can capitalize on preserved cognitive and social abilities to participate in conversation. The SCA program involves training conversation partners to acknowledge the competence of individuals with aphasia and help them reveal what they think, know, and feel.

Kagan and colleagues (2001) investigated the efficacy of SCA in a single-blind, randomized, controlled, pre-post design study. Forty dyads consisting of a volunteer conversation partner and an adult with moderate to severe aphasia were divided evenly between a control and an experimental group. Fifteen percent of the participants with aphasia were diagnosed with global aphasia. The groups participated in videotaped semistructured interviews with or without SCA training. The SCA training focused on acknowledging and revealing the competence of adults with aphasia through supported conversation. For example, the topics for acknowledging competence included keeping talk as natural as possible, avoiding patronization, and explicitly indicating that competence of the person with aphasia is not in question; those for revealing competence included ensuring the person with aphasia understands what is being communicated and is given the opportunity to express what he or she knows, thinks, or feels and verifying that the conversation is on track from perspective of person with aphasia. The techniques

included gesture, writing key words, and drawing accompanied by pictographic resources. Two rating scales were developed to measure the amount of support provided by the conversation partner and the level of participation by the adult with aphasia. Trained volunteers scored significantly higher than untrained volunteers on ratings of acknowledging and revealing competence in their partners with aphasia. The adults with aphasia in the experimental group also performed significantly higher than their counterparts in the control group on measures of social and message exchange skills, even though they had not participated in the training. These results were interpreted as support for the efficacy of this particular approach to aphasia rehabilitation.

FUTURE TRENDS

Clearly, future clinical research must better identify the conditions under which treatment for global aphasia is maximally effective. To do so, several issues must receive further exploration. One of these concerns outcome from global aphasia and includes (a) identifying the factors that differentially account for evolution in some patients with global aphasia to less severe aphasic syndromes, (b) establishing or refining prognostic indicators or profiles that can reliably predict outcome in global aphasia, and (c) specifying the relationships between site and extent of lesion for outcome in global aphasia. A second issue concerns how this outcome information can be better applied to management decisions for patients with global aphasia. Naeser (1994) provides one example of the use of outcome information obtained during the acute phase of recovery for these purposes. This approach must be further developed to improve specificity and accuracy. Third, clinicians must continue to identify specific assessment and treatment approaches that are sensitive to the capabilities of patients with global aphasia and produce reasonable outcomes in functional communication relative to the time and effort expended during the rehabilitation process. Finally, greater emphasis will be placed on improving not just communication, but the overall quality of life of the patient with global aphasia. Rehabilitation programs will incorporate increasingly sensitive measures to evaluate the psychosocial outcomes of treatment. Common practice will extend the continuum of care for these patients to support groups and other community organizations following the completion of formal speech and language treatment.

KEY POINTS

1. Global aphasia may be one of the most frequently occurring types of aphasia; age and sex do not appear to have a differential effect on the incidence of global aphasia.

2. Global aphasia may result from extensive cortical lesions of the dominant hemisphere, lesions confined to either the anterior or posterior cortex, or lesions restricted to subcortical regions. Patients with global aphasia and large pre- and postrolandic middle cerebral artery infarcts generally have a poor recovery, but some individual patients with this lesion pattern may demonstrate outstanding outcomes.
3. Patients with global aphasia have several isolated areas of relatively preserved comprehension, including specific word categories, familiar environmental sounds, famous personal names, and personally relevant information. The verbal output of these patients consists primarily of stereotypic recurring utterances or speech automatisms.
4. Nonverbal cognitive impairment is correlated with the degree of language impairment in global aphasia.
5. Patients with global aphasia rely most heavily on nonverbal communication that may be nearly as effective as the communication strategies employed by patients with other types of aphasia.
6. Global aphasia most often results from middle cerebral artery occlusion below the point of branching, but cases have occurred from illnesses such as epilepsy and demyelinating disease.
7. Patients with global aphasia who are receiving treatment demonstrate substantial improvements during the first 3 to 6 months post-onset as well as continued improvement during the period between 6 and 12 months or more post-onset. Different patterns of recovery for language and non-language skills may be found during these periods.
8. Evolution from global aphasia is not simply the result of the time at which language is observed initially but, rather, is the result of a complex interaction of incompletely understood factors.
9. Younger patients with global aphasia and those without accompanying hemiparesis tend to have better prognoses for language recovery.
10. Greater right hemisphere asymmetries are associated with superior recovery of single-word language functions. Temporal lobe lesions that are limited to the subcortical temporal isthmus and spare Wernicke's area are associated with significantly better recovery of auditory comprehension following global aphasia.
11. Higher language test scores with greater variability among auditory comprehension and other language scores are consistent with a better prognosis. Patients with global aphasia who respond to yes/no questions, regardless of accuracy, may have a better outcome than those who cannot grasp the yes/no question format.
12. In the absence of accurate techniques for predicting recovery from global aphasia, the most powerful reasons for providing early treatment are the latent recovery observed in patients who receive acute speech and language treatment and the greater effects that are observed for patients with aphasia in general when treated during the acute period of recovery.
13. Early intervention in global aphasia has the multiple purposes of language stimulation directed toward cerebral reorganization and recovery, identification of successful communication strategies, and patient, family, and staff counseling.
14. Contemporary approaches to assessment include both formal and informal measures to establish a communication profile that documents not only the patient's areas of weakness but also the patient's strengths.
15. Treatment for global aphasia exploits the residual language capacity and/or other functional abilities of these patients to improve communication and the patient's quality of life.

B. Cognitive Neuropsychological Approaches to Treatment of Language Disorders

Chapter 22

Cognitive Neuropsychological Approaches to Treatment of Language Disorders: Introduction

Argye E. Hillis and Melissa Newhart

OBJECTIVES

The purposes of this chapter are to (1) describe an approach to assessment and treatment of individuals with aphasia that begins with identifying, in each patient, the cognitive mechanisms that are impaired and those that are intact, within a cognitive neuropsychological model of the affected language task; (2) provide examples of this general approach that have resulted in functional gains in communication abilities; (3) delineate the uses and limitations of this approach to clinical management of persons with aphasia; and (4) speculate on the future trends in the areas of cognitive science and language rehabilitation. To set the stage, we first describe the main goals of cognitive neuropsychology and how this model characterizes the normal cognitive mechanisms (mental representations and processes) necessary to accomplish a given language task, such as naming or reading, on the basis of patterns of impaired performance due to brain damage. More recently, clinicians have used cognitive neuropsychological models of normal language to characterize impaired and spared cognitive processes important for focusing treatment of individuals with aphasia.

DEFINITION

This section provides illustrations of a general approach to the assessment and treatment of specific language tasks that makes use of cognitive analyses and models developed within the discipline of cognitive neuropsychology—a branch of psychology that seeks to understand normal human cognitive mechanisms through evidence from how cognitive mechanisms are modified by brain damage. This approach begins, for each patient, with identifying which cognitive processes and representations underlying the language task are impaired and which are intact. Treatment then focuses either on remediation of the impaired cognitive processes, compensation via the intact cognitive processes, or both. This framework involves consideration of the patient's performance of the task in light of a model of the cognitive processes and representations that underlie normal performance of the task. It should be emphasized that the treatment procedures themselves are not usually based on models from cognitive neuropsychology, although some computational models have been used to guide selection of treatment stimuli (Kiran & Thompson, 2003) or even treatment strategies (Martin, Lane, & Harley, 2003). However, most therapies are based on principles of learning, clinical experience with the sorts of input that successfully elicit better performance, and the clinician's other skills, talents, and knowledge—just like other therapy strategies in speech-language pathology. In fact, the selection of the chapter contributors reflects the fact that

this approach has its foundations in the integration and cooperation across the professions of cognitive neuropsychology, speech-language pathology, behavioral neurology, and other professions within the discipline of cognitive science. Related areas include cognitive psychology (a branch of psychology devoted to the study of normal cognitive processing), psycholinguistics (a branch of psychology devoted to the study of rules and representations that underlie normal language comprehension and production), and linguistics (a profession devoted to investigation of the structure and computation of language). No one profession can lay claim to the sort of rehabilitation described in this section, although clinicians in each profession can engage in it equally.

PRINCIPLES AND PROCEDURES OF THE “COGNITIVE NEUROPSYCHOLOGICAL” APPROACH

The goal of cognitive neuropsychological research is to develop models of normal language processes, in the form of the cognitive architecture of specific language tasks. A model

of this type specifies the mechanisms for solving the necessary computational problems of a particular task, such as naming, as a set of representations (i.e., stored visual, orthographic, semantic, or phonologic information) and the processes required to compute or activate each representation from earlier ones. So, for example, we might propose that picture-naming involves, at the very least, the following: discrimination of the lines, edges, and shadings of the picture to develop a representation of the visual image; matching the computed visual representation to a stored representation of the physical structure of the object (i.e., accessing the “structural/visual description”); accessing stored information about the set of instances with a particular name (i.e., accessing a “semantic representation”); accessing the stored pronunciation (the “phonologic representation”) of the word to which it corresponds; and activating representations of the motor programs involved in articulating the word.

One such processing model of the lexical system is schematically depicted in Figure 22–1. This figure depicts some of the principal cognitive processes underlying reading, spelling, and naming, understood as a series of transformations of mental representations. Many models include

Figure 22–1. Schematic representation of the components of lexical processing.

additional levels of processing, such as a “lemma,” a modality-independent syntactic representation that specifies the word class (and mass/count and gender in some languages), prior to accessing a phonologic or orthographic lexical representation. It is important to note that although each component is dedicated to a particular aspect of lexical processing, some of the components are involved in more than one lexical task. For example, both reading and naming involve computing the phonologic representation of a word for output from a semantic representation. Hence, if computation of the phonologic representation were to be disrupted by brain damage, it should be manifest as impairment in both reading and naming, although the consequences for output may be somewhat different in the two tasks. In the case of reading, additional information about the pronunciation of the name is available from the printed word. Therefore, if the patient is unable to compute “chair” from the semantic representation of CHAIR, he or she will be unable to name the pictured chair but may yet be able to correctly read *chair* on the basis of orthographic-to-phonologic conversion mechanisms (i.e., by “sounding out” the word). Of note, some models of naming are more explicitly computational in that they simulate the process of a limited number of neurons like units that represent features or even whole words. Some of these models also simulate learning or re-learning.

Motivation for proposing specific representations and processes comes from considering the computational requirements of the cognitive task, and the proposals are supported by empirical evidence from studies of normal subjects and from patterns of impaired performance by brain-damaged subjects. To illustrate, evidence for proposing separate mechanisms for computing phonologic and orthographic representations of words from a semantic representation comes from patients who show good comprehension of printed and spoken words (indicating adequate access to the semantic representation) and are able to write the corresponding written word (in dictation or picture-naming tasks), but are not able to access the pronunciation of the same word. Such a pattern of performance (Caramazza & Hillis, 1990; Ellis, Miller, & Sin, 1983; Hier & Mohr, 1977) is inconsistent with an alternative proposal that computation of the orthographic representation first requires computation of the phonologic representation. Thus, such models are constrained by patterns of performance of brain-damaged patients that cannot be otherwise explained by proposing specific loci of damage to the existing model. The subsequent chapters will cite cases that provide evidence for proposing those components of lexical processing that are involved in naming (Raymer & Gonzalez Rothi, Chapter 23, this volume; see also Fink, Brecher, Sobel, & Schwartz, 2005; Hillis, 1994), reading and writing (Beeson & Henry, Chapter 25, this volume; see also Beeson, 1999; Beeson & Hirsch, 1998; Beeson, Rewega, Vail, & Rapcsak, 2000; Coltheart, Patterson, & Marshall, 1980; Ellis, 1982; Friedman & Lott, 1996; Friedman & Lott, 2002; Friedman, Lott, & Sample,

1998; Friedman, Sample, & Lott, 2000; Goodman & Caramazza, 1986; Hillis & Heidler, 2005; Patterson, Coltheart, & Marshall, 1985; Rapp, 2005), and sentence processing (Mitchum & Berndt, Chapter 24, this volume; see also Garrett, 1980; Thompson & Shapiro, 1995; Thompson & Shapiro, 2005; Thompson, Shapiro, Ballard, Jacobs, & Tait, 1997; Thompson, Shapiro, Tait, Jacobs, & Schneider, 1996).

In turn, the models guide our understanding of performance patterns by individuals with aphasia. That is, language disorders resulting from brain damage (which disrupts previously normal language) can be characterized by proposing deformations of one or more of the constituent mental representations or processes underlying language tasks. For example, imagine a patient who understands spoken and written words and writes the names of pictures adequately but is unable to say the correct names, despite unimpaired motor skills for articulating the correct name. We might propose in this case that the patient is unable to retrieve the accurate pronunciation of the word from among the stored pronunciations of all words he or she knows (“the phonologic output lexicon”). Therefore, a pattern of performance that indicates a proposed locus of disruption in the lexical system at the level of the phonologic output lexicon would include (1) demonstrated access to the semantic system from printed and spoken words (i.e., intact reading and auditory comprehension) and from pictures, and (2) access to printed words from semantics (i.e., intact written expression of names and of self-generated ideas), but (3) failure to access the phonologic representation from pictures or objects (impaired oral naming) or from written words (impaired oral reading). This example illustrates that the data crucial to proposing a specific locus of damage include the patient’s performance profile across lexical tasks in all modalities. To understand a patient’s writing, for example, we need to know about his or her reading, comprehension, and speech, as well as performance on various spelling tasks. In addition, an analysis of the types of errors made in the affected task(s) and the stimulus parameters that influence performance (e.g., word frequency, part of speech, word length, and so on) may be required, as illustrated in several cases in the following chapters. Recent studies indicate that disruption of separate components of the lexical process are caused by distinct site of brain dysfunction (DeLeon et al., 2007).

Basic Assumptions

There are a few basic assumptions of cognitive neuropsychological research, which if proved to be incorrect would undermine the usefulness of this approach for understanding normal language processing. First, the universality assumption states that everyone has essentially “the same” cognitive processes. Certainly, there may be different modes of learning and thinking that reflect variable reliance on one type of processing relative to another, but presumably we all develop the same types of mental representations and processes.

Second, the “transparency assumption” states that brain-damaged patients also have basically the same cognitive processes, except for a focal modification at some level(s) of representation or processing, “transparently” revealed by the performance pattern in various tasks. In other words, brain damage does not result in new types of mental representations or operations, although it may change *which* of our normal components we rely on to accomplish a task. For example, referring to Figure 22–1, normal oral reading of a word such as “yacht” is accomplished by accessing a representation in the phonologic output lexicon (the repository of stored “pronunciations” of familiar words). However, when there is damage to the phonologic output lexicon a patient may now read aloud via letter-to-sound conversion mechanisms. This local modification in the system is transparently revealed by pronunciation of the word yacht as “yached” (/jæɪSt/, rhyming with thatched). Normally, oral reading of English is likely to be accomplished by an interaction of the two mechanisms (access to the phonologic output lexicon from semantics and letter-to-sound conversion mechanisms (Hillis & Caramazza, 1991, 1995), although some readers may rely more on one or the other, at least in learning to read.

Different Types of Cognitive Models

The classical cognitive neuropsychological model is the so-called “serial” or “box and arrow” schematic representation of the cognitive representations and their interactions that underlie a given task, such as reading, spelling, naming, or sentence production. These representations and processes do not necessarily correspond to locations in the brain. Rather, they represent distinct functional components of a cognitive operation. Several models of this type are illustrated in the following chapters, and a “serial” model of the lexical system is shown in Figure 22–1. The basis for proposing each level of representation comes from patients whose performance of the task, and pattern of performance across tasks, can be understood by proposing selective damage to that cognitive component and dependence on the other spared components. Such schema are described as serial because it was initially assumed that processing at each level of representation was completed before processing at the next level was started. In serial models, feedback from one level of representation to a prior level, and integration of the various components, were not considered. However, several cognitive mechanisms may interact to select or “access” a specific lexical representation at a subsequent level (Hillis & Caramazza, 1991, 1995; Patterson, Graham, & Hodges, 1994), and that information may “cascade” from one level to the next, such that several representations are simultaneously active and contributing to the final output (Humphreys, Riddoch, & Quinlan, 1988).

The concepts of integration and feedback are best seen in more recent, computational models of specific language tasks. This type of model is a computer simulation of the

cognitive representations and procedures that underlie the task, utilizing several levels of “nodes” with feedback and feedforward connections between each level. In some of these models, the strength of the connections between nodes is not “programmed in,” but is learned through many repeated simulations (Plaut & Shallice, 1993; Seidenberg & McClelland, 1989). Evidence for postulating specific characteristics of each model comes from patients whose pattern of performance can be simulated by “damaging” the simulation in some way (e.g., by reducing the connection strength between two levels of nodes). It is likely that each of these types of serial and computational models captures some of the characteristics of normal language processing. It is plausible that there are both feedback and feedforward interactions between at least some levels. (Dell, 1986; Dell, Burger, & Svec, 1997; Rapp & Goldrick, 2004). It is also likely that lexical and semantic representations consist of activation distributed across component units, some of which are shared by other, related representations (Plaut & Shallice, 1993; Seidenberg & McClelland, 1989).

Application of Models to Treatment

Focusing Treatment

The clinician’s primary goal in understanding the patient’s deficit is to focus treatment on just those levels of processing that are impaired or to identify methods that will allow the patient to process language successfully by “getting around” the deficit. Thus, the predominant usefulness of cognitive models is in identifying the level(s) of processing that are impaired in each patient, so that therapy can be directed toward remediation of that component and/or strategies to compensate for the loss of that component. Among the first illustrations of this application was a study by Byng and Coltheart (1986) showing that selective damage to particular components of the reading system in their patient could be treated successfully by focusing treatment on the impaired component (see Beeson & Henry, Chapter 25, this volume). Additional notable examples of studies in which cognitive analyses have been used to focus intervention are described in the subsequent chapters in this section. In each case, a model of the normal processes underlying the treated task served to pinpoint the patient’s deficit and thereby focus intervention. For example, patient JJ (reported in Hillis & Caramazza, 1991), whose pattern of performance across lexical tasks indicated a disruption at the level of the semantic system, showed more improvement in naming performance when treatment tasks explicitly required semantic processing (printed word/picture matching) than when treatment tasks did not overtly require semantic processing (oral reading with phonologic cues). In contrast, patient HW, whose naming impairment could be localized to the phonologic output lexicon, showed greater improvement in naming performance as a consequence of the facilitated oral-reading

treatment than as a consequence of treatment using printed word/picture matching to enhance semantic processing (see Hillis & Caramazza, 1994, for details and discussion). Raymer, Thompson, Jacobs, and LeGrand (1993) (see also McNeil et al., 1999; Thompson, Raymer, & LeGrand, 1991) also reported that phonologic strategies to facilitate naming (e.g., using rhyming word cues) improved naming performance of patients whose impairment was localized to the phonologic output lexicon. Additional reports of treatment focused on specific components of the naming process are reported by Raymer and Gonzalez Rothi in Chapter 23 (this volume). However, many types of naming treatment described in the literature, including those that directly facilitate production of the name in response to the picture, might improve naming at either the level of the semantic system or the level of the phonologic output lexicon or both (Hillis, 1989; Howard, Patterson, Franklin, Orchard-Lisle, & Morton, 1985; Linebaugh, 1983; Thompson & Kearns, 1981).

Another use of cognitive neuropsychological models has been in the prediction of patterns of generalization across tasks and across items. For example, in Chapter 25 of this volume, Beeson and Henry describe a patient, HG, whose performance across lexical tasks could be explained by assuming that she had partial damage to semantic representations of words and profound damage to the phonologic output lexicon (Hillis, 1990, 1994). In various tasks, such as written and spoken naming, repetition, written word/picture matching, and spoken word/picture matching, HG made semantic errors, such as “tulip” named or understood as “rose.” However, her errors were inconsistent. Tulip might be named on one occasion as “rose” and on another occasion as “daisy.” Furthermore, when shown a picture of a tulip she would accept the name “rose,” “daisy,” “tulip,” or any other flower as the name of the picture. This pattern can be explained by assuming that HG accessed underspecified semantic representations, or meanings, of words. In this case, she might have had a semantic representation of “tulip” that consisted of a partial set of features that define tulip. While the normal semantic representation of “tulip” might include all of the features that jointly define a tulip and allow it to be distinguished from all other flowers, such as <flower>, <bulb>, <upright petals>, <slender, upright leaves>, <spring blooming>, <dutch>; HG’s semantic representation might include only <flower> and <spring blooming>. Therefore, she would accept any word that corresponded to these features in word/picture verification. Furthermore, her underspecified semantic representation would access all phonologic representations and orthographic representations that correspond to these features, so that a picture of tulip might be named as any one of many spring flowers. In addition, HG mispronounced nearly every word in all tasks with spoken output (repetition, oral reading, spoken naming). This aspect of HG’s performance was attributed to an additional deficit in accessing phono-

logic representations for output. Initially, treatment focused on her semantic impairment (see Chapter 25, this volume), by teaching her the features that distinguish semantically related words, for certain categories of words, such as foods and clothing. Based on the model in Figure 25–1, it was predicted that treatment (teaching/improving specific semantic representations) should improve her performance of all tasks that involve the semantic component—for example, spoken and written naming, and spoken and written word comprehension. And, indeed, although treatment engaged the task of written naming only, her reduction in semantic errors generalized to tasks of spoken naming and spoken and written word comprehension. However, the treatment was expected to be specific to the trained categories of words. That is, teaching her features that distinguish various types of clothing should not reduce her semantic errors in naming or understanding of furniture. And, consistent with this prediction, her gains generalized to untrained items within the trained categories, but not to untrained categories. Furthermore, the treatment of semantic representations utilizing the task of written naming was not expected to improve her pronunciation of words in spoken output, and it did not. Subsequent therapy directed toward teaching her accurate pronunciations by reestablishing phonologic representations (or access to them) in the task of oral reading did result in more accurate pronunciations in not only oral reading, but also in oral naming and repetition. In this case, treatment was item-specific, as expected, since reteaching a phonologic representation of “tulip” would only improve pronunciation of tulip. Behrmann and Lieberthal (1989) reported comparable generalization results—improvement in categorization of *untreated items* within *treated categories*—of a therapy strategy that also focused on teaching semantic distinctions among related items. Their patient, like HG, showed a pattern of performance consistent with damage to the semantic system, as indicated in particular by his category-specific impairment in comprehension (but unlike HG he showed some improvement of items in one of the untrained categories). Additional reports in the literature of item-specific treatment include treating reading of function words using association with visually/phonologically similar content words (Hatfield, 1983) and improving printed-word recognition by reinforcing correct word/nonword, semantic, and phonologic decisions about the “treated” set of words (Hillis, 1993). These reports are consistent with the hypothesis that if treatment influences specific representations (or access to them), performance involving the target representations (treated stimuli) should improve across tasks, but performance would not be expected to improve for other representations (of untreated words).

A different type of generalization concerns changes in performance across treated and untreated stimuli. Here, we would expect that if treatment influences a general processing mechanism (say, holding representations in a short-term

memory system), processing should improve across all stimuli that are subject to that mechanism (Rapp, 2005). Many examples of therapy that influenced both treated and untreated stimuli have been reported, such as improving reading speed by reinforcing rapid semantic decisions about printed words (“gestalt processing”) (Gonzalez Rothi & Moss, 1989), improving comprehension of sentences (Byng & Coltheart, 1986), improving use of a self-correction strategy in spelling (Hillis & Caramazza, 1987), and improving use of sublexical letter-to-sound conversion mechanisms or “phonologic assembly” to improve oral reading (Berndt & Mitchum, 1994; de Partz, 1986; Hillis, 1993) or sound-to-letter conversion mechanisms to improve spelling (Carlomagno, Iavarone, & Colombo, 1994; Hillis Trupe, 1986). Generalization to untrained items might be increased by starting of more complex or less prototypical examples (Kiran & Thompson, 2003). The problem in making predictions as to whether or not to expect improvement across stimuli is that we have no way of knowing, *a priori*, how treatment affects processing. Indeed, we might instead use treatment results to propose whether a general mechanism or specific representations were affected by our treatment (see Goodman-Schulman, Sokol, Aliminosa, & McCloskey, 1990, for discussion and illustration).

Finally, we always work toward ensuring that treatment effects generalize to other tasks and settings outside the therapy session. For example, patient HG (above) showed dramatically improved use of trained words not only during therapy, but also in the job setting (documented by her job coach), at home (documented by her mother), and in restaurants (observed by her therapist). Hinckley, Patterson, & Carr (1999) also reported that treatment that focused on specific cognitive skills—“the cognitive neuropsychological approach”—resulted in better generalization of improvements to untrained tasks, such as the Communicative Abilities in Daily Living (CADL; Holland, 1980), than treatment that focused on a particular functional activity.

Limitations

Several authors have argued that cognitive neuropsychological models are simply models of cognitive tasks, not models of rehabilitation. That is, most current models of cognitive processing provide no direct motivation for specific treatment strategies. For example, knowing the patient’s level of disruption in the naming process does not guide the clinician as to how to treat the problem (see Caramazza, 1989; Caramazza & Hillis, 1991; Wilson & Patterson, 1990 for discussion). In fact, such knowledge does not even guide the clinician as to what to treat. Should we treat the damaged component of processing, or should we try to exploit the preserved components in the hopes for more functional, but not normal, language processing? The models alone do not help us in this regard, because they do not specify which components are

subject to remediation, nor how the system might be reorganized following damage to circumscribed parts. Hence, choices of treatment must rely (as usual) on the clinician’s intuitions about what might help, the goals of the person seeking therapy, and ongoing evaluation of treatment effects. Empirical reports of improvement in functioning associated with specific treatment approaches in well-described cases of damage to selective components of language processing might give the clinician hope that a particular component is treatable. However, valid predictions about improvement in a different case of damage to the same component would also require evidence regarding the patient characteristics that influence outcome and the nature of damage to the impaired component (see Hillis, 1993; Hillis & Caramazza, 1994, for detailed discussion). In fact, even patients who have the “same” deficit with respect to the level of representation in some cognitive task do not consistently respond to the same treatment. It is not clear, from considering the model, whether the differential response to treatment is due to different forms of damage to the same component or due to different overall learning abilities, motivation, or other patient characteristics. However, some authors have described how patients with different deficits (within a computational model of lexical processing) have responded to different therapies, as shown by many studies cited in the chapters in this section.

Another limitation in applying these sorts of models to treatment is that the analyses required to determine the patient’s level of damage are often extremely time-consuming and may not be cost-effective (Schwartz, 1998). That is, with the recent limitations on the number of reimbursable therapy visits, and requirements to document improvement at each visit, it is often impractical to spend hours of time testing a patient to pinpoint precisely which components of each task are impaired. However, in other cases, such extensive evaluation may be justifiable. For instance, in the case of HG, whose deficits were quite complicated, it was difficult to know where to even begin treatment until damage to specific components of lexical processing were identified. She had undergone years of unfocused therapy for “cortical deafness” and other inaccurate psychiatric and language diagnoses, with virtually no improvement in language or communication, prior to careful analysis of her impairments. She made useful, albeit slow, gains after delineating her deficits. Furthermore, it is often possible to identify with some precision the impaired cognitive process(es) with relatively brief testing using carefully selected tasks and stimuli.

It has also been argued that treatment based on cognitive neuropsychological models fails to generalize across items or categories (for evidence for and against this claim, see Schwartz, 1998 and chapters in this section). Although this failure of generalization to untrained items or categories is far from ideal, item-specific gains are better than no gains. Recall HG, a patient described earlier in this chapter as having a semantic impairment, demonstrated by identical

rates and types of semantic errors in all lexical tasks (oral naming, written naming, auditory word/picture matching, written word/picture matching, and writing to dictation). HG's improvements in oral production were item-specific, and her improvements in semantic processing generalized only to items that were semantically related to trained items (see also Hillis, 1998). Nevertheless, as mentioned above, HG's gains served a significant function. She gradually regained a functional vocabulary for daily activities (such as dining out and riding public transportation) and a vocabulary specific to the job for which she was training (as a stock clerk in a fabric store). Her item-specific gains, which generalized well across tasks and settings, thus permitted HG to obtain and maintain a job and independence in activities of daily living. At the time of this writing HG, who was globally aphasic for more than 6 years, remains gainfully employed.

Similarly, the "phonologic" therapy with a patient HW (see above and Chapter 25, this volume) that involved cued oral reading treatment seemed to result in improved access to specific phonologic representations in the output lexicon, irrespective of the setting. Like patient HG, patient HW produced mostly fluent speech with few content words before this item-specific therapy was initiated more than 5 years post-stroke. Her impairment was localized to the phonologic output lexicon (Fig. 22-1), because (1) she showed flawless performance in auditory word/picture and written word/picture matching tasks and was able to define both words and pictures she could not name, indicating that her processing of words and pictures was unimpaired through the level of the semantic system; (2) she produced accurate or recognizable written names of 100% of pictures, even though she could not produce the spoken name, indicating that semantics and access to the orthographic output lexicon were intact; and (3) she had perfect fluency, articulation, and repetition of words she could not name, ruling out a motor-speech deficit as the basis for her impaired spoken naming. HW's improvements in producing a trained set of words using the phonologic therapy were sufficiently rapid that she was able to receive treatment for many sets of words she selected. She was also observed to use trained words in conversation at home, in restaurants, and over the telephone in follow-up calls. In describing the "Cookie Theft" picture from the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1972), HW improved in the number of accurate content-units produced, from five before the phonologic treatment to 12 after treatment (c.f. Yorkston & Beukelman, 1980, for description of content-units). Furthermore, not only were her gains maintained more than a year after treatment, but additional gains were achieved: She later produced 15 content-units in describing the picture. The further progress was probably achieved in part through HW's oral-reading practice with her husband providing cues (which probably provided "treatment" of thousands of words).

Thus, item-specific gains that generalize across tasks and settings can lead to dramatic functional improvement resulting from therapy for naming and other oral production tasks. Gains that generalize across tasks but not always to other settings have also been reported for sentence production/comprehension therapies (see Mitchum & Berndt, Chapter 24, this volume). Several authors have reported not only generalization of improvements from comprehension to production (or vice versa) for the same items, but also generalization across trained and untrained sentence types (Ballard & Thompson, 1999). And, as previously discussed, improvements in many model-based treatments do show generalization to untrained stimuli as well as untrained tasks, if treatment addresses a process common to many stimuli or compensatory strategy that will result in improved access to a variety of stimuli.

An important limitation of conclusions reached about the results of a given treatment for an individual patient is that it is not possible to determine, *a priori*, which other patients will respond to the same treatment in the same way. Ideally, we would like to be able to conclude that treatment of a specific component of cognitive processing would help all patients with damage to that component. Unfortunately, such conclusions are not possible in light of our current levels of theory. As noted previously, we have no way of knowing how any specific mechanisms are actually modified by our interventions (see Baddeley, 1993 and Hillis, 2005 for discussion). Thus, the observation that a "semantic" approach was associated with improved naming in a patient with a semantic deficit does not directly imply that all patients with semantic deficits will show improved naming with that treatment. Earlier studies have shown that sometimes patients with putatively "the same" locus of impairment do not respond to the same treatment approach, but different approaches have been beneficial for individuals, and sometimes patients with different loci of damage in the lexical system respond to the same treatment (Fridrikson et al., 2005; Hillis, 1993; Hillis & Caramazza, 1994; Rapp, 2005). This finding is not unexpected, since the characteristics of the patient and the form of impairment at any given level of processing that may influence treatment outcomes have yet to be precisely defined. Although studies have identified recovery as a function of a variety of individual factors, these studies have not been integrated with (a) the specific cognitive mechanisms that are impaired in the patient, and (b) the cognitive mechanisms that might be influenced by the treatment.

This inability to predict whether a particular patient will benefit from a given treatment strategy is certainly not specific to the approach described in this chapter, which relies on a cognitive analysis of patient performance, but applies equally to other "schools" of treatment.

In summary, cognitive neuropsychological models of specific language tasks are useful for understanding the nature of impairment consequent to brain damage in individual

patients but do not constitute a theory of language rehabilitation. The latter would require motivated hypotheses about how mental representations or transformations are modified, how particular interventions bring about these modifications, and how particular patient characteristics influence response to treatment. Moreover, a theory of rehabilitation would need to specify the interactions among these variables, in order to make predictions about results of a given treatment approach. Nevertheless, the following chapters illustrate how cognitive neuropsychological models can be useful in planning and designing individualized therapy, selecting stimuli, and predicting patterns of generalization across tasks or stimulus types.

INTRODUCTION TO THE CHAPTERS IN THIS SECTION

Scope of the Section

There has been no attempt to cover every domain of cognition in this section, nor even every domain of language. Instead, we have chosen to include chapters on those domains that have received the most attention in the cognitive neuropsychological literature. Therefore, there are chapters on spoken-word comprehension and naming, written-word comprehension and production (reading and writing), and sentence comprehension and production. Perhaps as a consequence of the number of studies in these areas, the models in these domains are the most clearly articulated and most widely (although not universally) accepted. Although each chapter will discuss models of tasks limited to that domain (e.g., a model of the cognitive processes underlying reading), it is important to understand that there is a great deal of overlap in the cognitive representations and processes that underlie reading, writing, naming, and word and sentence comprehension and production. For example, as discussed in the case of HG, it is likely that a single set of phonologic representations (a phonologic output lexicon) is accessed in the course of all tasks that have spoken-word output: oral reading, oral naming, repetition, oral sentence production, and spoken conversation. Similarly, a single semantic system is engaged in a variety of tasks that involve comprehension and/or production of words. Therefore, identifying the patient's problem in oral naming may require assessment of oral reading, comprehension, written naming, and so on. It is probably never possible to be sure of the level of damage by assessing performance on only one task.

It is also crucial to note that other cognitive abilities, such as attention and memory, are engaged in every language task. Impairments of sustained attention, selective attention, spatial attention, and/or short- or long-term memory can affect performance on any given language task. Although there are models and theories of each of these areas, we have not addressed them, since the focus of this book is on lan-

guage intervention. Other important domains that have received much attention in the psychological literature are procedural and episodic memory, and the so-called "executive functions" such as planning, judgment, organization (sequencing, switching and maintaining tasks, etc.). Investigations in these domains have not yielded the types of models of specific component cognitive representations of the type we are considering in these chapters. Nevertheless, awareness of deficits in these areas is often helpful in understanding patients' responses or failure of response to particular treatment strategies.

Content of the Chapters

In Chapter 23, Anastasia Raymer and Leslie Gonzalez Rothi describe clinical diagnosis and treatment of spoken-word comprehension and production. They identify impairments at different levels of cognitive processing that result in poor auditory word comprehension and/or poor oral naming. The authors further report rehabilitation strategies that rely on this type of diagnosis, made in view of a cognitive neuropsychological model of word comprehension and naming. In Chapter 24, Charlotte Mitchum and Rita Berndt discuss evaluation and rehabilitation of sentence comprehension and production based on cognitive neuropsychological models of sentence processing. They focus on issues of the relationship between theory and therapy and issues of generalization. Finally, in Chapter 25, Pelagie Beeson and Maya Henry describe how to identify an individual patient's underlying deficit in comprehension or production of written words. This chapter focuses on assessment and treatment of reading and spelling at the single-word level, and shows how treatment can generalize to improved reading and spelling in untrained tasks.

FUTURE TRENDS

This section illustrates the integration of speech-language pathology with cognitive neuropsychology and behavioral neurology (the three disciplines represented by the chapter authors). The authors have been involved in integrative research centers in Gainesville, Tucson, and Baltimore. Other excellent interdisciplinary centers for aphasia research and rehabilitation exist in Philadelphia, Ann Arbor, and Pittsburgh in the United States, and in Belgium (the Brussels Neuropsychological Rehabilitation Unit), the United Kingdom, Italy, the Netherlands, France, Germany, and Australia (see Appendix 22-1 for contact person and names of several such centers). Many centers are also collaborating with other disciplines in the field of cognitive science, such as artificial intelligence, linguistics, and neuroscience. For example, interdisciplinary collaboration at Moss Rehabilitation, Temple University, Carnegie Mellon, and elsewhere have led to the development of computational models of naming that

have been useful in understanding various forms of naming impairment (e.g., Dell et al., 1997b). It is expected that such collaborations are only a hint of what may come. Several authors have predicted that computational models of language may become important in directing rehabilitation as well (Plaut, 1996). Certainly, computational models are helping us to understand learning and recovery, two crucial aspects of rehabilitation. Functional imaging techniques (such as functional magnetic resonance imaging [fMRI], positron emission tomography [PET], magnetic resonance perfusion, and spectroscopy) have been used in many studies to shed light on physiologic aspects of learning and recovery. Perhaps more importantly, anticipated advances in cognitive neuroscience in understanding how the brain recovers through reorganization of neural representations (Hillis, 2005; Jenkins & Merzenich, 1987; Jenkins, Merzenich, & Recanzone, 1990), and how the brain changes with learning, through changes in neural synaptic strength and genetic expression (Kandel, Schwartz, & Jessell, 1995), will surely contribute to developing an interdisciplinary theory of aphasia rehabilitation.

► **Acknowledgments**—This work was supported in part by NIH grant RO1 DC05375. The author is grateful to Pelagie Beeson, Charlotte Mitchum, Roberta Chapey, Anastasia Raymer, and Leslie Gonzalez Rothi for helpful comments on an earlier draft.

KEY POINTS

Chapters 23 to 25 will illustrate how therapy for a particular patient with aphasia can be guided by pinpointing his or her impairment to one more components of a model of the cognitive processes underlying the specific language task to be treated. This approach to intervention has its foundations in the fields of cognitive neuropsychology, speech-language pathology, and behavioral neurology.

1. Most strategies utilized are not truly model-based interventions, since the strategies themselves rely more on clinical intuitions and experience than on the model of the language task to be treated.
2. Reference to a model of the task being treated often allows the therapist to understand when, how, and why a particular therapy procedure is likely to have an effect on performance.
3. Models can also sometimes help us to understand why therapy “works” for some individuals with aphasia and not for others.
4. Future developments through cooperative efforts in these fields, as well as in other areas of cognitive neuroscience, may further guide our models and our therapies.

APPENDIX 22.2

Glossary

Behavioral neurology—branch of neurology devoted to understanding the neural mechanisms of behavior and cognition.

Cognitive neuropsychology—branch of psychology devoted to understanding normal cognitive processes through the study of people who have sustained brain damage.

Computational model—computer simulation of a particular task.

Lexical processing—mental representations and processes involved in comprehension and production of single words in various modalities.

Orthographic representation—stored spelling of a word.

Phonological representation—stored “sound” of a word.

Semantic representation—stored meaning of a word.

Chapter 23

Impairments of Word Comprehension and Production

Anastasia M. Raymer and
Leslie J. Gonzalez Rothi

OBJECTIVES

The objectives of this chapter are to describe a model of lexical processing that represents the mechanisms involved in word comprehension and production; delineate impairments in lexical comprehension and production with respect to breakdown of the mechanisms of lexical processing; review evidence for clinical application of this model for assessment, recovery, and treatment of lexical impairments; and consider the limitations and future trends in the use of lexical models in the clinical setting.

DEFINITION

Impairments of word comprehension and, in particular, word retrieval, are pervasive among patients with acquired aphasia (Goodglass, Kaplan, & Barresi, 2001). The nature of the lexical impairments, most often tested in constrained picture-recognition and naming paradigms, vary among patients in terms of their cognitive and neural bases. Traditional methods of aphasia-syndrome classification are usually insufficient to distinguish the mechanisms of lexical failure that occur among patients with aphasia—differences that may influence treatment decisions for those patients (Nickels, 2002; Raymer, Rothi, & Greenwald, 1995). An alternative approach to characterize the diverse lexical impairments that patients may display has its foundation in cognitive neuropsychology (CN) (Coltheart, 2001; Hillis, 2001), the study of brain-impaired individuals to provide evidence for theories of cognitive processing, including language. In the past two decades, much research has transpired using the CN approach as a backdrop to clinical

assessment and treatment of impairments related to lexical comprehension and production.

MODEL OF LEXICAL PROCESSING

Figure 23–1 depicts a model of lexical processing that forms the basis for this discussion of lexical impairments for spoken words. Recent years have seen an evolution in the structure and functioning of lexical models toward a more computational approach, such as that described by Nadeau and Rothi (see Chapter 19). Nonetheless, cognitive neuropsychological models, as shown in Figure 23–1, have served as a backdrop to a large clinical literature examining lexical impairments in aphasia, and will form the basis for this discussion of assessment and treatment of lexical impairments. Although the details vary to some extent across versions of such models, the fundamental components are similar (e.g., Goldrick & Rapp, 2007; Hillis, 2001; Lambon Ralph, Moriarty, & Sage, 2002; Nickels, 2001). The model includes a complex system of distributed and interconnected modules that allow for processing of different types of lexical information in cascade fashion (Chialant, Costa, & Caramazza, 2002). The activation of peripheral sensory structures with some form of sensory input, such as spoken or written words or viewed objects, triggers cognitive mechanisms in the central nervous system to recognize, conceptualize, and respond to that input. Subsequently, peripheral motor processes allow for planning and executing a response to the stimulus in the form of speech, writing, or gesture. The focus of this chapter is on the mechanisms involved in processing spoken words, so the description will center on the central mechanisms critical for lexical phonologic processing. In addition, because lexical tasks often incorporate visual stimuli, we will also briefly consider the mechanism responsible for object recognition.

To acquire skill in any behavior implies that the person is more efficient in the production of that behavior than in the production of less-skilled behaviors. The central nervous system can increase efficiency by storing memories based on previous exposure to a stimulus such that subsequent pro-

Figure 23-1. Model of Lexical Processing.

cessing experiences with that information can be expedited (Rothi, Raymer, Maher, Greenwald, & Morris, 1991). The model of lexical processing shown in Figure 23-1 indicates that lexical abilities are dependent upon the integrity of a number of different types of stored representations. We will review the mechanisms that make up this complex system and the types of impairments that we might observe associated with dysfunction of these mechanisms. Finally, we will mention the neurologic site of lesion often associated with dysfunction of the lexical mechanisms to suggest neural regions that mediate aspects of lexical processing.

Recognition Level Mechanisms

Following early sensory processing, stimulus-recognition processes allow for activation of representations that closely correspond to the input stimulus. Recognition represents the point at which a stimulus is identified as familiar compared to other physically similar stimuli (Tyler, 1987). It allows the individual to say “yes” when asked whether a stimulus is a familiar object or word. It does not yet allow the individual to state what that object or word means. Recognition processes provide a processing advantage that allows us to react quickly to whatever form the stimulus exemplar may take. For example, if the word is spoken with

an accent or written in an unusual font, or if an object is viewed from an unusual orientation, stimulus-recognition mechanisms allow for the quick realization that the stimulus is familiar in spite of input perturbations.

A number of lines of evidence support the notion that recognition-level processes are modality specific (Hillis, 2001), that is, that separate components represent knowledge for different types of familiar sensory stimuli (Fig. 23-1). The phonologic and orthographic lexical recognition stages represent stores of familiar spoken and written words, respectively. The object-recognition system stores memories of familiar objects. Other mechanisms for processing in other sensory modalities, such as visual gestures, touch, or smell, also may exist.

Visual Object Recognition

Impairments related to visual object representations will affect performance in lexical tasks that require the patient also to process viewed objects. For example, on clinical examination, patients may be impaired in picture-naming, and they may have difficulty in word-to-picture matching tasks that test comprehension. In contrast, the same patient may be able to name in response to other sensory inputs, such as spoken definitions, or to demonstrate comprehension

with printed word-to-word matching tasks. That is, difficulty may occur only when visual stimuli are incorporated in the task.

Impairments may take different forms depending upon which stage of object processing is affected (Farah, 1990; Riddoch & Humphreys, 2001). “Agnosia” is the term used for failure (as a result of brain damage) to recognize a sensory stimulus, such failure not being attributable to dysfunction of peripheral sensory mechanisms. Dysfunction of early visual processes involved in developing a percept for the viewed object, prior to activation of visual object representations, may lead to apperceptive or integrative forms of visual agnosia (Lissauer, 1890/1988; Riddoch & Humphreys, 2001; Warrington & Taylor, 1978). These patients, who have adequate visual acuity, may be unable to copy a line drawing or even to match simple drawings. However, their stored object knowledge appears to be intact as they may be able to answer questions about the visual characteristics of named objects in visual imagery tasks. Patients with impairment of visual object representations have a form of visual associative agnosia (Riddoch & Humphreys, 2001), in which they can perform tasks dependent upon early visual processes such as matching line drawings or copying figures. Errors in naming may include visual misperceptions (e.g., “pen” for “dart”), or failures to respond (“I don’t know”) (Farah, 1990). Patients may be impaired in tasks requiring knowledge of the structure of a visual stimulus, such as distinguishing familiar from nonsense objects (visual object decision), drawing from memory, or answering questions about the visual characteristics of objects.

A phenomenon often discussed in the realm of visual object agnosia is optic aphasia, in which patients also experience naming failure restricted to the visual modality (modality-specific). They may, however, be able to describe the function of viewed objects, sort objects into categories, or gesture the appropriate use for the objects they are unable to name, arguing against visual agnosia in which meaning for viewed objects is not appreciated. One interpretation of optic aphasia is that it represents a visual-to-semantic access impairment in which visual object representations are unable to activate full semantic representations corresponding to the viewed objects (Hillis & Caramazza, 1995a, 1995b; Marsh & Hillis, 2005; Riddoch & Humphreys, 1987d). Thereby, some semantic information is available regarding a picture for the patient to sort by category or to provide an appropriate gesture, but the full semantic representation must be activated for accurate picture-naming to occur.

Several papers that have analyzed lesions in patients with visual agnosia and optic aphasia suggest brain regions critical for the neural representation of object knowledge (Iorio, Falanga, Fragassi, & Grossi, 1992; James, Culham, Humphrey, Milner, & Goodale, 2003; Marsh & Hillis, 2005; Schnider, Benson, & Scharre, 1994). Although bilateral-

posterior cerebral cortex lesions were commonly reported, researchers have also described visual associative agnosia in patients with unilateral left-posterior mesial cortex infarctions. Schnider and colleagues proposed that patients with visual agnosia tend to have less damage to the splenium of the corpus callosum, and apparently access and employ the impaired left-posterior hemisphere, which is a critical region for object recognition. Patients with optic aphasia, in contrast, have more extensive splenial lesions, preventing access to the damaged left hemisphere, and presumably must rely on the right hemisphere’s contribution to visual and semantic processing (Coslett & Saffran, 1989, 1992; Raymer, Greenwald, Richardson, Rothi, & Heilman, 1997).

Phonologic Recognition

Damage affecting phonologic lexical recognition (Fig. 23-1) leads to impairments in any tasks that require patients to process spoken words, such as auditory word-to-picture matching tasks, naming to spoken definitions, or gesturing to verbal commands. Some general parallels may be seen between the impairments of object processing and phonologic lexical processing as represented in patients with pure word deafness (Boatman, 2002; Franklin, 1989; Polster & Rose, 1998; Vignolo, 1982). Some patients seem to have a pre-lexical impairment that affects processing of phonemic and other types of acoustic stimuli (Buchman, Garron, Trost-Cardmone, Wichter, & Schwartz, 1986; Buchtel & Stewart, 1989), similar to apperceptive visual impairments. In contrast, some patients reported with Wernicke’s aphasia seem to have impairments of the phonologic lexicon as represented by modality-specific auditory comprehension impairment (Ellis, Miller, & Sin, 1983; Hillis, Boatman, Hart, & Gordon, 1999; Semenza, Ciolotti, & Denes, 1992). Because the reported patients had retained comprehension for written material, semantic processing was judged to be intact and the auditory comprehension impairment presumably related to presemantic, phonologic lexical processing. Some early theories had proposed that the processing of the orthographic word forms occurred subsequent to phonologic activation (Caplan, 1993), a dependency that leads to the prediction that patients with phonologic recognition dysfunction should also have impaired reading comprehension. Thereby, patients with selective impairment for phonologic input in the face of intact reading comprehension provide evidence for distinct input mechanisms for orthographic and phonologic lexical processing.

The phonologic correlate of optic aphasia may be represented in some patients with word-meaning deafness (Francis, Riddoch, & Humphreys, 2001; Kohn & Friedman, 1986). For example, one report described a patient who could process the phonologic components of words as indicated by preserved ability to discriminate and repeat words, and to perform auditory lexical decision, which presumably

depends upon the integrity of phonologic input representations (Franklin, Turner, Ralph, Morris, & Bailey, 1996). Although the patient demonstrated intact reading comprehension, he had difficulty in auditory-comprehension tasks, particularly for abstract, low-frequency words. Franklin and colleagues attributed the failure to an impairment in activating the full semantic specification for spoken words, an argument similar to that proposed for optic aphasia.

Some studies have described the neural correlates of phonologic lexical recognition impairments. Individuals with pure word deafness typically have bilateral temporal or subcortical left-hemisphere lesions affecting input to Wernicke's area (Polster & Rose, 1998), suggesting that these regions are important for prelexical stages of phonologic processing. Cases of Wernicke's aphasia associated with left-posterior perisylvian lesions, including Wernicke's area, (Kertesz, Lau, & Polk., 1993; Weiller et al., 1995) may be characterized by an impairment of phonologic recognition. Therefore, it appears that the posterior portion of the left superior temporal cortex is a critical neural region subserving phonologic lexical knowledge.

Semantic Processing

Once a recognition-level representation achieves sufficient activation, it initiates activity in the semantic system (Fig. 23-1). Semantic representations contain stored knowledge shared by speakers of a language, including meanings for words, objects, or actions. The lexical model incorporates a unitary semantic system that can be accessed from any input modality and can access any output mode as appropriate. Semantic representations presumably involve a network of information about words, objects, and ideas that includes superordinate, coordinate, associated, and subordinate relationships. Discussion in cognitive neuropsychology continues regarding the structure of the semantic system (Funnell, 2000). Some proposals view semantic representations as modality-independent in that a single unitary semantic system provides meaning for a stimulus, regardless of input modality or output mode (Chialant et al., 2002; Hillis, Rapp, Romani, & Caramazza, 1990; Shelton & Caramazza, 2001). A contrasting view holds that the semantic system is structured into subsystems for different sensory information and knowledge systems, such as verbal semantics and visual semantics (Allport, 1985; Paivio, 1986; Saffran, 1997; Shallice, 1988).

A patient with a semantic impairment will have difficulty performing any tasks that require semantic mediation, including comprehension of spoken and written words, interpreting the meanings of objects and gestures, and spoken and written picture-naming. Performance in oral word-reading and writing to dictation may also be affected if alternative sublexical letter-sound conversion mechanisms are unavailable for decoding or encoding written words. If the

unitary semantics system proposal is correct, the performance of individuals with semantic system impairment should demonstrate quantitatively and qualitatively similar impairments across lexical tasks. Researchers have described this association of impairments in some patients with vascular lesions (Hillis et al., 1990; Howard & Orchard-Lisle, 1984) and progressive neurologic impairments (Chertkow, Bub, & Seidenberg, 1989; Hodges & Patterson, 1996; Lambon Ralph, Ellis, & Franklin, 1995; Raymer & Berndt, 1996).

Researchers have also described individuals with aphasia whose naming and comprehension impairments fractionate, demonstrating selective preservation or impairment for specific semantic categories. Patients have demonstrated impairments for categories such as living and non-living things (Laiacina, Capitani, & Caramazza, 2003; Rosazza, Imbornone, Zorzi, Farina, Chiavari, & Cappa, 2003; Silveri, Gainotti, Perani, Cappelletti, Carbone, & Faxio, 1997; Warrington & McCarthy, 1983); fruits and vegetables (Farah & Wallace, 1992; Hart, Berndt, & Caramazza, 1985); tools (Ochipa, Rothi, & Heilman, 1989); and animals (Caramazza & Shelton, 1998; Ferreira, Giusiano, & Poncet, 1997; Hart & Gordon, 1992; Hillis & Caramazza, 1991). At first, one might use these unusual dissociations to infer that the semantic system is structured in a fashion that represents these specific categories of knowledge. Warrington and her colleagues (Warrington & McCarthy, 1983, 1987, 1994; Warrington & Shallice, 1984) attributed semantic category dissociations to the type of semantic information that is a defining characteristic for that category. They propose that category-specific deficits arise because the semantic system is structured along lines of sensory modalities and output modes in a complex network of subsystems (Allport, 1985; Saffran, 1997). Disruption of selective subsystems leads to impairments that affect semantic categories for which that subsystem contributes critical semantic information. For example, because visual semantic information may be critical for distinguishing exemplars within the category of animals, impairment of the visual semantic subsystem results in category-specific impairment for animals (Warrington & Shallice, 1984).

In contrast, Caramazza and colleagues (Caramazza, Hillis, Leek, & Miozzo, 1994; Caramazza & Shelton, 1998; Laiacina et al., 2003) have argued for a unitary semantics account of category-specific impairments. Rather, Caramazza and Shelton (1998) proposed that category-specific impairments arise because of texturing in the interconnections of properties comprising semantic representations for members of a category of objects. If critical shared properties happen to be localized in a neural region that is damaged by neurologic disease, any concepts that include those properties in their semantic representations will be affected. In particular, items within certain natural categories such as plants or animals may have a number of highly interconnected

properties, making all exemplars of the category vulnerable upon neurologic injury and leading to category-specific deficits.

Regarding neural correlates of semantic-system impairments, lesion analyses in patients with semantic dysfunction provide clues as to the neural instantiation of semantic knowledge. In particular, left-hemisphere posterolateral cortical regions appear to play a critical role, as these regions are implicated in individuals with degenerative dementias leading to semantic dysfunction (Graham, Patterson, & Hodges, 1998; Hodges, Patterson, Oxbury, & Funnell, 1992; Kertesz, Davidson, & McCabe, 1998). Left posterior temporal regions also are compromised in patients with acute vascular lesions (Foundas, Daniels, & Vasterling, 1998; Hart & Gordon, 1990; Hillis et al., 2001; Hillis, Chaudhry, Davis, Kleinman, Newhart, & Heidler-Gary, 2006; Raymer, Foundas et al., 1997). In addition, the left thalamus also seems to be implicated in the complex semantic network. Transcortical sensory aphasia, a syndrome associated with semantic dysfunction, is observed in many individuals with vascular lesions affecting the left thalamic nuclei (Crosson, 1992; Raymer, Moberg, Crosson, Nadeau, & Rothi, 1997).

Neural regions associated with category-specific impairments also suggest critical regions representing specific aspects of semantic knowledge. Viral encephalitis, which has a predilection for damaging the inferior and mesial temporal cortex, has been associated with impairments for the category of living items (Warrington & Shallice, 1984). Damasio, Grabowski, Tranel, Hichwa, and Damasio (1996) investigated the location of lesions associated with impairments for three different semantic categories: (1) persons: left temporal pole lesions; (2) animals: left inferotemporal lesions; (3) tools: left temporoparietal-occipital lesions. Finally, Crosson, Moberg, Boone, Rothi, and Raymer (1997) reported a category-specific naming impairment for medical terminology associated with a left-thalamic hemorrhage. Findings from these lesion studies provide further support that damage to left-posterior temporoparietal-occipital and thalamic regions may lead to disruption of semantic processing.

Lexical Phonologic Output

Once recognition of a word or object has occurred and meaning has been activated, a response is initiated with activation of lexical representations in the output lexicons (Fig. 23-1). Evidence suggests that the output lexicons are modality-specific as there are separate stores for familiar spoken and written words as well as for gestures (Rothi, Ochipa, & Heilman, 1997). In this discussion, we focus on the mechanism for spoken words: lexical phonologic output processing. There is some indication that words are stored in phonologically similar groupings and that root morphemes are separated from affixes (e.g., “walk+” “-ed”, “-ing”, “-s”) (Badecker &

Caramazza, 1991; De Bleser & Cholewa, 1998; Miceli & Caramazza, 1988). Word class distinctions (e.g., nouns and verbs) also appear to be represented at the level of the output lexicon (Caramazza & Miozzo, 1997; Chialant et al., 2002; Hillis, 2001). Factors such as age of acquisition and word frequency seem to exert their influence at this stage of processing (Goldrick & Rapp, 2007).

Dysfunction of lexical phonologic output processing leads to impairment in all verbal tasks that depend on the integrity of the stored phonologic representations. Patients will have difficulty in all oral naming tasks (e.g., picture-naming, name to definitions), and in oral reading, particularly for exception words (e.g., “choir,” “yacht”), as sublexical grapheme-phoneme assembly processes are insufficient to derive accurate pronunciations for those words. Production errors may take a variety of forms, including semantic and phonemic paraphasias, no responses, or neologisms (Hillis, 2001), depending on the nature and severity of lexical phonologic dysfunction. Some individuals may have greater difficulty activating the output representations (Caramazza & Hillis, 1991; Le Dorze & Nespoulous, 1989; Miceli, Giustolisi, & Caramazza, 1991), leading to semantic or no-response errors. Others may have a disturbance affecting the internal structure of representations, resulting in neologistic responses (Kohn, Smith, & Alexander, 1996) or phonemic paraphasias (Ellis, Kay, & Franklin, 1992).

Researchers have inferred key features of the structure of the lexical system from observed lexical dissociations among brain-damaged patients. For example, some patients demonstrate retained auditory comprehension for words they are unable to pronounce (Kay & Ellis, 1987; Maher, Rothi, & Heilman, 1994; Nickels & Howard, 1995), a dissociation providing evidence for the input/output distinction for lexical phonologic processing. Some patients have selective impairments for phonologic production in the context of retained performance in written word spelling (Bub & Kertesz, 1982; Caramazza & Hillis, 1990), a dissociation that supports the distinction between phonologic and orthographic output stores, the latter remaining intact in some patients with phonologic output impairments. Nevertheless, it is often the case that neurologic injury affects multiple lexical mechanisms, so patients may be impaired in a variety of lexical tasks (e.g., impairments of both verbal and written output, Caramazza, Berndt, & Basili, 1983; Miceli et al., 1991; impairments of both phonologic input and output, Ellis et al., 1983, Kohn et al., 1996).

Whereas many studies of lexical retrieval impairments have focused largely on noun retrieval, other studies have also described disturbances of verb retrieval in some patients (Damasio & Tranel, 1993; Miceli, Silveri, Villa, & Caramazza, 1984; Shapiro & Caramazza, 2003; Zingeser & Berndt, 1990). Several patients have now been described who have more difficulty with nouns than verbs or with verbs than nouns, but within only one output modality, spoken or

written production (Caramazza & Hillis, 1991; Hillis & Caramazza, 1995c; Hillis, Tuffiash, & Caramazza, 2002). These patterns of dissociation provide evidence that the grammatical class distinction observed only within a specific mode of output is represented at the level of the output lexical representations.

Distinct neural regions appear to be associated with impairments affecting lexical phonologic output. In particular, researchers typically have described noun-retrieval impairments in patients with fluent aphasia and left-posterior perisylvian cortex lesions, often including temporal regions (Damasio & Tranel, 1993; Miozzo, Soardi, & Cappa, 1994). In particular, area 37 at the inferior temporal/occipital junction has been associated with impairments of phonologic lexical retrieval (Antonucci & Beeson, 2004; Hillis et al., 2001, 2006; Raymer, Foundas et al., 1997). In contrast, impairments are worse for verb retrieval than noun retrieval in association with nonfluent aphasia and left-inferior frontal lesions (Caramazza & Hillis, 1991; Damasio & Tranel, 1993; Shapiro & Caramazza, 2003; Zingeser & Berndt, 1990).

In summary, studies examining impairments of lexical processing in a variety of patients with aphasia have provided evidence for a complex, distributed system of lexical processing as depicted in Figure 23-1. Overall, it is the left hemisphere that plays the key role in representing lexical knowledge, although the right hemisphere may contribute to certain aspects of lexical-semantic processing (Joanette & Goulet, 1998). Controversies persist regarding details of processing and representation in the lexical system; for example, whether there is an intervening amodal lexical representation stage (e.g., lemma level) between semantic and lexical phonologic output processing. Nevertheless, this general model provides a rational theoretical basis for guiding this discussion of clinical management for patients with lexical impairments.

CLINICAL APPLICATIONS OF THE LEXICAL MODEL

The model of lexical processing provides a framework for exploring the implications of the cognitive neuropsychological (CN) approach as applied within the clinical process. The CN framework may influence the form that lexical assessment takes. In addition, researchers have applied this approach to analyses of treatment of lexical impairments in patients with aphasia. The CN approach also has direct implications for predictions regarding generalization of treatment effects.

Assessment

The goal of assessment within cognitive neuropsychology is to characterize a patient's language impairments with respect

to a cognitive model. The model of lexical processing shown in Figure 23-1 provides a basis for discussion of impairments specifically related to spoken word comprehension and production. Raymer and colleagues (1995) illustrated how a CN analysis played a significant role in distinguishing the lexical impairments of two patients whose standardized aphasia assessments acutely indicated anomia. When clinicians evaluated the profound word-retrieval impairments in greater detail, it became clear that the two patients differed considerably in the cognitive mechanisms for their word-retrieval impairments. One patient had an impairment affecting semantic activation of the lexical output mechanisms (Raymer, Foundas et al., 1997). The other had impairments affecting at least two stages of lexical processing: visual object activation of the semantic system, and semantic activation of lexical output (Raymer, Greenwald et al., 1997). Assessment results then had consequences for treatment for the word-retrieval impairment in the second patient (Greenwald, Raymer, Richardson, & Rothi, 1995). The challenge to clinicians is to tailor assessments to evaluate the integrity of the lexical mechanisms.

Mode/Modality Comparisons

A key concept in an assessment geared to identifying impairments in the lexical system is mode/modality comparisons. The lexical assessment should include a variety of single-word processing tasks in which the clinician systematically varies input modalities and output modes, and analyzes patterns of performance for tasks sharing modalities/modes of processing. Table 23-1 lists a number of lexical tasks that result when combining input modalities (auditory verbal, written, viewed objects) and output modes (speech, writing, gesture). The lexical assessment typically includes key tasks such as oral picture-naming, written picture-naming, naming to spoken definition, oral word reading, writing to dictation, auditory word comprehension, and written word comprehension, among others. Published psycholinguistic tests are available that allow systematic assessment of lexical processing (e.g., Psycholinguistic Assessments of Language Processing in Aphasia, Kay, Lesser, & Coltheart, 1992), and several research groups also have developed experimental batteries (Hillis et al., 1990; Raymer et al., 1990; Roach, Schwartz, Maratin, Grewel, & Brecher, 1996; Zingeser & Berndt, 1990).

Lexical Stimuli

A second important consideration in lexical assessment is the selection of appropriate stimulus materials. As tasks contrast modalities/modes of processing, it is important, to the extent possible, to employ the same set of stimuli across tasks. For example, in the Florida Semantics Battery (Raymer et al., 1990), we incorporated the same set of 120 nouns across tasks. (See Appendix 23-1 for the full set of 120

TABLE 23–1

Lexical Tasks to Include in Assessment

Output Tasks	Input Tasks
*Oral picture-naming	*Auditory word-to-picture matching
*Written picture-naming	*Written word-to-picture matching
*Oral naming to spoken definitions	Auditory word-picture verification
Written naming to spoken definitions	Written word-picture verification
*Oral word-reading	*Semantic-associates matching
*Writing to dictation	Auditory lexical decision
Name to tactile-object presentation	Written lexical decision
Name to environmental sounds	Category sorting
Gesture to command	
Gesture to viewed objects	

*Indicates key tasks in the general lexical assessment.

nouns.) Patients complete blocks of stimuli systematically across experimental tasks to control for effects of repeated exposure to the same stimuli. In this way, the clinician can attribute differences observed across tasks to the modality of processing and not to differences in stimulus variables.

On the other hand, there will be times when the clinician wants to evaluate performance for contrasting sets of materials, for example, when contrasting performance for nouns versus verbs, or for different semantic categories. In many studies examining factors influencing word retrieval in patients with aphasia, investigators often have discussed the effect of word frequency, as higher-frequency words are named better than lower-frequency words (Capitani & Laiacina, 2004; Raymer, Foundas et al., 1997; Zingeser & Berndt, 1988). However, carefully controlled studies have demonstrated that word frequency has a less potent effect on lexical processing than factors such as imageability, length, familiarity, and, especially, age of acquisition (Bell, Davies, Hermann, & Walters, 2000; Colombo & Burani, 2002; Cuetos, Monsalve, & Perez, 2005; Hirsh & Ellis, 1994; Kremin et al., 2001; Nickels & Howard, 1994, 1995) (Table 23–2). Words learned early in life are particularly resilient. Therefore, the clinician should evaluate the effect such variables have on their patient's performance, as certain factors may have implications for which materials are chosen for use in treatment. Several online resources are available for determining the psycholinguistic attributes of stimuli (e.g., MRC data base, Center for Research in Language data base).

Comprehension Tasks

In tasks that assess comprehension of single words, it can be difficult at times to detect an impairment, as the patient often can provide a correct response, sometimes by guessing. In word-to-picture matching tasks, individuals may

respond correctly to an item on the basis of only basic semantic information if a target picture (e.g., “apple”) and the distractor pictures are unrelated (e.g., “apple,” “chair,” “hammer,” “dress”) (Raymer & Berndt, 1996). For this reason it is important to evaluate comprehension performance in the context of semantically related distractors (e.g., “apple,” “orange,” “banana,” “grapes”), which will require subjects to activate more specified semantic information to derive the correct answer.

An alternative task to assess comprehension is picture-word verification, in which the patient sees a picture and must decide (yes-no) whether a given word is the correct label. To be credited with a correct response, the patient must verify (yes) the correct name and reject foil names (no) that are semantically or phonologically related to the target

TABLE 23–2

Linguistic Factors That May Affect Performance for Items Within Lexical Tasks, with Selected Normative References

Word frequency (Francis & Kucera, 1982)
Grammatical category (noun, verb, functor)
Semantic category (living items, fruits, animals)
Lexicality (word, nonword)
Regularity (Berndt, Reggia, & Mitchum, 1987; regular spelling-“mat,” exceptional spelling-“yacht”)
Age of acquisition (Gilhooly & Logie, 1980)
Imageability (Coltheart, 1981; Gilhooly & Logie, 1980)
Operativity (Coltheart, 1981; tools and objects tools act upon)
Length (syllable length, phoneme length)
Familiarity (Snodgrass & Vanderwart, 1980)

word. Breese and Hillis (2004) compared performance in word-picture matching and word-picture verification tasks in a large sample of participants with left-hemisphere stroke. With 78% of participants performing more poorly in verification than matching, and only 8% showing the opposite pattern, the verification task was much more sensitive for identifying subtle deficits in word recognition. Semantic foils were more problematic than phonologic foils, suggesting the types of foils that might be more sensitive to mild comprehension impairments.

Error Patterns across Lexical Tasks

Another key concept to consider in the lexical assessment is the pattern of errors produced across tasks. Table 23-3 provides a list of some typical errors observed for verbal responses in lexical tasks (Mitchum, Ritgert, Sandson, & Berndt, 1990). The types of errors may provide clues as to the mechanism of a patient’s lexical impairment. The same quantitative and qualitative pattern of errors should be observed in all tasks that engage the impaired mechanism.

TABLE 23-3

Types of Production Errors Commonly Observed in Lexical Tasks

Error Type	Description
Visual	In object-naming, names of objects sharing visual characteristics, e.g., “pencil” for “screwdriver”; in oral reading, words that share orthography, e.g., “chain” for “choir”
Semantic	
Superordinate	Semantic category name for the viewed object or word
Coordinate	Name of alternative item within the semantic category, e.g., “apple” for “pear”
Associate	Words bearing some relationship (e.g., function, location, attribute) to the target picture or word, e.g., “pound” for “hammer”
Circumlocution	Description of the semantic attributes of the object or word
Phonemic	Response sharing phonemic attributes of target; at times is a real word, e.g., “trick” for “truck,” or nonword, e.g., “trut” for “truck”
Unrelated	Responses bearing no relationship to target, e.g., “cow” for “lamp”
No response	Refusal or inability to retrieve response, e.g., “I don’t know”

For example, a deficit of semantic processing will affect performance in all comprehension and naming tasks (Hillis et al., 1990). Dysfunction of lexical phonologic output will result in parallel patterns of impairment in all verbal production tasks (e.g., oral naming of pictures and oral reading of single words with exceptional spellings) (Caramazza & Hillis, 1990).

Examination of the type of error itself within one lexical task is not sufficient to distinguish the level of lexical impairment responsible for the error. Semantic errors in picture naming are a case in point (Hillis, 2001). For example, for the target picture of a carrot, semantic-naming errors may include responses such as “vegetable” (superordinate), “celery” (coordinate), or “rabbit” (associated). On the surface, one might assume that these errors represent semantic-system dysfunction (see Fig. 23-1). Indeed, in some patients, semantic errors may represent semantic-system impairment (Hillis et al., 1990; Howard & Orchard-Lisle, 1984). Caramazza and Hillis (1990) describe a patient who produced semantic errors only for oral picture naming and oral word reading, but none in written picture naming and writing to dictation, suggesting that the semantic errors arose from a disturbance of the phonologic lexicon. In contrast, patients with optic aphasia often produce large numbers of semantic errors in picture-naming tasks (oral and written), but no semantic errors in naming to definition (Hillis & Caramazza, 1995a; Raymer, Greenwald et al., 1997), a pattern that may represent an impairment of visual object activation of the semantic system. These observations underscore the need to analyze error patterns across lexical tasks to develop an accurate hypothesis regarding the source of the lexical error (Raymer & Rothi, 2000).

Stage-Specific Analyses

Many lexical tasks involve processing at multiple stages in the lexical system. It is necessary to contrast performances across tasks sharing processing at one stage to develop a precise hypothesis about the nature of the impairment affecting performance at that stage. In this section we will review tasks that the clinician may administer to assess performance at each stage of lexical processing.

Visual Object Representation Tasks

Tasks that require processing of familiar pictures will depend on the integrity of visual object representations. Therefore, general tasks such as object naming and word-to-picture matching provide an initial screening for this mechanism. Object-recognition impairment is suspected if performance improves for contrasting tasks that don’t require picture or object processing (e.g., name to definitions, word-to-word matching), or when patient responses in picture naming represent visually similar objects (e.g.,

“pencil” for “screwdriver”). Tasks that more directly target processing by visual object representations require subjects to determine the familiarity of objects or to use knowledge of the visual form of objects. Object decision, which requires a patient to decide whether a viewed stimulus is a familiar object, presumably depends on an intact visual object representation. Similarly, drawing from memory or answering questions about visual attributes of objects (i.e., visual imagery) also may tap this object-recognition process. Because impairments of object recognition may take a number of forms, tasks such as copying and matching line drawings may be necessary to distinguish early object-processing impairments from impairments affecting visual object representations themselves. The key feature is that impairment will be specific to the visual modality.

Lexical Phonologic Recognition Tasks

Any tasks that present stimuli through the auditory verbal channel will require activation of lexical phonologic recognition. Testing will include tasks that are part of the general lexical assessment, such as auditory word-picture verification (especially in the presence of semantic distractors), naming to spoken definitions, and gestures to verbal command. As in visual object representations, stage-specific phonologic tasks require patients to process auditory aspects of familiar phonologic stimuli. Auditory lexical decision, in which patients decide whether a given stimulus is a real or nonsense word, is such a task. Additional phonologic tasks such as phoneme discrimination, repetition, or identification of familiar environmental sounds may be useful to determine whether the impairment for phonologic lexical information relates to pre-lexical auditory impairments. A modality-specific dysfunction is suspected if performance improves when stimuli are presented through other nonphonologic modalities, such as written or viewed object input, and when responses to phonologic stimuli suggest misperception or confusion with phonologically related words.

Semantic-System Tasks

All lexical comprehension and production tasks presumably depend upon adequate processing by the lexical-semantic system, regardless of input modality and output mode. However, performance for oral reading and writing to dictation of regularly spelled words may be spared in the face of semantic impairments if sublexical print-sound conversion processes remain intact. In practice, it may be possible for a brain lesion to cause extensive damage to lexical input and output stages simultaneously, leading to mode/modality-consistent impairments that mimic semantic dysfunction. It can therefore be useful to administer additional semantic tasks that require more specific processing of the semantic attributes of stimuli or that avoid the use of lexical stimuli. Sorting objects by category, systematically manipulating the distance between categories, may

help detect semantic impairment. Asking patients to provide definitions for words also taxes semantic processing. A semantic-associates task, such as the Pyramids and Palm Trees test (Howard & Patterson, 1992), may be useful to detect semantic impairments. In the semantic-associates task, participants match a target item (e.g., “carrot”) to a semantically associated item from several choices (e.g., associate-“rabbit”; distractors-“squirrel, cake”). This test can be sensitive to subtle impairments in semantic activation (Raymer, Greenwald et al., 1997).

Because semantic impairments can fractionate along the lines of specific semantic categories, it is useful to include tasks that are structured according to this dimension. Some experimental batteries incorporate the semantic category distinction (e.g., Florida Semantics Battery, see Appendix 23-1). Within standard aphasia tests, an astute examiner may notice either impaired or spared performance related to selective categories by noting errors and then exploring category distinctions with additional testing with relevant materials (e.g., animals, tools). It is also helpful to ask patients whether they notice problems for specific categories. During an extended hospitalization, one patient complained of experiencing great difficulty with medical words. Careful examination substantiated his complaint of a selective impairment for medical terminology (Crosson et al., 1997).

Clinicians may find it useful to develop informal sets of stimuli that include items from a variety of semantic categories that stress different types of semantic content. For example, visual information is purportedly an important characteristic of living categories such as animals, fruits, and vegetables; action output/operativity is relevant to categories of garage tools, kitchen implements, and office supplies. The results of testing that identifies selective categories of difficulty for a patient may allow the clinician to streamline efforts in rehabilitation.

Lexical Phonologic Output Tasks

On the general lexical assessment, tasks requiring verbal production of familiar words will require activation of lexical phonologic representations. Impairment in oral naming, oral word reading, or repetition tasks in the presence of good performance in auditory and reading comprehension, written naming, and writing to dictation leads one to suspect impairment of lexical phonologic output (Caramazza & Hillis, 1990). However, this dissociation may arise with subsequent post-lexical dysfunction (e.g., apraxia of speech). Furthermore, differences between nouns and verbs in word-retrieval tasks may indicate impairments of lexical phonologic output. It may be necessary to administer additional tasks to evaluate further the integrity of lexical phonologic representations. One such task is rhyme verification for picture pairs, in which the patient views two pictures and must determine whether their names rhyme (e.g., “whale-nail”).

The rhyming task will prove difficult for individuals who fail to activate a full phonologic lexical representation for the pictures (Hillis, 2002). Word-nonword repetition is another task that may help determine whether an impairment stems from lexical phonologic output or beyond. Patients with post-lexical impairments often have greater difficulty for nonword stimuli (Kahn, Stannard, & Skinner, 1998), whereas patients with lexical impairments may have greater difficulty with word stimuli (Hillis et al., 2001).

Summary of Assessment

Overall, the CN approach to assessment of lexical function is distinguished by its systematic examination of patterns of performance across modalities of input and modes of output. Rather than employing a specific assessment protocol, assessment will be individualized on the basis of deficits identified in preliminary testing. Additional testing will proceed as the clinician develops hypotheses regarding suspected levels of impairment.

The CN assessment approach has a number of advantages (Raymer et al., 1995). Many patients with extensive neurologic lesions have dysfunction affecting multiple levels in the lexical system. An in-depth assessment will frequently suggest not only what mechanisms in lexical processing are impaired, but also what mechanisms are spared. In addition, the clinician may identify specific linguistic factors that affect performance across tasks. These types of information may be beneficial as the clinician turns toward devising treatments for each patient.

Some clinicians may argue that in these days of limited resources, it is unrealistic to promote such a lengthy assessment. Clinicians may adapt these methods using a more circumscribed set of available materials (e.g., Breese & Hillis, 2004). For example, it might be possible to select 10 stimuli representing a variety of semantic categories and to vary mode/modality of processing for key lexical processing tasks listed in Table 23-1. A systematic assessment may indeed be more cost-effective as clinicians understand their patients' impairments and direct treatments in the most expeditious manner.

RECOVERY OF LEXICAL IMPAIRMENTS

Researchers have described diverse lexical impairments in individuals with a variety of neurologic disorders. In general, the etiology of the brain disorder and the size and extent of the brain lesion will have the greatest influence on the prognosis for recovery of lexical impairment (Rothi, 1997). Recently, investigators have described more detailed analyses of language recovery in order to identify lexical factors predictive of recovery from aphasia. Recovery analyses described by Kohn and colleagues (1996) and Laiacona, Capitani, and Barbarotto (1997) provide information to help clinicians pre-

dict which patients are likely to recover from lexical impairment. Kohn and colleagues examined recovery of neologistic verbal output in four subjects with lexical impairment related to lexical phonologic output processing; only two demonstrated substantial improvement after 6 months. The distinguishing characteristic in the nonrecovering subjects was a perseverative phonemic pattern in their neologisms at onset. The authors proposed that the patients who recovered had an impairment that affected retrieval of phonologic representations, whereas the two with no recovery had substantial loss of lexical phonologic representations.

Laiacona and colleagues (1997) described recovery of lexical abilities in two patients with category-specific lexical impairments for living items as compared to nonliving items. One patient was initially less impaired than the other and had normal performance for nonliving items across tasks. One year later, that patient had improved to normal levels of performance for living items as well. In contrast, the second patient was initially severely impaired across categories, with an advantage for items in the nonliving category. After 2 years, performance had improved significantly only for the category of nonliving items; living items remained severely impaired. The authors proposed that distinct mechanisms of word-retrieval failure led to different resolution of the category-specific impairments in the two patients. Like the argument of Kohn and colleagues (1996), an impairment characterized by loss of semantic representations was associated with more limited recovery than an impairment that affected semantic-system access to intact lexical output representations.

Recovery analyses may serve to distinguish hypotheses generated to account for lexical impairments in individuals with similar patterns of impairments. Raymer, Foundas and colleagues (1997) described a patient with impaired word retrieval in oral and written naming tasks and intact performance in comprehension tasks. They proposed that the impairment arose at a late stage in semantic processing as semantic representations activate subsequent lexical output mechanisms. When Raymer and colleagues (Raymer, Maher, Foundas, Rothi, & Heilman, 2000) assessed the pattern of recovery for their patient, parallel patterns of improvement, qualitatively and quantitatively, were evident for both oral and written naming, as might be predicted if the impairment arose at a common stage in lexical processing. These parallel recovery patterns across output modes further substantiate the original proposal that the lexical impairment for speech and writing is related to a common stage in lexical-output processing.

Although fewer studies have assessed recovery from a CN perspective, those to date have demonstrated the implications of such analyses. Recovery analyses may allow researchers to confirm and contrast interpretations made regarding lexical impairments observed early after a neurologic lesion. Over time, clinicians may use the knowledge

derived from recovery analyses to direct clinical efforts toward lexical processes that are predicted to recover. And finally, recovery analyses may ultimately provide additional evidence to validate proposed models of lexical processing (Martin, 1996).

TREATMENT

A number of clinical researchers have voiced optimism that CN models may provide a sound theoretical foundation on which to develop rational treatments for patients with aphasia (Riddoch & Humphreys, 1994; Seron & Deloche, 1989). Of course, cognitive models are not the sole determinant of decisions made in treatment for patients with aphasia (Caramazza & Hillis, 1993; Hillis, 1993). Clinicians also weigh a number of other medical, neurologic, and social factors as they develop a treatment plan for a given patient to optimize success.

Cognitive models of lexical processing lend themselves well toward a distinction in the kind of treatment to be attempted, restitutive or substitutive (Rothi, 1995). Restitutive treatments target semantic or lexical phonologic processes that clinicians have identified as impaired following the systematic lexical assessment. Substitutive treatments incorporate cognitive processes that remain intact and might be used to circumvent or facilitate processing by the impaired lexical mechanism. Clinical researchers have applied the CN approach in a number of lexical studies, some of which used a restorative approach, and others which used a substitutive approach.

Treatments for Comprehension Impairments

The process of word comprehension, in which meaning is applied to a lexical referent, involves activation of both lexical phonologic recognition and semantic processing. Restitutive treatments for auditory comprehension might target those mechanisms, whereas substitutive treatments would use alternative processes to accomplish word comprehension. A small number of studies have applied a CN approach in the treatment of auditory-comprehension impairments.

Restitutive Comprehension Treatments

Morris and colleagues (Morris, Franklin, Ellis, Turner, & Bailey, 1996) described a phonologic treatment for a patient with impairments of auditory comprehension arising at a prelexical phonologic stage of processing. In their treatment, the patient participated in a series of tasks engaging phonemic processing, including phoneme-grapheme matching, phoneme discrimination, auditory-word to picture and auditory-word to written-word matching and verification, and nonsense CV syllable discrimination. As needed, the

clinician provided additional lip-reading cues and hand signals (substitutive strategies) to embellish the phonemic input. Following 6 weeks of twice-weekly treatment, the patient demonstrated significant improvements in a variety of phonologic tasks, but no improvement in written word-comprehension and picture-naming tasks that do not involve phonologic recognition, indicating that the effect was modality-specific and not due to spontaneous recovery.

Grayson, Hilton, and Franklin (1997) implemented a semantic treatment for a patient with severe deficits of lexical comprehension related to dysfunction at both phonologic and semantic processing stages. They chose first to target the semantic impairment by having the patient execute a number of lexical tasks requiring semantic processing: auditory word- and written word-to-picture matching in which they systematically increased the number and relatedness of distractors; category-sorting for pictures and written words of increasing semantic relatedness; and matching associated written words. After 4 weeks of treatment, the patient improved in other word-picture matching tasks, but not in a phoneme-discrimination task. Subsequently, the clinicians added a phonologic component to their semantic treatment as they asked the patient to perform a word-picture matching task using all rhyming word foils. After an additional 4 weeks of treatment, improvement was seen in auditory word-picture matching tasks as well as a nonword phoneme-discrimination task, suggesting that repeated exposure to the treatment tasks affected both phonologic and semantic processing.

Raymer, Kohen, and Saffell (2006) used a similar semantic training paradigm to address the auditory comprehension and naming impairments in two patients with semantic dysfunction. The patients completed spoken word- and written word-to-picture matching tasks in the context of semantic distractors administered via a computer. They also rehearsed the spoken production of words, adding a phonologic component to the training. Both improved their comprehension of words rehearsed in training, and one improved for untrained word comprehension as well.

Behrmann and Lieberthal (1989) applied a semantic treatment in a patient with category-specific comprehension impairments that were particularly severe for the categories of body parts, furniture, and transportation. Clinicians trained the patient on superordinate and specific semantic details about the three targeted categories and then had the patient perform visual and verbal matching tasks applying the semantic information. Following treatment, their patient demonstrated improved categorization of items in the trained categories as well as one untrained category. Little improvement was noted in other semantic processing tasks.

Substitutive Comprehension Treatments

Substitutive treatments for auditory-comprehension impairments may take a number of forms. Some researchers have

advocated the use of a lip-reading strategy to provide additional visual information during the course of phonologic processing (Ellis et al., 1983; Morris et al., 1996). Shindo, Kaga, and Tanaka (1991) demonstrated an advantage in processing spoken words when given lip-reading cues in four patients with impairments of phonologic recognition. Maneta, Marshall, and Lindsay (2001), however, reported that lip-reading was less effective than teaching a spouse to use communicative strategies to promote comprehension in a patient with word deafness. Thus, lip-reading may be useful to support auditory comprehension in some patients with intact semantic processing in the presence of phonologic processing impairments.

The orthographic recognition system is another modality for use in patients with phonologic processing impairments. Francis and colleagues (2001) reported their treatment of auditory-comprehension problems in a patient with word-meaning deafness, presumably due to disruption of access from phonologic recognition to semantic processing. They compared outcomes of two different treatments, a substitutive one in which the patient was presented all words only in written form, and a second one in which written words were paired with spoken presentation of stimuli. Both treatments led to improved comprehension of trained words, but the second treatment had more lasting effects, presumably acting more directly to restore phonologic processing.

In summary, having patients complete tasks that require some form of phonologic or semantic processing has the potential to improve future processing abilities for spoken input. It appears that these improvements relate to changes in phonologic recognition and semantic stages of lexical processing, as improvements were less evident in control conditions. Other nonverbal strategies also may be helpful to circumvent or support impaired comprehension abilities.

Treatment for Naming Impairments

Researchers have reported many studies applying the CN approach in the treatment of word-retrieval impairments in patients with aphasia. Word retrieval requires both semantic and phonologic output stages of lexical processing. Thereby, a number of studies have examined the usefulness of restitutive treatments incorporating various semantic and phonologic tasks, either independently or in combination, as shown in Table 23-4. Substitutive treatments, in contrast, have incorporated alternative modes of output to either circumvent an impairment or to vicariously encourage word retrieval through alternative means.

Restitutive Word-Retrieval Treatments

Semantic Treatments

Recognizing the common role the semantic system plays in both word comprehension and retrieval, a number of studies

TABLE 23-4

Semantic and Phonologic Treatments Used to Improve Word Retrieval

Semantic Treatments

- Semantic comprehension tasks (e.g., auditory word or picture matching; written word or picture matching; yes/no verification)
- Contextual priming (e.g., word or picture matching and rehearsal of related sets of words)
- Semantic features descriptions (e.g., distinguishing features between similar objects)
- Semantic matrix training (e.g., category, function, attribute, associates)

Phonologic Treatments

- Phonologic questions tasks (e.g., rhyming comprehension, syllable-number verification, initial-phoneme verification)
- Oral word reading
- Word repetition
- Phonologic cueing hierarchy (e.g., rhyming word, initial phoneme, repetition)
- Phonologic choice tasks (e.g., choose from correct and incorrect phonemic cues)

have implemented *comprehension treatments* in an attempt to facilitate word retrieval. Over several sessions, patients complete semantic processing tasks such as picture categorization with related categories (e.g., fruits vs. vegetables), spoken and written word-to-picture matching in the presence of semantic distractors (e.g., target-“corn,” distractors-“beans, tomato, squash”), and answering yes/no questions about semantic attributes of target words (e.g., “Does corn grow on a tree?”). At times, the patients also say the word during the performance of the comprehension tasks, adding a phonologic component to the treatment (Byng, Kay, Edmundson, & Scott, 1990; Davis & Pring, 1991; Kiran & Thompson, 2002; Marshall, Pound, White-Thomson, & Pring, 1990; Nickels & Best, 1996). Following semantic comprehension treatments, a variety of individuals with word-retrieval impairments related to either semantic or phonologic dysfunction have demonstrated significant improvement in word-retrieval abilities, largely limited to words incorporated in training (Nickels, 2002).

Subsequent studies contrasted treatments in which semantic comprehension tasks were performed with and without phonologic production of target words to determine what role the phonologic-production component played in the treatment (Drew & Thompson, 1999; Le Dorze, Boulay, Gaudreau, & Brassard, 1994). Drew and Thompson (1999) showed that participants benefited maximally when training combined semantic comprehension

tasks with phonologic rehearsal of target words compared to semantic comprehension tasks alone, a finding compatible with the interactive nature of semantic and phonologic lexical processing mechanisms.

One study used a word-retrieval training protocol in which semantic comprehension tasks were administered via the MossTalk computer program (word-picture matching with semantic distractors) along with spoken rehearsal of training words (Raymer, Kohen, & Saffell, 2006). All participants improved their production of trained words, with greater improvement in the three participants with phonologically based retrieval impairments than in the two with severe semantic impairments.

Earlier studies of semantic comprehension training targeted noun-retrieval abilities. Recent studies have examined effects for verb retrieval as well (Raymer & Ellsworth, 2002; Raymer et al., 2007; Rodriguez, Raymer, & Rothi, 2006; Webster, Morris, & Franklin, 2005). Improvements were evident in retrieval of trained verbs, with little generalization to untrained verbs. Some generalized improvements were reported in measures of communicative effectiveness and sentence production using trained words, presumably because of the important role verbs play in sentence generation. Gains were greater in patients whose verb-retrieval impairments stemmed from phonologic as compared to semantic dysfunction.

A modified version of semantic comprehension treatment is seen in studies of *contextual priming* (Martin, Fink, & Laine, 2004; Martin, Fink, Renvall, & Laine, 2006; Renvall, Laine, & Martin, 2005). Participants view a set of several pictures that are related either semantically (e.g., animals), phonologically (e.g., words beginning with “r”), or not at all. They then match spoken word to picture and repeat the name several times. Martin and colleagues reported that, although patients sometimes experience considerable interference from word to word during training, patients ultimately improved production of trained words. Improvements are less potent in patients with semantically based naming dysfunction (Martin et al., 2006).

In another modification of semantic treatment, Wambaugh and colleagues (1999, 2001, 2002, 2003) have examined effects of *semantic cueing treatment* (SCT) for word retrieval in patients with aphasia. In SCT, patients perform a spoken description-to-picture matching task, followed immediately by attempts to name the target picture. If unable to name the picture, patients are given a series of semantically loaded cues to elicit the target word, ending with repetition of the word, if necessary. Across studies, treatment was effective for improving retrieval of trained nouns and verbs in several patients whose word-retrieval impairment arose from semantic, phonologic, and mixed semantic plus phonologic dysfunction.

Some patients with semantic dysfunction seem to lack specific details of semantic knowledge, and thereby produce

many semantic errors. Following a lexical assessment that indicated a word-retrieval impairment related to underspecified semantic representations, Hillis (1998) devised a semantic treatment for her patient in which she provided *semantic information* about target pictures the patient was unable to name, and contrasted those features with the semantic features of a closely related object. Ochipa, Maher, and Raymer (1998) used a similar semantic treatment with their patient with word-retrieval impairment stemming from semantic dysfunction. Patients in both studies demonstrated significant improvements in naming trained pictures as well as generalization to untrained pictures and untrained lexical tasks incorporating semantic processing (written-word production). Hillis also reported that this semantic-features treatment was more effective than a traditional cueing hierarchy treatment in her patient.

In another type of semantic treatment, developed on the basis of cognitive theories of how semantic representations are structured, clinicians attempt to improve word retrieval using *semantic-feature matrix training* (Haarbauer-Krupa, Smith, Sullivan, & Szekeres, 1985). Clinicians teach subjects to use a viewed matrix of printed cue words (e.g., function, properties, category, etc.) to assist in retrieving semantic information about a target picture along with its name. After training with a semantic-feature matrix, participants demonstrated improved naming of trained pictures as well as generalization of the strategy to some untrained pictures and conversational measures (Boyle, 2004; Boyle & Coelho, 1995; Conley & Coelho, 2003; Lowell, Beeson, & Holland, 1995). The psycholinguistic basis for word-retrieval impairment among patients was not well characterized in these studies, however.

Phonologic Treatments

Other studies have used treatment protocols presumably engaging lexical phonologic stages of word retrieval. A shared phonologic output representation may be activated in oral reading, word repetition, and oral picture-naming. Capitalizing on this relationship, Miceli and colleagues had their patient repeatedly *read aloud* or *repeat* target words (Miceli, Amitrano, Capasso, & Caramazza, 1996). Both procedures resulted in improved picture-naming for trained words in one subject with phonologically based word-retrieval failure. Mitchum and Berndt (1994) used a similar phonologic rehearsal treatment (incorporating repetition practice) in their patient with a selective verb-retrieval impairment. Following training, their subject demonstrated improvements in verb retrieval, but little improvement in the formulation of complete sentences using the trained verbs.

Other studies have incorporated treatments using a *phonologic cueing hierarchy* to assist patients in retrieving target words. Subjects who were repeatedly exposed to a hierarchy of initial phoneme, rhyme, and word-repetition cues

demonstrated improvements in word retrieval for trained words (Greenwald et al., 1995; Hillis, 1993, 1998; Raymer & Ellsworth, 2002; Raymer, Thompson, Jacobs, & le Grand, 1993). Among these studies, treatment was effective for subjects with either semantic or phonologic word-retrieval dysfunction, although improvements were more limited in patients with semantic impairment (Raymer et al., 1993). Studies that systematically examined the impact on word retrieval of word repetition alone demonstrated improvements that were not as potent or lasting as when repetition was paired with other phonologic or semantic processing tasks, however (Greenwald et al., 1995; Raymer & Ellsworth, 2002).

Another treatment paradigm that presumably focuses on lexical phonologic stages of processing incorporated yes/no questions about the *phonologic characteristics* of target words (Howard, Patterson, Franklin, Orchard-Lisle, & Morton, 1985; Robson, Marshall, Pring, & Chiat, 1998). In these studies, patients completed tasks in which they made judgments about words, such as the number of syllables, the initial phoneme of words, or whether the words rhymed. Participants demonstrated improvement in retrieving words trained with this strategy, with some showing generalization of the process to naming of untrained pictures (Robson et al., 1998).

Some studies that contrasted semantic and phonologic training protocols seem to indicate that semantic treatments have longer-lasting effects than phonologic treatments (Howard et al., 1985). Hickin and colleagues reasoned that the difference in semantic treatments compared to phonologic treatments is the need to make a choice, which perhaps promotes deeper processing of the linguistic stimuli (Hickin, Best, Herbert, Howard, & Osborne, 2002). In their phonologic treatment protocol, therefore, participants attempted to name target words when given a *choice of two phonemic cues*, starting with initial phonemes and increasing to syllables and the full word if needed. Significantly improved naming was evident in five of seven participants trained.

In summary, the findings of a number of studies indicate that different types of restitutive semantic and phonologic treatments are effective in improving word retrieval for trained words. One observation is that there is little direct correlation between type of word-retrieval impairment (semantic or phonologic) and the most effective type of treatment (Hillis, 1993; Nickels, 2002). Either semantic or phonologic treatment seems to improve word retrieval in individuals with either semantic or phonologic impairments. In fact, the best restitutive treatments appear to be those that combine semantic and phonologic information during the course of training, to encourage the process of word retrieval in a manner compatible with the typical process (Drew & Thompson, 1999; Le Dorze et al., 1994). Patients with severe semantic dysfunction often show a more limited

response to treatments than those with phonologic retrieval bases of impairment (Nickels, 2002).

Substitutive Word-Retrieval Treatments

An alternative approach to rehabilitation of word-retrieval impairments is to devise treatments that either circumvent the impaired lexical mechanism or develop an alternative means to vicariatively mediate word retrieval using other cognitive mechanisms. For example, the use of semantic circumlocution to describe a concept when a word-retrieval failure occurs would be a substitutive semantic strategy to circumvent failure at the subsequent stage of phonologic lexical retrieval. Some treatment studies have evaluated the effects of methods to vicariatively activate word retrieval.

Orthographic Mechanisms

Some patients with word-retrieval impairments stemming from failure to access lexical phonologic representations nevertheless may be able to access some knowledge about the word's spelling. In turn, using print-to-sound conversion processes, it may be possible to self-cue and generate the appropriate spoken form of the word. Patients with some retained spelling knowledge for words they were unable to produce were successfully taught either to type the letters into a computer, which in turn generated the initial phoneme of the word (Bruce & Howard, 1987), or to write the letters and self-cue the spoken production of the words (Bastiaanse, Bosje, & Fraansen, 1996). Some patients may need to be trained in print-to-sound conversion, however, before written self-cueing is useful to promote spoken naming (Nickels, 1992).

Hickin and colleagues (2002) used a task in which patients chose between two written-letter cues to promote production of target words. In a subsequent study they compared the effects of multiple written cues versus only one cue and showed that both techniques led to improvements in picture-naming (Hickin, Greenwood, Grassly, Herbert, Howard, & Best, 2005). Because repetition was used as a final step in training, it is likely that this training engaged both orthographic and phonologic stages of lexical processing. DeDe, Parris, and Waters (2003) used a similar rationale in their training study in which their patient practiced writing target words, given a choice of written cues from one letter to several letters as necessary. In addition, the patient rehearsed the use of tactile cues (e.g., hand-pointing to neck for "k"), corresponding to the word's initial letter, and phonemic cues to produce target words. Positive treatment effects were reported for spoken-naming, which may be a result of changes in orthographic or phonologic stages of lexical processing. Finally, Laganaro, Di Pietro, and Schnider (2006) used a computer-training protocol in which participants practiced written spellings of words. When spelling errors occurred, the participant was provided with

more and more information about the spelling until the word was correctly spelled. Apparently, participants never said the words aloud during training, constraining the training paradigm largely to the orthographic modality. Nonetheless, their participants improved markedly in spoken-naming of words they had practiced spelling.

Some studies, in contrast, have used oral-reading treatments to promote spoken-naming abilities. Hillis (1998) described a remarkable patient who spontaneously used retained print-to-sound conversion abilities to support her impaired word retrieval. This patient often mispronounced words using regularized pronunciations (e.g., “/brid/” for “bread”) when a word-retrieval failure occurred. Listeners who were familiar with her maladaptive technique could often perform a reverse translation and figure out the word the patient was attempting to say. To circumvent this awkward strategy, Hillis taught her patient to read aloud regularized spellings of common words with exceptional spellings (e.g., “kwire” for “choir”). Improvements in oral reading also were evident in oral naming of the same words. Similarly, Kiran, Thompson, and Hashimoto (2001) demonstrated in their patients with phonologic dysfunction that practice in oral reading of words led to improvements in spoken-naming of the same words.

Gesture

An alternative method that researchers have applied to mediate word retrieval is the use of the gestural-processing mechanisms through pantomime. Cognitive models of lexical and praxis processing recognize the interactive nature of the two systems (Rose, Douglas, & Matyas, 2002; Rothi et al., 1997), suggesting that gesture may be useful to mediate activation of lexical retrieval. Arbib (2005) has argued for a close relationship between gesture and language processing, making gesture particularly appropriate for use as a language-treatment modality. A desirable consequence of gestural facilitation with pantomimes is that, should verbal processes not improve with training, the patient may increase the use of gesture as an alternative communication mode. A number of single-participant studies have demonstrated that gestural training paired with spoken production of words improved word retrieval in individuals with aphasia (Pashek, 1997; Raymer & Thompson, 1991). For example, Rose and colleagues (2002) showed that treatment with iconic gestures was as effective as use of phonologic-orthographic cues in improving word retrieval in one individual with phonologic-retrieval dysfunction. Similarly, Rodriguez and colleagues (2006) reported that gestural training was as effective as semantic-phonologic training in one individual with phonologic-retrieval impairment for verbs. Three other participants with semantic impairments did not improve spoken verb-naming abilities during either treatment, although two demonstrated dramatic increases in the use of gestures corresponding to verbs.

Druks (2001) noted a close relationship between networks engaged in verb and gesture knowledge, suggesting that gestural treatment may be especially effective for verb retrieval as compared to noun retrieval. One participant described by Pashek (1998) improved retrieval of both nouns and verbs following gestural training, though improvement was greater for verbs than for nouns. In a larger study, Raymer and colleagues (2006) reported that gestural training led to improved word retrieval for both nouns and verbs in five of nine participants in the study, with no difference between noun and verb outcomes. Improvements in word retrieval were greater in individuals with phonologic-retrieval impairments and mild to moderate semantic impairments than in those with severe semantic impairments.

One problem with earlier gesture studies is that the integrity of the action mechanisms (limb apraxia) was often not well documented in the subjects with aphasia. Patients with severe limb apraxia may not be able to use pantomime as a viable communication mode, as their gestures are often unrecognizable. However, the studies by Raymer and colleagues (Raymer et al., 2006; Rodriguez et al., 2006) showed that patients with severe limb apraxia can improve their ability to produce recognizable gestures, even when word retrieval does not improve.

Summary of Treatment Research

Studies have demonstrated that restitutive treatments are effective for improving performance in individuals with impairments of either lexical comprehension or production. Other studies have shown that substitutive treatments also can benefit word comprehension and retrieval in some patients. One observation noted across treatment studies is that, whereas patients may present with impairments that implicate either semantic or phonologic stages of lexical processing, there is no direct relationship between type of impairment and type of treatment that seems to be most effective for naming recovery (Hillis, 1993). Some patients with semantic impairments benefit from treatment that focuses on phonologic output, and vice versa. In general, recovery of word-retrieval functions is more limited in patients with severe semantic dysfunction. Although simple rehearsal of spoken words can help a person improve word retrieval, the most effective treatments were those that engaged either semantic, phonologic, and, in particular, semantic plus phonologic processing within one treatment protocol. That is, treatments that attempted to facilitate the multistage process of word retrieval were often most effective.

GENERALIZATION

The CN approach has specific implications for analyzing the generalization of treatment effects for lexical impairments (Hillis, 1993; Raymer, Rothi, & Heilman, 1995).

First, if treatment facilitates processing in a particular lexical mechanism, improvements should be evident in all tasks that require processing by that mechanism. Hereafter, this type of generalization will be referred to as “generalization across tasks.” Second, as treatment strengthens targeted lexical representations, other semantically or phonologically related lexical representations may benefit from the treatment as well. This type of generalization will be referred to as “generalization to untrained stimuli.”

Generalization across Tasks

A number of studies have examined the effects of word-retrieval treatment on other untrained lexical tasks that draw upon semantic or phonologic mechanisms presumably impacted by treatment. Hillis (1998) examined generalization across untreated lexical tasks following her semantic-features treatment for word retrieval. Benefits of semantic treatments should be evident in all tasks involving semantic activation, including oral- and written-naming, comprehension, and possibly oral-reading and writing to dictation. Although semantic treatment focused solely on written-naming, improvements were also evident in all other lexical tasks, as predicted. Likewise, Ochipa and colleagues (1998) reported improvement in written-naming following semantic-features treatment targeting oral-naming. Similarly, benefits of phonologic treatments should be evident in oral-naming and oral-reading, and less likely in written-naming and comprehension. So, for example, when Hillis (1998) trained her patient to pronounce regularized spellings of words with exceptional spellings, her patient improved pronunciation of the same words in picture-naming and word repetition as well, but not in written-naming.

There are times, however, when treatment effects observed in additional lexical tasks extend beyond those predicted. For example, Raymer and colleagues (1993) used a phonologic cueing hierarchy to train oral picture-naming, and observed generalized improvements in oral word-reading as well as written picture-naming in one patient. Although one might expect that the phonologic training largely impacted on phonologic stages of word retrieval, semantic aspects of processing also may have been strengthened, leading to improvements in written-naming as well. In contrast, Greenwald and colleagues (1995) reported improvements in oral picture-naming following visual-semantic training, but no improvement in a visual picture-associate matching task that they predicted would also improve following training. These patterns of generalization that are contrary to the predicted patterns suggest that the complexity of the lexical mechanisms and the types of processing that occur among mechanisms also influence treatment in important, but as yet unspecified, ways.

Finally, the results of the CN assessment may assist the clinical researcher in selection of tasks to demonstrate that

the effects of treatment indeed result from treatment and not from spontaneous recovery (Raymer et al., 1995). The clinician can identify other independent areas of cognitive/linguistic impairment that should not be affected by treatment and probe performance over time. The clinician demonstrates internal validity when treatment improves performance in the targeted task but not in the untreated task.

Generalization to Untrained Stimuli

Generalization to untrained stimuli may occur in two ways. Some treatments affect a lexical process, teaching patients to use this process or strategy to improve performance for a set of trained stimuli. If the patient learns this strategy or improves functioning in this process, performance should be affected when applying that process for all stimuli, trained or untrained. An example of such a process that may affect word-retrieval abilities is semantic-feature matrix training, in which clinicians train patients to use a matrix of cue words to encourage the recall of semantic information for a target word and ultimately word retrieval. Boyle and Coelho (1995; Boyle, 2004) and Lowell and colleagues (1995) reported that their patients who responded to semantic-feature matrix training also demonstrated some improvements in naming untrained pictures. It may be that the patients learned to self-generate semantic information whenever a word-retrieval failure occurred, thereby leading to activation of lexical responses for untrained words as well.

A second way in which generalization to untrained stimuli might occur is at the level of lexical representations. If word-retrieval training somehow restores features of representations to a more optimal state, then all items sharing those features should be affected. Therefore, generalization may be evident in predictable ways to items that share semantic or phonologic features. It may be this type of effect that can account for generalization to semantically related items found after semantic-feature training (Hillis, 1998; Ochipa et al., 1998) and after contextual priming with semantically related words (Martin et al., 2004).

Some studies have evaluated generalization of word-retrieval training effects that target specific semantic categories. Behrmann and Lieberthal (1989) evaluated generalization of category-specific semantic-comprehension treatment to naming of untrained items within trained and untrained categories. They observed generalization to untrained items within one trained category, as might be predicted. But they also noted improved naming in one untrained category, which cannot be completely explained on the basis of restoration of semantic features. Kiran and Thompson (2002d) provided word-retrieval training for subsets of words within a semantic category (e.g., birds, vegetables) and compared the effects when trained words were more typical exemplars of a category in that they have the characteristic features common to that category (e.g., robin,

carrot), versus atypical exemplars that have unique features that differ from other exemplars in the category (e.g., peacock, olive). In keeping with computational simulations (Plaut, 1996), Kiran and Thompson found that training with atypical exemplars led to greater generalized improvements when naming untrained typical exemplars of the category than when training typical exemplars in four patients with semantically based anomia. Stanczak, Waters, and Caplan (2006) replicated the typicality findings in word-retrieval training for one patient with a semantic plus phonologic dysfunction, but the pattern of generalization was not seen in a second patient with a phonologic naming dysfunction. They proposed that training with atypical exemplars has a more global influence on semantic networks than does training with typical exemplars. Patients with semantic dysfunction may benefit more than those with phonologic dysfunction from training with atypical category exemplars.

More often than not, improvements in trained lexical tasks seem to be item-specific, and limited improvements are evident for untrained words. For example, Raymer and colleagues (1993) systematically assessed generalization of the effects of a phonologic cueing hierarchy to items that were either semantically or phonologically related to trained pictures. They observed no clear patterns of response generalization among the patients. It is interesting that studies showing more positive generalization to untrained items typically incorporated semantic treatments. However, not all semantic treatments led to response generalization (Pring et al., 1993). Because there is no indisputable reason to predict generalization to untrained items, it would be sensible to select treatment words that respect the functional needs of each individual patient. For example, Hillis (1998) used a cueing hierarchy to train her patient to retrieve the names of different types of fabrics after the patient took a job at a fabric store.

LIMITATIONS OF THE COGNITIVE NEUROPSYCHOLOGICAL APPROACH

While this discussion has focused largely on the positive ramifications of the CN approach for the clinical rehabilitation process, the CN approach has some recognized shortcomings. The systematic, in-depth assessment of lexical abilities advocated in this approach proves tremendously difficult to accomplish in many clinical settings. However, clinicians may find it possible to use this approach in a more condensed format to accumulate the information necessary to make informed treatment decisions. Clinicians may be able to complete a series of lexical tasks with a circumscribed set of materials in the course of diagnostic treatment in an attempt to characterize lexical abilities more specifically. It may prove helpful for clinicians to characterize impairments accurately, but, in addition, to identify retained lexical abilities,

as the clinician may capitalize upon those retained abilities to devise appropriate substitutive treatments for lexical impairments. Furthermore, observations of overall patterns of impairments may eventually allow clinicians to develop better prognoses for impairments they observe in their patients. For example, disturbed oral-naming in the presence of preserved oral word-reading skills seemed to be predictive of best response to word-retrieval treatments (Raymer et al., 1993; Pring et al., 1990).

Although one of the initial goals of the CN approach was to identify more rational treatments that target identified impairments in the lexical system (e.g., semantic treatments for semantic impairments, and so forth), the findings to date do not support this notion. But the considerable body of research certainly has suggested a more favorable course to follow when attempting restorative treatments with patients with aphasia. Treatments that encourage activation of multiple stages in the lexical process (see Fig. 23-1) in the course of one treatment protocol appear to be most effective. Although the lexical mechanisms are distinct and distributed, they are highly interactive in the course of lexical processing.

Some clinicians have argued that the CN approach, which emphasizes impairment-oriented treatments, has few consequences for overcoming the disabling conditions posed by aphasia (Wilson, 1999). Because earlier treatment studies often neglected to report the functional aftermath of lexical treatments, this argument may have some merit. Substitutive treatments that researchers have generated on the basis of lexical theories definitely encourage progress in functional communication in a variety of patients. Recent studies have attempted to improve methods to document the substantial impact that impairment-oriented treatments have for patients and their families.

Hillis (1993) noted that although an assessment may help the clinician to characterize the nature of the patient's impairment, it does not help determine what specific strategy will be most effective—that is, how to treat the impairment. A number of additional neurologic, cognitive, and social factors also must play a role in the treatment decision. As researchers accrue a greater body of knowledge about treatment effects across patients, clinicians may be better at making predictions about who, what, and how to treat.

FUTURE TRENDS

A review of the limitations of the CN approach to lexical treatment suggests a number of areas for future research. Much of the treatment literature has reported the effects of one type of treatment, so that clinicians are unable to judge whether that treatment was as effective as other possible treatment options. Some recent studies have implemented crossover designs (e.g., Rodriguez et al., 2006) to add to the body of knowledge of what clinicians know are the most beneficial treatments. Future studies need to implement

prospective randomized trials to solidify the evidence-base for treatments founded on the cognitive neuropsychological approach.

Also, the impairment-oriented approach to aphasia treatment has received much criticism and skepticism. Therefore, future studies must incorporate methods to evaluate the functional consequences of treatments for daily communication situations (Herbert, Best, Hickin, Howard, & Osborne, 2003). Finally, imaging studies are beginning to document the neural changes associated with successful behavioral treatments. Continued research in each of these areas will advance the effectiveness and efficiency of clinical practice for our patients with aphasia.

KEY POINTS

1. The lexical system is a complex, distributed system of modules that store information in sensory modality-specific and output mode-specific mechanisms that interact by way of a semantic system.
2. Lexical impairments take many forms depending on which component of the lexical system is affected.
3. Assessment focuses on mode/modality comparisons across lexical tasks. Patterns of performance, quantitatively and qualitatively, help the clinician develop an informed hypothesis about the nature of lexical impairments.
4. Recovery analyses may assist clinicians in predicting which patients will recover and in which direction, and may serve to confirm hypotheses generated on initial assessment.
5. Restitutive treatments target impaired lexical mechanisms. Treatments that are putatively semantic in nature, and others that focus on phonologic aspects of lexical information, have induced changes in auditory comprehension and word retrieval in a variety of patients. However, contrary to early predictions about the CN approach, there is not a direct correspondence between types of impairments and most effective treatments. Treatments that incorporate multiple stages of the lexical process seem most beneficial.
6. Substitutive treatments capitalize on retained aspects of lexical processing to either circumvent an impairment at some stage in lexical processing or to vicariously mediate activation of the impaired mechanism.
7. Generalization of treatment effects is observed across all tasks for which the mechanism facilitated by treatment plays a necessary role in accurate performance. Generalization of treatment effects to untrained stimuli has been more limited, although there are

indications that semantic treatments incite greater generalization to untrained semantically related words.

8. Less research has been focused on the functional outcomes of these impairment-oriented treatments.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. What is modality-specificity as it relates to the model of lexical processing?
2. What is the difference between lexical phonologic recognition, lexical semantics, and lexical phonologic output?
3. A dysfunction of the phonologic-recognition mechanism will result in a pattern of impairment in which lexical tasks and preserved performance for what other lexical tasks?
4. What is the pattern of lexical performance seen in patients with optic aphasia?
5. What is a category-specific impairment? For what semantic categories might we observe category-specific impairments?
6. What is the purpose of mode/modality comparisons in the cognitive neuropsychological assessment?
7. The presence of semantic errors in naming may represent dysfunction at which three stages of lexical processing?
8. Describe one stage-specific assessment task to target processing in each of the following: object recognition, lexical semantics, and lexical phonologic output.
9. How are analyses of lexical recovery useful in clinical practice?
10. Describe restitutive and substitutive treatments that may be useful to improve functioning in an individual with phonologic recognition impairment.
11. Why are semantic comprehension tasks useful as a restitutive treatment for word-retrieval impairments?
12. What are three different tasks a patient may practice to encourage restoration of functioning in the lexical-phonologic output stage of word retrieval?
13. How can the graphemic system be used in a substitutive strategy for word-retrieval impairments?
14. How do models of lexical processing assist in predicting generalization effects to untrained tasks?

APPENDIX 23.2

Glossary

Category-Specific Semantic Impairments—Disturbances in comprehension or production for selective semantic categories, with preserved performance for other categories.

Lexical Decision—Task in which the patient decides whether a given stimulus is a familiar real word or object, or a nonsense word or object.

Lexical Phonologic Output Processing—Mechanism of representations for familiar spoken words that have previously been produced.

Lexical Phonologic Recognition—Mechanism of representations for familiar spoken words that have previously been heard.

Lexical System—Complex, distributed set of mechanisms storing representations for familiar words, objects, and actions, as well as processes for decoding and encoding unfamiliar stimuli.

Optic Aphasia—Visual modality-specific impairment in naming viewed objects in the presence of basic semantic processing indicated through circumlocutions or gestures associated with the unnamed object.

Pure Word Deafness—Auditory modality-specific impairment in processing spoken input.

Recognition—The point in stimulus-processing at which a stimulus is distinguished and found to be familiar and previously experienced.

Restitutive Treatments—Strategies that encourage restoration of functioning in a manner compatible with normal language processing.

Semantic System—The lexical mechanism responsible for storing meaning representations for familiar words, objects, and actions.

Substitutive Treatments—Strategies that attempt to circumvent a dysfunctional language mechanism using other intact language and cognitive processes.

Visual Agnosia—The failure, as a result of brain damage, to recognize a viewed stimulus that is not due to a peripheral sensory visual disorder.

Visual Object Representation—The mechanism storing memories for familiar objects that have previously been seen.

Word-Meaning Deafness—Impairment in the ability to apply meaning to heard words despite intact phonologic processing.

Chapter 24

Comprehension and Production of Sentences

Charlotte C. Mitchum and
Rita Sloan Berndt

OBJECTIVES

In this chapter we illustrate how cognitive neuropsychology has been applied to assessment and intervention of sentence-processing disorders in aphasia. This approach differs from traditional assessment measures that classify subtypes of aphasia; it does not seek to establish a clinical label based on measures of contrasting symptoms (e.g., Broca's aphasia vs. Wernicke's aphasia), or to obtain a general measure of relative severity. Rather, specific symptoms are contrasted with normal sentence processing, with the goal being to identify how brain damage has altered normal functions.

Using a model of normal sentence processing is somewhat hampered by the lack of a complete understanding of all the details involved in sentence production and comprehension. There is no theoretic model that can fully account for normal sentence processing, nor can a model account for the myriad of problems observed in aphasic language (Berndt, 2001). Treatment can be guided by hypotheses about what needs to be restored or bypassed, but the mechanisms of change established with therapy remain poorly understood. Nonetheless, we illustrate how reference to a theoretic framework has provided a valuable mechanism for sorting out the array of symptoms associated with aphasic sentence processing, and has inspired new and effective approaches to the treatment of sentence-processing disorders.

SENTENCE-LEVEL DEFICITS IN APHASIA

Interest in aphasic symptoms that are specific to sentences has a long history in neurology (Luria, 1947; Pick, 1913) and linguistics (Jacobson, 1956); these symptoms have been interpreted primarily as grammatical disturbances. An important contrast is the one between "agrammatism,"

which typically occurs in the context of nonfluent (especially Broca's) aphasia, and "paragrammatism," which occurs in sentences produced by more fluent speakers (especially those with Wernicke's aphasia). The difference between these manifestations of grammatical disturbance has been widely described as involving distinct problems with grammatical morphemes (both bound and free), with agrammatism characterized primarily by omission of these elements and paragrammatism by their misuse (Goodglass, 1993). The following speech samples illustrate the differences between a typical Broca's pattern and the type of disordered sentences often produced by more fluent speakers (pauses > 1 sec are noted):

Pattern Associated with Broca's Aphasia

Cinderella (4s) poor and (4s) poor meaning not to be (3s) fire and all thing but (2s) stepsister two (4s) rich (2s) powerful man and (3s) well that after (6s) slim chance (3s) me and cleaning the house and serving the (2s) meals and rich man (3s) well the prince is (2s) going to (4s) east (2s) feast

Pattern Associated with (Mild) Wernicke's Aphasia

the Cinderella was his his father and his father but he's . . . passed away so she's his his mother-in-law was the really little bit angry and everything . . . and the Cinderella in the cellar . . . she also had the sisters-in-law two sisters and they have all they have all the sisters was old . . . nose and teeth and awful

Although these types of speech patterns sound markedly different to the listener, considerable overlap exists in the types of errors that can be noted. Analyses of such speech samples from patients demonstrating both of these patterns reveal omission and substitution of grammatical morphemes (Butterworth & Howard, 1987). In some cases, grammatical disturbances are primarily structural in nature, with relatively preserved use of grammatical morphology but an inability to produce a normally structured and elaborated sentence (Saffran, Berndt, & Schwartz, 1989; Tissot, Mounin, & Lhermitte, 1973). Although many different accounts of grammatical morpheme omissions in agrammatism have been offered (see Berndt, 1998 for review), it is important to note that impaired use of grammatical morphology is only one of many structural impairments observed in the

Figure 24–1. Examples of Stimuli Used to Assess Comprehension of Sentences Based on Lexical (“L”) or Structural (“S”) Cues to Meaning.

sentences of speakers with aphasia. It is also now widely recognized that symptoms associated with agrammatism do not always co-occur and are not unique to Broca’s-type aphasia.

Agrammatism was long believed to be a uniquely “expressive” impairment, since patients with Broca’s aphasia (by definition) demonstrate good comprehension on clinical testing. However, a set of studies in the late 1970s showed that agrammatic patients often failed to understand sentences correctly when the stimuli were constructed to require interpretation of grammatical features (Caramazza & Zurif, 1976; Schwartz, Saffran, & Marin, 1980). These studies revealed a pattern of impaired comprehension associated with Broca’s aphasia that suggested that interpretation

of sentences was frequently based on semantic cues such as noun animacy, or on heuristics based on word order, rather than on sentence structure.

This type of sentence-comprehension disorder emerged only in tests that systematically eliminated the possibility of using non-syntactic cues to meaning. For example, sentence-picture matching tasks present a spoken sentence with two pictures showing a pair of actors performing the same action, but with the noun roles reversed. Other items in the test assure that patients’ understanding of the individual words in the sentence is intact. As shown in Figure 24–1, it is possible to identify the depiction of “the girl kicking the boy” (vs. “the girl kicking the ball”) simply by knowing the difference between the meaning of the words “boy” and

“ball.” That is, an interpretation based on single-word meaning may give the impression that the sentence has been fully comprehended. In the pair of pictures on the right, the same target sentence “the girl is kicking the boy” cannot be interpreted using the meaning of individual words because “boy,” “kick,” and “girl” are shown in both pictures. In this arrangement, the grammatical cues to the sentence meaning—word order, verb inflection, i.e., the syntactic structure—must be interpreted in order to identify which of the two nouns is *doing the kicking*. To test for a “first noun is agent” word-order strategy, active and passive versions of the same sentence are presented with pictures showing the correct depiction and a reversal of the thematic roles stated in the stimulus sentences. Patients cannot perform correctly on both the active and passive versions of the sentence if they assume that the first noun mentioned is the agent of the action.

Variants of these “semantically reversible” sentences have been very widely used to investigate structurally based comprehension disorders (see Berndt, Mitchum, & Haendiges, 1996 for review). In addition, tasks designed to test reversible sentence *production* reveal similar errors involving difficulty matching correct word order to sentence structure. This is observed when patients are “constrained” to begin their response with the noun that is not the agent of the action (Caramazza & Berndt, 1985). For example, if forced to start a sentence to describe the picture shown in Figure 24–1 (top) with the word “boy,” it is difficult for some speakers with aphasia to produce a passive sentences (e.g., “the boy is kicked by the girl”). A typical error is to produce a sentence in the active voice and thus violate the sentence’s meaning (e.g., “the boy is kicking the girl”).

The finding that speakers with agrammatic aphasia frequently had difficulty interpreting structural cues to meaning in comprehension generated enormous interest in Broca’s aphasia because it suggested that such patients suffered from a “central” syntactic deficit affecting all elements of language use. Agrammatism was viewed as a constellation of inseparable symptoms associated with the halting, telegraphic speech of Broca’s aphasia. The characteristics of agrammatism were generally believed to include the following symptoms: (1) “closed class” word errors, especially the omission of free and bound grammatical morphemes; (2) “open class” word production, which mostly spared concrete nouns; (3) simplified syntactic complexity and reduced phrase length; and (4) poor comprehension of semantically reversible sentences (Berndt & Caramazza, 1980).

Although some researchers who still maintain some elements of this “syntactic deficit hypothesis,” including the view that “Broca’s area” of the brain is specialized for aspects of syntactic processing (Grodzinsky, 2000), there is strong evidence from many studies that these symptoms can dissociate from one another (see Berndt, 1991; Martin, 2006, for reviews). Current approaches to the study of sentence production and

comprehension in aphasia do not assume that these symptoms will always occur together. Rather, recent work more often seeks to explain how a particular symptom contributes to the sentence-processing pattern observed in individual cases, or in groups of individuals who share (at least) a symptom of interest (Berndt, 1998; Berndt et al., 1996).

NORMAL SENTENCE PROCESSING

Normal speakers produce and comprehend sentences with little apparent effort, yet the cognitive operations that support the creation and interpretation of sentences must be remarkably complex. To utter or understand even a single sentence requires, at the very least, the integration of the products of lexical retrieval, syntactic formulation, phonologic encoding, and articulation. Exactly how the interplay of these components normally yields a final product is not well understood. Theories of normal sentence processing draw upon several sources of data in an attempt to describe the inner structure of language, including analyses of normal “slips of the tongue,” results of psycholinguistic experiments, and computational modeling. The theories that result can be very useful for the speech-language clinician interested in understanding how aphasic language deviates from language that is unimpaired (Hillis, 1993; Mitchum & Berndt, 1995). In the sections to follow, we will identify subcomponents of sentence production and comprehension, within the context of what we know about normal language, and in light of evidence from cognitive neuropsychological studies.

Sentence Production

Operations necessary for sentence production range from the creation of an intended message to its ultimate articulation. Even in the absence of a formal theory, it would seem likely that sentences evolve through a series of fairly independent stages. Thoughts form a rough, preverbal idea of what one wants to say. Although thoughts may be candidates for verbal expression, they are not lexically specified or grammatically well-formed; many thoughts never become phonologically encoded. For selected thoughts, however, we seem to readily convert the unspecified message into an ordered utterance that contains both lexical (open-class) content and grammatical (closed-class) structure. The utterance is made known using an articulatory code common to both speaker and listener. However, this informal description tells us little about how these events are coordinated. That is, how do we construct a verbal sentence from thought? Importantly, for the speech-language pathologist, how do we determine what can go wrong in aphasic sentence production?

The production model proposed by Garrett (1975, 1982, 1988) characterizes the processes involved in creating a series of distinct sets of representations that transform ideas into speech. Figure 24–2 is a schematic of normal sentence

Figure 24–2. A Model of Normal Sentence Production Based on Garrett (1988).

production adapted from Garrett (1988), which we have elaborated to illustrate how the model conceives of the elements needed to produce a sentence. In this example, the message to be conveyed is that a girl is kicking a boy. We focus here on the top three levels of the model and do not consider the requirements of articulatory coding. This is not to diminish the importance of these operations, but to emphasize the issues that have been the primary focus of research on sentence processing in aphasia. It is important to keep in mind that this model describes only the representations that are constructed serially during sentence production. What are not detailed are the processes through which the speaker moves from one level to the next.

The three distinct levels within the model to be considered here consist of the following: A Message Representation may derive from a variety of verbal and nonverbal sources, and may be thought of as the conceptualization of some proposition that the speaker wants to convey. A Functional Representation encodes the conceptual proposition into abstract lexical entries representing word meanings and their functional (thematic) roles. Structural order is established at the Positional Level as phonologically specified lexical items are inserted into a surface structure based on their grammatical roles (e.g., subject, verb, object).

These levels of representation are motivated primarily by evidence from errors produced by normal speakers. For example, the postulation that word retrieval requires two steps (one semantic, one phonologic), as well as the details about what information these levels encode, is supported by regularities in the types of errors that occur in normal speech. Word-exchange errors demonstrate distinct characteristics from sound exchanges (exchanged portion italicized; all examples from Garrett, 1982):

- a. "Well you can cut *rain* in the *trees*"
"Why was that *horn* blowing its *train*?"
- b. "No . . . it's . . . Briath Keen" (Brian Keith)
"And this is the *larietal* pobe" (parietal lobe)

Word-exchange errors (as in a.) tend to involve words in different phrases that are in the same grammatical category, whereas sound exchanges (b.) tend to occur within a phrase and to involve words of different grammatical classes. These distinctions lead to the postulation of a multiphrasal planning level in which the identity and phrasal role of words is important (i.e., the Functional Level), in addition to a single-phrase planning level at which (phonologic) form and serial order are represented (the Positional Level). The hypothesis is that word-exchange errors occur in the creation of Functional-Level structures from the message level, whereas sound exchanges arise in the construction of the Positional Level from Functional-Level structures.

One important characteristic of word- and sound-exchange errors is that they almost always involve words from major lexical categories (nouns, verbs, adjectives, and

adverbs) rather than grammatical words (pronouns, auxiliary verbs, prepositions), suggesting that these two types of words are generated by different processes. This distinction is supported by another type of exchange error that generally occurs within phrases:

- c. "that's why they sell the *cheaps drink*" (drinks cheap) "she *writes* her *slanting*" (slants her writing)

These errors typically involve the "stranding" of inflections in their proper positions even though their stems are exchanged, suggesting that the construction of the Positional Level involves the insertion of phonologically specified major lexical items into a planning frame with inflectional elements and grammatical words already specified.

Many variants of this framework with relevance to aphasia have been proposed over the years, including an argument that bound and free grammatical morphemes are generated independently in the construction of phrasal frames (Lapointe, 1985), suggestions that there must be feedback from Positional to Functional Level to account for "mixed" (phonologic/semantic) speech errors (Dell & Reich, 1981), and debate about the level at which grammatical class information is encoded (Caramazza, 1997). Nonetheless, there is widespread agreement on the major distinctions expressed by the model, and it has been used frequently as a starting point for analyses of aphasic sentence production (Saffran, 1982; Schneider & Thompson, 2003; Schwartz, 1987).

Sentence Comprehension

It is likely that sentence comprehension shares many of the more abstract components that Garrett identifies for sentence production (e.g., at the Message and Functional Levels), whereas the details of the phonetic representations (acoustic/articulatory) for input and output must be quite different. Because Message- and Functional-Level representations are assumed to be shared for production and comprehension (Levelt, 1989; Levelt, Roelofs, & Meyer, 1999; Vigliocco & Hartsuiker, 2002), it is sometimes argued that if comprehension of Message and Functional elements is intact, then the source of a patient's production impairment must arise at a later point (Caramazza & Hillis, 1989). For this reason, and in the absence of a suitably detailed model of sentence comprehension, it is useful to consider a schematic of the components of the production model working in reverse as they decode the acoustic signal (see also Jacobs & Thompson, 2000).

Saffran (2001) presents a framework for sentence comprehension that corresponds to the Functional/Positional level distinguished by Garrett. As depicted in Figure 24-3, the listener interprets the acoustic signal by segmenting the phonetic sequence into recognizable spoken word forms and matches them to lexical entries. As each word is recovered, it is held in temporary storage as the syntactic structure of the

Figure 24–3. A Model of Normal Sentence Comprehension Based on Levels of Representation Similar to Those Proposed for Sentence Production.

sentence is assigned at the Positional Level. As the “structural components” (grammatical roles such as subject or object) of the words become available, they are linked to their thematic counterparts (agent, theme/patient) at the Functional Level. As sentence meaning unfolds, a concept is formed and the sentence is interpreted.

Normal sentence interpretation is based on access to, and memory for, a wide range of intermediate elements that the listener must immediately coordinate and integrate across several different levels of information (Saffran, 2001). Any

number of possible points of interruption could undermine sentence comprehension in aphasia. Some of these seem clearly to implicate the point of integration between syntactic structure (at the Positional Level) and sentence meaning (at the Functional Level).

Translating between Levels of Representation

The models described above were conceptualized as serial, feed-forward operations that specify how information is represented for processing. This type of framework is increasingly being challenged by production models that postulate two-way interaction among levels of representation; some of these studies support their assertions with computational implementations (Dell, 1986; Dell, Chang, & Griffin, 1999; Harley, 1995). These models have focused attention on the mechanisms by which information flows between the types of representational levels identified by Garrett.

Details of inter-level interaction is of great importance to considerations of aphasic language, in which it seems likely that perturbations in the timing and coordination of elements across levels could create much difficulty. Even for normal speakers, errors occur with the slightest aberrations in the normal flow of language, such as minor blocks to word-finding, or a change in thought, motivating a modification of the sentence under construction (Garrett, 1982; Levelt et al., 1999). Such aberrations in the normal flow of information are likely considerably greater for the speaker with aphasia, creating challenges for the comparison of aphasic speech to normal speech.

Several hypotheses have been put forth that implicate limitations of memory or other processing resources as critical causes of some types of sentence-processing failure. For example, Kolk (2005) attributes the fragmentary and poorly structured speech produced by many persons with aphasia to interruptions in the normal flow of information, caused either by delay in the activation of the relevant representations or by abnormally fast decay of such information, or by both. These deficiencies then cause strategic adaptations in which patients simplify or truncate structures, or rely on comprehension heuristics.

The lack of detail regarding how information is normally conveyed between levels, and about the memory and other resources necessary to support these processes, makes it difficult to identify a point of disruption in normal processing, since aphasic language problems clearly can involve both degraded representations and limitations on their translation between different forms (or levels).

IDENTIFYING THE SOURCE(S) OF APHASIC SYMPTOMS

Despite these challenges and limitations, considerable evidence suggests that reference to the normal model is an

important and useful tool—one that can help to identify the sources of the overt symptoms of aphasia.

Message-Level Impairment

As noted previously, Message-Level representations are conceptual, nonverbal ideas about people, things, their attributes, and their relationships that might be expressible as language or understood from language. Although the types of “messages” that trigger sentence production are likely to differ somewhat from those that arise as sentences are understood, there is little evidence that these differences are either substantial or measurable. If this is the case, Message-Level impairments, when they occur, should be manifested in both production and comprehension.

Several studies of aphasic sentence processing that implicate a Message-Level impairment have identified an inability to construct “event representations” that establish a basis for sentence production (Dean & Black, 2005; Marshall, Pring, & Chiat, 1993; Nickels, Byng, & Black, 1991). These studies focus on difficulty with the extraction of linguistically relevant information from a concept of some action-based scenario (i.e., a “motion event”). Failure to construct event representations results in poor expression of noun/verb role relations—that is, of *who is doing what to whom*. This may be evident in aphasic production when what the patient says demonstrates no relational link between nouns and verbs; in other words, when it fails to establish a predicate-argument structure. This might be manifested as a preponderance of unlinked nouns in an utterance that does not appear to reflect solely impaired verb retrieval (Dean & Black, 2005). In the following excerpt, the speaker with aphasia is unable to express how two nouns in a pictured event (shown in Figure 24-4) relate to one another, although the speaker clearly perceives the independent activity of each noun:

Pt.: “the girl is in the sand . . . the boy is motionless.”

Ex: “tell me about how they are interacting” (points to boy and girl)

Pt.: “the girl in the sand . . . the man . . . the girl is in the sand . . .” (points in the picture to where the sand is being poured) “. . . the girl is in the sand . . . pouring the woman . . . man . . . two separate . . . equal but . . . the girl is in the sand.”

The use of copular constructions appears to reflect an inability to describe the interaction of the boy and girl depicted in the scene. Although her difficulty may involve impaired verb retrieval, note that she is unable to link a relevant verb “pour” to its correct noun arguments when she does eventually produce it. Thus, it is possible that at least part of the problem is a failure to appreciate the interactional nature of the event.

Another characteristic of aphasia that may reflect impaired event perception is the production of nouns that

Figure 24-4. Stimulus Drawn to Elicit a Sentence (such as “The boy is burying the girl (in the sand)”).

may express some part of a concept, but have no relevance to description of the *event*. Dipper, Black, and Bryan (2005) suggest that the lack of propositional thinking yields the type of noun-listing pattern of production associated with severe nonfluent aphasia, as is evident in the following speech sample in which a speaker with aphasia is retelling the story of Cinderella (from Marshall et al., 1993, p. 180):

crying . . . yes nice . . . (writes ‘12’ on a pad) eleven o’clock yes . . . er dance . . . er wine . . . cherio . . . er horses . . . horses . . . er twelve . . . finish . . . shoe . . . no no no (gestures towards her feet) ah . . . ball . . . shoe . . . shoes . . . no no no big ones.

Although such a sample shows no evidence of propositional thinking, it is also possible that the symptoms arise from poor verb retrieval. Both Message-Level and verb-retrieval impairments could contribute to poor performance when the evidence is limited to verbal tasks such as storytelling. To address these concerns, nonverbal tests of conceptual-event processing have been developed that eliminate the lexical retrieval component of production and allow a clearer understanding of patients’ Message-Level representations. Nickels and colleagues (1991) assessed event understanding in individuals with aphasia using a sorting task with pictures that portrayed an action event (a car being driven) or a “non-event” (a street scene without action). Successful sorting of the event pictures at baseline was associated with a more successful outcome following a sentence-production therapy that assumed intact ability to utilize message representations.

Several tasks designed to assess the ability to understand events have been reported in experimental studies (Dean & Black, 2005; Marshall & Cairns, 2005; Marshall et al., 1993), and a few have been published for clinical use. The Event Perception Test (Marshall et al., 1993; Nickels et al., 1991)

assesses the ability to recognize fine distinctions in verb meaning that engage conceptual/semantic features of verbs (e.g., “pour” vs. “drip”). Performance on this measure is often assessed in conjunction with the Role Video Test (Marshall, 1995; Marshall & Cairns, 2005), in which the person with aphasia is asked to match a video scene to a photo showing the outcome of the event. For example, a video scene showing a woman burning a newspaper is matched to one of three photos: the target (burned paper) and two related distractors (torn paper; burned box). A different version of the task shows reversible scenarios that require knowledge of thematic role assignment (who is doing the action) to interpret the outcome of the event. The ability to interpret the nonreversible events is assumed to require broad decisions about cause and effect, as well as intact ability to interpret complex scenes. Understanding of the reversible scenarios requires the ability to extract role relations from events.

The assessment of patients’ understanding of events and of other aspects of complex concepts is relatively unexplored in aphasia assessment. Yet it seems clear that it is critically important to understanding the nature of aphasic impairments, since difficulties at this level would be expected to have wide-ranging effects on sentence production and comprehension. Treatments that focus solely on specifically linguistic aspects of patients’ performance are unlikely to succeed if patients do not have a secure understanding of concepts such as causality, agency, and temporal order within events.

Functional-Level Impairments

A major feature of the Functional-Level representation is the retrieval and interpretation of abstract lexical representations in accordance with the message (for production) or as dictated by the surface structure (in comprehension). Also created at this level is a representation of the thematic relations among selected lexical elements. By many accounts, a critical element at this level is the selection or interpretation of the verb. It is assumed in many models of normal sentence processing that the verb represents various types of information that contribute to the structure and meaning of a sentence. The choice of verb expresses the semantic concept of the action component of the event, and it determines the predicate-argument structure that will express the thematic relations between the verb and noun(s) involved in the event (c.f., Bresnan & Kaplan, 1982). For example, in describing an event showing a transaction between two people in a store, the speaker can use one of several different verbs (e.g., buy, sell) to express the event, and the choice of verb will influence the assignment of thematic (and grammatical) roles to the nouns. In comprehension, the listener matches the meaning of the verb to the thematic roles of its noun arguments.

Verbs are often classified into types based on their inherent features, such as the manner of motion (run/walk), or how they effect a change of state (melt/burn). Kemmerer (2000), based on Pinker (1989), proposed that grammatically relevant features of verbs are those that determine their syntactic argument structure, whereas features that enable verbs to encode more conceptual information, such as manner of motion or changes of state, are grammatically irrelevant. This finding is supported by evidence that speakers with aphasia can make very subtle perceptual and conceptual judgments about verbs, yet fail when making structure-relevant judgments about the same verbs. For example, Kemmerer (2000) showed that some patients could distinguish between the verbs “drip,” “pour,” and “spray” in tests of verb meaning, and yet were unable to judge the grammatical integrity of sentences using the same verbs, accepting as correct items such as “Sam is dripping the paper with water.”

These findings suggest that different aspects of verb meaning may be differentially subject to disruption in aphasia, with different consequences for sentence processing. This semantic/syntactic distinction within verbs may not be quite so clear as the above results suggest, however. Berndt and Mitchum (1998) reported a pattern of response to sentence-comprehension therapy that indicated sensitivity to conceptual features of verbs that affect the ease of the assignment of thematic roles, independent of the sentence’s argument structure. The relative complexity among types of verbs was indexed by such factors as the extent of relative motion of the event participants, and of degree of change of state experienced by the entity undergoing the action, that were encoded in the verbs’ meanings. Verbs whose meanings implied an asymmetric distribution of motion and degree of affectedness across the sentence’s nouns (e.g., “kick”) were easier to understand following reversible sentence-comprehension therapy than were those with more symmetric distribution of such features (e.g., “chase”) (Jones, 1984; Saffran, Schwartz, & Marin, 1980).

A hierarchy of verb difficulty based on these meaning components was generally supported in a larger study that demonstrated their effects on thematic role assignments in normal and aphasic participants listening to reversible active- and passive-voice sentences (Berndt, Mitchum, Burton, & Haendiges, 2004). The verb hierarchy also predicted response to treatment of reversible sentence comprehension, with more “symmetric” verbs responding more poorly to treatment than verbs with less inherent symmetry (Mitchum, Haendiges, & Berndt, 2004).

An impairment occurring at the Functional Level could give rise to a number of symptoms involving lexical selection and thematic role assignment, but as noted earlier it is often difficult to ascertain that Message-Level representations were sufficient to motivate the correct structures, on the one hand, and that later Positional structures were ultimately

available to support correct productions, on the other hand. Although much testing typically must be carried out before a Functional-Level impairment can be confidently identified, occasionally such a deficit is relatively clear even from limited data. One speaker with aphasia showed an unusual pattern of excellent sentence production in connected speech, with good control over grammatical morphology and a wide range of complex structures. However, she had great difficulty understanding semantically reversible sentences, scoring at chance on numerous administrations of sentence/picture-matching tasks probing active- and passive-voice sentences. In contrast, her ability to detect grammatical violations in spoken sentences was intact. This speaker's great difficulty interpreting thematic roles in comprehension is difficult to reconcile with her excellent sentence production: if comprehension and production share Functional-Level representations, comprehension problems arising at the Functional Level should be mirrored by problems expressing thematic roles. The only way to make this problem evident is with production tasks that require expression of thematic roles. The following sample demonstrates that this is indeed the case when the production task is designed specifically to assess expression of thematic relations. The example also demonstrates how poor expression of thematic roles can occur despite excellent control over grammatical morphemes and a clear ability to obtain a relevant "message" from the picture stimulus shown in Figure 24-5.

Target response: The girl is leading the sheep (with a leash).

Instruction: "Describe this picture by telling me a sentence that starts with 'the girl'."

Response: "the little girl is being pulled along by the sheep. That's not good."

[repeats the sentence twice more, then studies the picture]

Instruction: "Try again."

Response: "the little girl is being pulled forward by the sheep . . . but that's wrong because the sheep is actually

behind . . . the little girl is following the sheep on a leash . . . the little girl is taking the sheep on a walk."

In this case, despite retained ability to produce sentences in the passive voice, and despite obvious appreciation of the event depicted, the speaker had difficulty integrating the order of the nouns with the verb she accurately chose to describe the picture. Note that the final sentence, though clearly correct, relied on a "light" verb construction that did not encode the *direction* of the action. This example clearly indicates that the problem of expressing thematic role relations is not limited to agrammatic speakers or to production of non-canonical structures in which the agent of the action is not the subject of the sentence (as in passive voice).

The impaired sentence production of some speakers with aphasia suggests an inability to assign nouns to the thematic roles dictated by the verb. As noted above, picture-description tasks (in which the target is known to the listener) sometimes elicit sentences with noun order that violates thematic role assignment. Role-reversal errors are infrequent in spontaneous aphasic speech (Menn & Obler, 1990), but can be elicited with carefully constructed tests (Schwartz, Fink, & Saffran, 1995). Production tasks (such as described above) are designed to elicit specific sentence structures and to assess the patient's ability to detect his or her own word-order errors (Caramazza & Berndt, 1985). Such impairments, although clearly implicating some problem with understanding of the thematic relations encoded by verbs, also seem to involve other problems with full expression of the sentence's structural frame at the Positional Level.

Positional-Level Impairment

Realization of a Positional-Level representation is a critical step of grammatical encoding. Although this aspect of sentence production appears especially vulnerable in aphasia, it is not easy to predict how a deficit specific to this level of processing would manifest itself. One problem is the difficulty in distinguishing between a deficit located at this level and one that emerges from failure to elaborate the information that feeds into this level (i.e., from the Message and Functional levels).

Caramazza and Hillis (1989) argued that an impairment arising from the Positional Level would be evident when the structural difficulties with sentence production co-occur with intact single-word retrieval and normal comprehension of reversible sentences (on the assumption that Functional-Level representations are also used in comprehension). This profile suggests that Functional-Level operations (word-meaning retrieval and thematic role assignment) are fully operational, thus localizing the symptom to a point at which the grammatical elements of the sentence are realized for production. Below we describe such a case in which a person with aphasia demonstrated excellent comprehension of active and passive reversible sentences, but was unable to

Figure 24-5. Stimulus Drawn to Elicit a Sentence (such as "The girl is leading the sheep (with a leash)").

produce passive-voice sentences. However, the functional locus of impaired sentence processing in this case was interpreted quite differently (see also Mitchum, Greenwald, & Berndt, 2000).

Exactly how the grammatical elements are derived at the Positional Level is left largely unspecified in Garrett's (1982, 1988) model of normal sentence production. Some patterns of production (as in the examples above) clearly indicate that the speaker has the ability to retrieve grammatical function words, but does not seem to know where to place them to form a structural sentence frame (Berndt, Haendiges, Mitchum, & Sandson, 1997). Further support that a variety of grammatical frame structures are available, but underutilized, comes from investigations using structural sentence "priming." Several studies have shown that some speakers with aphasia are significantly more likely to produce a specific structure immediately after hearing a different, but structurally similar, sentence that serves as a model or "prime" (Saffran & Martin, 1997), even for particularly difficult structures such as passive voice. In normal speakers, there is evidence that structural priming effects are sustained for a remarkably long time, measuring as many as 10 intervening sentences between the auditory prime and production of the primed sentence structure (Bock & Griffin, 2000).

Hartsuiker and Kolk (1998) obtained experimental evidence that the syntactic priming effect was diminished when participants with aphasia were explicitly told to model the priming sentence. When the same task was given without instruction to use the model, the effect of priming for agrammatic speakers was robust for both active and passive sentence types. This finding implies that the construction of a Positional-Level representation may be undermined by conscious effort in aphasic production, perhaps because the resources required to use the provided structure causes the patients to divide their attention from the content of the target sentence to its structure. Interestingly, the inverse was observed for control subjects: priming was facilitated when normal speakers were explicitly asked to match the structure of the model sentence.

USING THE MODEL TO MOTIVATE THERAPY: VERB PRODUCTION

The results of the studies described above can inspire novel approaches to aphasia therapy, and may be helpful in interpreting the effects of more traditional approaches. While there are diagnostic advantages of attempting to isolate a hypothetical component of normal sentence processing, therapies driven by the diagnostic findings tend to be more closely aligned to the symptom. This is due, in part, to underspecification of how representational levels are formed (as noted above) and to the possible interactive nature of subcomponent processes of production (Dell et al., 1999; Harley, 1995). Most therapies guided by normal models target a specific

symptom of sentence-processing impairment, then attempt to restore function by improving the integrity of the degraded representation, and/or access to it. Here we focus on the symptom of poor verb retrieval, especially with regard to its effect on the processes that support sentence production.

The effect of poor lexical access to verbs has been well studied in aphasia. Careful observation and analysis of spoken production can reveal patterns of verb omission, or strategic avoidance of lexical verbs in sentences, as described above. Although poor verb retrieval is highly correlated with structurally impaired sentence production, the correlation with clinical aphasia is imperfect (Berndt, Haendiges, et al., 1997; Berndt, Mitchum, Haendiges, & Sandson, 1997; Caramazza & Hillis, 1989). In the preceding section, the importance of the verb in many aspects of sentence processing was highlighted; yet it cannot simply be assumed that verb difficulties actually cause the grammatical disturbance. The nature of the relationship between verb retrieval and sentence production has been explored using experimental paradigms that improve access to lexical verbs by speakers with aphasia who have difficulty producing verbs in sentences. Tasks of "cued production," in which the phonologic form of an uninflected verb is provided to the speaker with aphasia to use in a sentence, have yielded mixed results (Berndt, Haendiges et al., 1997; Berndt, Haendiges, & Wozniak, 1997; Farouqui-Shah & Thompson, 2003; Marshall, Pring, & Chiat, 1998). Such variability underscores the complexity of the relationship between poor verb retrieval and impaired sentence production.

One of the problems in elucidating the role of the verb in aphasic sentence production has already been described: difficulties associated with verbs may arise at a number of levels within the normal stream of sentence formation and production, making it difficult to pinpoint the source(s) of disruption within a single person with aphasia. Moreover, problems arising at a specific point may give rise to different symptoms in different speakers with aphasia, depending on such things as the unique combination of associated problems and the indication that the strategies to overcome (even mask) the impairment. In addition, it is essentially impossible to avoid some engagement of several levels of processing with the clinical treatment tasks. For all of these reasons, it is more accurate to say that model-driven therapies "highlight" (rather than "isolate") specific representations or processing operations.

Message-Level (Event) Treatments

As suggested above, poor expression of propositional speech may be attributed in some cases to difficulty extracting relevant information from the Message. A few studies have specified therapy that directly targets the ability to understand events. Jane Marshall (1999) has pioneered these efforts

using a variety of nonlinguistic and language tasks. One approach to therapy at this level is to place conscious effort on “unpacking” the elements of an observed or imagined event. Marshall (1999) encouraged one speaker with aphasia, with apparent difficulty conceptualizing events, to extract propositional information from events using imagery and gesture (p. 124):

Examiner: “Imagine yourself with the dog. There he is at your feet (points to door). You go and get some string and make a lead (gestures holding leash). You set off . . .”

Response: (copies the gesture and moves it away from her body) “Take . . . yes take . . . take the dog to the house.”

The imagery and gesture therapy was used along with an attempt to help this woman focus on the aspect of a complex event that could be described with a simple proposition. The goal was to “promote the formation of highly focused concepts at the Message Level, which would place minimal demands on her language system.” To encourage this, Marshall employed a variety of exercises to “alter (Bock & Levelt, 1994) conceptual preparations for language” (p. 124).

To simplify things, a set of “light” verbs was established for verbal descriptions, each being matched to a broad conceptual category (established earlier in therapy). These included verbs such as “go”/“come” (movement), “give”/“get” (change of possession), “put”/“take” (removal and location), and so on. The use of gesture, a natural tendency observed in this particular speaker, was encouraged to compliment the imagery exercises and to promote focus on the action component of scenarios. Post-therapy results showed improved production of verbs with specific arguments in storytelling tasks (i.e., narrative speech). Communicative effectiveness was also measurably improved as determined by both trained and naïve judges.

Marshall (1999) interpreted the results as indicative of improved conceptual preparation and attention to linguistically relevant components of events. As anticipated, Marshall’s patient had learned to extract verb-relevant information that could be used in simple propositions. Of interest was that the use of light verbs as a substitute for lexical verbs was not considered an effective goal of therapy. Marshall found that such verbs were helpful in learning to isolate verb-relevant information from events, but that their use at later stages (i.e., as a substitute for lexical verbs) was actually a limiting factor.

Other therapies have been designed to help individuals with aphasia identify relevant conceptual information, addressing skills that have been described as “thinking for speaking” (Slobin, 1996). Such therapies attempt to filter, or “pare down” complex events to a single (expressible) proposition, and methodically increase event complexity as determined by the number of events and their variety of potential perspectives (Marshall & Cairns, 2005). In some cases, changes to the way events are interpreted can be guided to

match the propositional structures available to the speaker with aphasia. For example, Marshall (1999) describes a treatment that uses complex video scenes presented with a systematic cueing hierarchy. The speaker was guided through the event by focusing on a serial description of the smaller sequences (e.g., the clinician says: “now he’s at the door . . . what does he do next? Just the first thing.” Response: mimes action; “put the bag on the ground”) (p.124). A broader-ranging therapy described by Peach and Wong (2004) used written feedback to refine the conceptual content of spoken sentences, and to repair grammatical errors. This approach exercised a range of production levels to address the link from conceptual to Positional-Level representations.

Message-to-Functional Level Treatments

Verb-retrieval therapies that link the verb to possible noun arguments (sometimes described as “semantic” therapy) have been shown to improve the number of arguments produced (in sentences) in association with verbs. In some cases, the treatment must focus first on establishing that the patient understands the conceptual distinctions among different types of verbs. Marshall (1999) encouraged patient E.M. to recognize the intrinsic *manner* of verbs based on their motion (“spin”/“drive”), change of state (“melt”/“cook”), movement (“spray”/“splatter”), change of possession (“buy”/“learn”), or relative non-action (“bore”/“pity”). Queries enforced the fundamental verb concept (e.g., “When you *spray* paint on a wall, what moves? The wall or the paint?”). The therapy task also engaged conversation about the conceptual distinctions among the verb types.

Other therapies assume that the conceptual information is already available (i.e., that the problem is not in establishing a message), yet there is some difficulty identifying the correct verb at the Functional Level. Several studies describe treatment of sentence production using tasks that focus only on single-verb semantics. Marshall, Pring, and Chiat (1998), Raymer and Ellsworth (2002), and Schneider and Thompson (2003) describe therapy studies with different participants with aphasia that limited treatment to single words and used a semantic therapy, either in conjunction with, or contrasted with, other (nonsemantic) forms of single-word therapy. A common principle of these therapies is to allow the speakers with aphasia to appreciate a range of factors associated with a verb’s meaning *and* its relation to other sentence elements (primarily nouns). These therapies collectively suggest that single-word therapies can provide a basis for generalization to sentence production for some speakers with aphasia. However, it may prove critical that noun/verb role relations are highlighted in such therapies to obtain generalization to sentence-level production. That is, such generalization may rely on a realization of how the verb and its (noun) arguments relate to one another at the sentence level, even though the therapy tasks involve only single words.

Some studies explicitly address the production of specific types of predicate-argument structures (PAS). Sentence-ordering tasks can be used to assess understanding of verb-argument structure by having participants arrange written anagram phrases (verbs plus arguments) into meaningful sentences (Jacobs & Thompson, 2000; Marshall, Chiat, & Pring, 1997; Marshall et al., 1993; Mitchum et al., 2000; Murray, Ballard, & Karcher, 2004). Schneider and Thompson (2003) compared the effects of semantic tasks (addressing verb properties such as direction of motion or change of state) with the effects of argument-structure tasks that highlighted the number and place of verb arguments. For example, a depiction of the three-argument verb “fill” was accompanied by the following information: “This picture shows fill. It shows ‘the girl is filling the pitcher with water.’ The girl is the person doing the filling; the water is the thing doing the filling; and the pitcher is the thing being filled.” An attempt at production followed this instruction. Both forms of treatment (i.e., based either on semantics or PAS) yielded improved verb retrieval and sentence production. Webster, Morris, and Franklin (2005) describe a treatment study designed to target verbs’ PAS production using therapy tasks to improve verb retrieval, establish thematic role relations between verbs and nouns, and practice sentence generation. Post-therapy sentence production contained more verbs and nouns as obligatory arguments and a greater variety of argument structures in connected speech.

As these results indicate, there is actually little distinction among tasks that are said to address construction of the PAS, to improve lexical-verb production, and/or to improve semantic processing of nouns and/or verbs. All of these approaches potentially serve to link verb/noun role relations and contribute to the formation of a Functional-Level representation. These tasks can also be difficult to distinguish from tasks that target event-role interpretation (as discussed above), which are presumed to occur earlier at the conceptual/message level. It is likely that tasks that involve multiple levels of processing, or therapies that involve a variety of different exercises, engage a wider range of sentence-processing components. The assumption behind this therapy approach is that treatment should target a broad range of functions to improve the potential for effective results. The disadvantage of providing a range of therapy tasks is the lack of specificity regarding exactly which elements of the therapy effected a positive outcome in a particular case.

In general, verb-based therapies that integrate noun/verb role relations, even without working at the sentence level, appear to be effective with many patients with aphasia. Demonstration therapies have yielded robust results with regard to production of canonical (i.e., active voice) sentences, often with multiple arguments. There is no indication, however, that lexically based single-word therapies generalize to production of non-canonical structures, an

effect we elaborate on below with regard to treatments targeting the Positional-Level representation.

Functional-to-Positional Level Treatments

Verb Retrieval: Word Form

Therapies that practice simple stimulation of action words either with repetition/rehearsal (Raymer & Ellsworth, 2002) or with picture naming (Fink, Schwartz, & Myers, 1998; Mitchum & Berndt, 1994; Mitchum, Haendiges, & Berndt, 1993) may address only a part of the verb’s lexical representation. If the therapy task stimulates only production of the phonologic word form from pictured meaning (devoid of thematic requirements), it may address problems of retrieval at the Positional Level (i.e., word forms), while leaving the earlier (Functional and Message level) representations of the sentence production process “untouched” by intervention. If a speaker with aphasia has additional impairments involving the Functional-Level representation (which may be indicated if reversible sentence comprehension is poor), the treatment predictably would not improve sentence production.

Mitchum and colleagues (1993, 1994) studied the relationship between verb-retrieval therapy and sentence production in two speakers with chronic aphasia (7 to 8 years post-onset). In terms of superficial symptoms of aphasia, both were clinically quite different. One was fluent, yet showed all the features associated with agrammatic production: reduced phrase structure, use of simple sentence structures, poor verb retrieval in sentence production, and impaired use of verb-related grammatical morphemes. Both patients were poor at comprehending reversible sentences. The other person was severely nonfluent. Although he could not produce sentences verbally, his attempts at written sentence production revealed the same pattern of response elicited verbally from the other person.

Following extensive diagnostics, it was hypothesized that, for both participants, facile availability of verbs would improve sentence production if, in fact, the unavailability of verb word forms was a source of the sentence-production impairment. The same technique was used with both patients although responses were elicited verbally for one participant and in writing for the other. Several picture exemplars of action verbs were repeatedly presented to elicit a set of verbs that “name the action.” As criterion performance was reached for each targeted verb (correct response initiated within 3 seconds), a new verb was added until the treatment successfully established facile retrieval of eight verbs (an effect that was sustained for at least 1 month following therapy) (Mitchum & Berndt, 1994; Mitchum et al., 1993).

Despite significantly improved ability to retrieve specific lexical verbs, neither participant demonstrated an ability to *use* the newly acquired verbs in sentences. This result helps to clarify why traditional “naming therapies” that practice picture-naming (devoid of any attachment to morphologic

Figure 24-6. Sequential Picture Stimuli Used to Elicit Time-Marking Grammatical Morphemes (Future, Present, and Past Tense). (Target responses reflect the temporal order of an action event.)

elements or semantic relations) often have a limited effect on production beyond the single-word level. Berndt and colleagues (1997) argued that only a small percentage of cases involving impaired verb production may be attributed to a localized impairment involving access to verbs' word forms. This argument was based on results showing that verb-cued retrieval (i.e., providing an uninflected verb form for patients to use in a sentence) usually fails to improve sentence production.

Verb Retrieval: Verb Morphology

The sentence production patterns of speakers with aphasia with poor production of verb inflections vary considerably (Faroqui-Shah & Thompson, 2003). Druks and Carroll (2005) concluded that the unavailability of verb-tense information was the basis for the poor production of the speaker with aphasia in their study. DOR used few verbs in narrative speech, and benefited from cued retrieval only when provided with verbs inflected in the present-progressive form (-ing); past tense (-ed) did not cue sentence production. In action picture-naming, DOR produced some verbs, but often substituted a noun for a verb. He also tended to inflect nouns as if they were verbs (e.g., "afternoon maybe it's *computer-ing* or going out"; "today is *hoover-ing* and dusting" (c.f. classic examples in Saffran et al., 1980). Druks and Carroll (2005, p. 11) suggest that "verbs unmarked for tense, in contexts where tense is obligatory, are no longer grammatical units that participate in sentence construction; instead they are labels of actions." Further testing indicated that DOR appreciated the concept of tense (i.e., he was able to arrange sequential pictures into their temporal order), but suffered from a fundamental morphosyntactic problem marking and interpreting verb tense.

For many speakers with aphasia, verb morphology is available, but poorly used. In some cases, production is

improved when inflected verbs are provided as cues (Faroqui-Shah & Thompson, 2003). For example, dependence on the present-progressive verb inflection (-ing) is often observed in aphasic speech, either as a natural tendency of production (Goodglass, 1993; Mitchum & Berndt, 1994; Mitchum et al., 1993), in response to cued verb retrieval (Faroqui-Shah & Thompson, 2003), or as a post-therapy characteristic (Raymer & Ellsworth, 2002). This does not demonstrate use of this inflection as a morphologic element, but indicates only knowledge that an inflection (of some sort) is expected.

Mitchum and colleagues (1993, 1994) interpreted the lack of generalization to sentence production from the uninflected verb-form treatments (described above) as an indication that the grammatical frame of the sentence was unavailable, evidenced by the patients' over-reliance on the present progressive in all contexts. A second intervention carried out with the same two patients linked the production of verb-tense markers (auxiliary "will," bound morphemes -ing, -ed) to the expression of temporal information using sequential pictures (Fig. 24-6). In a series of steps, therapy systematically diminished cues needed to elicit structurally well-formed sentences to express a future-, present-, or past-tense sentence to describe each picture. The intervention was successful in establishing verb retrieval for trained and untrained lexical verbs, including irregular past-tense verbs (Table 24-1). In addition, the generalization to untrained verbs suggested a robust effect of therapy that tapped intact lexical-verb representations, and was not dependent on the elicitation conditions used in therapy. Significant improvement was also noted in a sentence-generation task in which the patient was asked to construct a sentence using a specific noun or verb. However, there was no generalization to untrained sentence types; in particular, the past-tense verb morphology, once available, was not produced as the superficially similar past participle to support passive structures.

TABLE 24-1

Proportion of Sentences Containing the Target Verb Morphology Needed to Describe Sequential-Action Picture Stimuli (shown in Fig. 24-6)*

M.L. (spoken)	"will" + verb	"is" + verb + "ing"	"has" + verb + "ed"
before therapy	0.25	0.75	0.00
after therapy	1.00	1.00	1.00
E.A. (written)	"will" + verb	"is" + verb + "ing"	"has" + verb + "ed"
before therapy	0.00	0.00	0.00
after therapy	0.75	0.88	0.38

**n* = 8 per type; elicited before and after therapy to improve grammatical sentence production. Pictures were not presented in sequential order for these assessments.

Two studies expanded upon the verb-tense training paradigm reported by Mitchum and Berndt (1994). Weinrich, Shelton, Cox, and McCall (1997) attempted to isolate the effects of verb-tense training to the Functional Level using a computerized iconic symbol system that focused therapy on the insertion of lexical terms (object/action icons) into a grammatical frame. Future-, present-, and past-tense morphology was trained using sequential pictures. All three participants (speakers with severe aphasia) showed marked improvement in verbal production and comprehension of sentences with tense-marked verbs following training; generalization to untrained verbs was also noted (Rochon & Reichman, 2003; Weinrich, Boser, & McCall, 1999). These studies observed no generalization to untrained sentence types.

Verb Retrieval: Non-Canonical Sentence Structures

The attention to grammatical frames focusing on verb tense exploits the structural information encoded in verb representations and draws attention to the need for structure in sentences. This points out to the speaker with aphasia that sentence meaning can be modified with grammatical elements. Verb-centered therapies have been generally successful in establishing improved sentence production as measured by increased use of lexical verbs (often within the trained verb class or semantic field), and of a greater number of verb arguments. However, there is considerable evidence that verb-centered therapy does not readily affect the production of non-canonical structures (Mitchum et al., 2000; Rochon & Reichman, 2003). Rather, improved production of non-canonical sentences requires explicit retraining.

Rochon and Reichman (2003) describe a phase of therapy in which their participant (DH) was trained to produce

non-canonical sentences using therapy tasks that demonstrated lexical insertion of nouns and verbs into passive sentence frames marked for tense with sequential pictures (future, present, past). In response to this therapy, DH learned to use passive sentences in narrative production and other untrained conditions, but at some expense to his ability to use active sentences.

Another example of therapy focused on non-canonical sentence production involved an unusual case of isolated impairment of passive-voice production. A.L. (described in Mitchum & Berndt, 2001; Mitchum et al., 2000) was a fluent speaker with intact comprehension of semantically reversible sentences and flawless repetition of active and passive sentences, all in conjunction with an inability to produce passive sentences in a constrained production task. As shown in Table 24-2, A.L. produced well-formed active-voice sentences without difficulty. However, when constrained to start his sentence with a non-agentive noun his responses were clearly impaired. The few responses that contained a passive structure were anomalous in meaning; presumably he was aware that walls cannot paint girls (see response to stimulus #1). Many attempts revealed either strategic avoidance of the target passive (as in stimulus #2), a lack of integration between the actor/object (stimuli #3 to #5), or some otherwise inadequate sentence (stimuli #6 to #8).

Following a demonstration that extensive sentence-repetition training was not effective in improving his passive sentence production (presumably because the source of impairment was at an earlier level), an intervention was designed to establish a link between active and passive sentence meanings at the pre-phonologic level. Using a written anagram version of a sentence-order task, A.L. learned to produce passive sentences by linking the change in word order and verb inflection of the passive to its counterpart active structure. After

TABLE 24-2

Sample of A.L.'s Responses in a Task of Picture Description*

Stimulus	Constrained Active Response	Constrained Passive Response
(1) girl painting wall	"The <u>girl</u> is painting the wall."	"The <u>wall</u> is painting the girl."
(2) girl kicking a boy	"The <u>girl</u> is kicking the boy."	"The <u>boy</u> is perturbed because the girl is kicking the boy."
(3) man drinking tea	"The <u>man</u> is drinking from the cup."	"The <u>tea</u> is hot."
(4) boy eating an apple	"The <u>boy</u> is eating the apple."	"The <u>apple</u> . . . is paramount."
(5) girl riding bike	"The <u>girl</u> is riding a bike."	"The <u>bike</u> is . . . not very pretty."
(6) man cutting a rope	"The <u>man</u> is cutting the rope."	"The <u>rope</u> is . . . piecemeal."
(7) boy pushing a box	"The <u>boy</u> is fixing the boxes."	"The <u>box</u> . . ."
(8) horse jumping a fence	"The <u>horse</u> is jumping."	"The <u>fence</u> . . ."

* Responses are constrained by the requirement that each sentence start with the agent noun (for active targets) or the non-agent noun (for passive targets), underlined in the examples. The same picture is used in separate test sessions to elicit each type of sentence.

12 sessions, therapy proved successful. Unlike the result obtained with D.L. by Rochon and Reichmann (2003), there was no decline in the production of active sentences following passive-sentence training. One factor in the different outcomes may have been A.L.'s intact comprehension of both active and passive sentences at the start of intervention, whereas D.L. required additional training in sentence comprehension.

A therapy procedure described by Jacobs and Thompson (2000) similarly linked canonical and noncanonical structures (passives and object clefts) to the same underlying meaning. Anagram words were used to build sentences, and to demonstrate the moved content words and changes in the grammatical frame for noncanonical sentences. The treatment was preceded by attention to the central action (verb) and its thematic role relations. Production treatment required oral reading of the final sentence; comprehension required pointing to constituents (in pictures) with no verbal response. The treatment was effective with all (four) participants and generalized to untrained exemplars, but not to (theoretically) unrelated sentence types. This study further supports the necessity of direct training of noncanonical sentence structures and of motivating them by attention to sentence meaning.

INTERPRETING THE EFFECTS OF TREATMENT

While many model-driven therapies attempt to target specific functional components, others consider how therapy can "exercise" integration of the various subprocesses that support production. Successful therapies do not need to pinpoint the locus of treatment effects to be clinically relevant (e.g., Peach & Wong, 2004). However, attempts to interpret the effects of aphasia treatments have led to better understanding of what might have occurred in therapy; that is, of which cognitive mechanisms were used to accomplish the

treatment task. An understanding of how therapy affects cognitive function will inevitably lead to a better understanding of which treatment approach is most appropriate, and has the potential to offer the most widely applicable results. Therapy studies designed and executed in the context of a normal production model have provided a basis for interpreting sentence-processing therapy effects.

The Mapping-Deficit Hypothesis

As noted above, early analyses of agrammatism (the "syntactic-deficit hypothesis") attributed both comprehension and production impairments associated with agrammatism to an inability to establish a full syntactic representation (at the Positional Level) either because of difficulty producing and interpreting grammatical morphemes (Kean, 1979) or because of a more general inability to elaborate a syntactic structure (Berndt & Caramazza, 1980). However, a series of studies demonstrated spared sensitivity to syntactic structure in grammaticality judgment tasks in patients with poor sentence comprehension and production of reversible sentences (Linebarger, 1990; Linebarger, Schwartz, & Saffran, 1983; Saffran, Schwartz, & Linebarger, 1998; Schwartz, Linebarger, Saffran, & Pate, 1987). These findings indicated that the patients' difficulties did not arise from poor representation of syntactic information, but rather from an inability to coordinate the representations of syntactic functions (e.g., subject/object) and thematic roles (e.g., agent/object). This is, in effect, an inability to relate surface-structure cues to the underlying sentence meaning, as expressed by thematic role assignment (for comprehension) or to express thematic roles appropriately in a sentence structure (for production). In Garrett's (1988) model this indicated an inability to map between the Functional- and Positional-Level representations. This failure has been termed the "Mapping-Deficit Hypothesis" (MDH) (Saffran

Canonical sentence order:**Noncanonical sentence order:**

Figure 24–7. Illustration of Canonical vs. Noncanonical Sentence Structure. (The arrows characterize the shift in word order for two sentence types with shared meaning.)

& Schwartz, 1988), and provides a clear example of the importance of considering the transfer of information from one level of the model to the next.

Identifying a Thematic Mapping Impairment

Impaired thematic/syntactic mapping has been attributed to two potential sources. The “lexical” variant arises from poor access to verb-specific mapping rules, in other words, the syntactic and grammatical information that is inherently part of the lexical-verb representation. According to Saffran and Schwartz (1988), this type of problem could explain poor interpretation of simple, canonical sentences with a transparent mapping between grammatical roles (subject, object) and thematic roles (agent, patient) (Fig. 24–7). For more complex sentences in which the mapping is not transparent (such as in passive-voice sentences in which the subject noun does not map to the thematic role of agent), Saffran and Schwartz and colleagues (1987, 1988) proposed a “procedural” variant of the MDH, implicating the processes that move noun arguments out of their canonical (deep-structure) positions.

Therapies Designed to Improve Thematic Mapping

The hypothesis that failure to produce and/or comprehend sentences in aphasia could arise from a failure to link two levels of intact representation has significant implications for therapy (for reviews of “mapping” therapies, see Fink, 2001; Marshall, 1995; Mitchum et al., 2000). Despite their different formats, many sentence-comprehension treatment studies shared the goal of linking sentence structure (Positional-Level representation) to semantic/thematic

structure (Functional-Level representation). Initially, the objective of these experimental studies was not so much to test the efficacy of the therapy procedure but to test the hypothesis that poor mapping ability (either lexical or procedural) was an underlying cause of impaired sentence processing. Extensive pre/post-therapy measures were provided from each study to interpret what, if any, changes were established, and how they may have occurred.

Mapping therapies have been generally quite successful in improving sentence comprehension for *trained* reversible sentences, but often reveal wide variability in patterns of generalization (or lack thereof) among the participants (Marshall, 1995; Nickels et al., 1991; Schwartz, Saffran, Fink, Myers, & Martin, 1994). Few speakers with aphasia have shown improvement on all post-therapy measures, and most demonstrate persistent sentence-processing impairment.

Extensive post-therapy analyses indicate that therapies designed to improve thematic mapping between the Functional and Positional levels cannot assume that each representational level is intact. The small number of highly successful results observed with mapping therapies have likely addressed a relatively pure mapping impairment in these particular participants (Byng, 1988; Rochon, Laird, Bose, & Scofield, 2005; Schwartz et al., 1994), or the cases in which treatment also addressed the additional impairments. Most of the mapping-therapy outcomes have revealed far more limited effects of therapy, and they implicate a different, and perhaps more extensive, source of impairment in the patients who participated (Fink, 2001; Marshall, 1995; Mitchum & Berndt, 2001; Mitchum et al., 2000; Nickels et al., 1991).

The collective outcome of mapping therapies leads us to a conclusion that parallels the direction of other research in cognitive neuropsychology. Therapies cannot be based on the assumption that grammatically based symptoms of production and comprehension represent a homogenous entity. Rather, it appears far more promising to look at the relative symptom in individual cases that seems to give rise to the grammatical-processing impairment. The question(s) of interest have become more specific. Model-based treatment studies are motivated by assessment of what the speaker (or listener) fails to establish at the various representational levels, and whether or not information is communicated between levels.

Studying the Generalization of Treatment Effects

Cognitive-neuropsychological treatment studies typically assess aphasic participants’ ability to acquire trained and untrained exemplars of the treatment material, and to generalize what is learned to other (related and/or unrelated) materials and conditions. Studies of how sentence-level treatments generalize across input/output modalities indicate that therapy tasks that address structural cues to sentence meaning effectively improve sentence *comprehension*,

but tend to remain specific to comprehension (Berndt & Mitchum, 1998; Haendiges, Berndt, & Mitchum, 1996; Mitchum, Haendiges, & Berndt, 1995). Sentence-comprehension therapies that explicitly point out verb-centered thematic role relations and retrieval of predicate-argument structures have some effect on sentence production, particularly with regard to increased use of lexical verbs and an increased number of noun arguments (Byng, 1988; Fink et al., 1998; Jacobs & Thompson, 2000; Marshall, 1995). In contrast, sentence-production therapy has been shown to have little transfer to sentence comprehension (Jacobs & Thompson, 2000; Mitchum & Berndt, 1994; Mitchum et al., 1993; Murray et al., 2004; Rochon et al., 2005; Rochon & Reichman, 2003, 2004).

Research findings regarding cross-modal generalization are both theoretically and clinically important: patterns of generalization suggest how certain aspects of sentence processing are shared across modalities, and they may point to the most efficient approaches to therapy. Although considerable insights have been gained in recent years with regard to generalization of treatment effects, it remains important to recognize that our current impressions are influenced by a number of complicating variables, including variations in the techniques used in therapy, symptomatic differences among participants, and the methods used to measure generalization.

Interpreting Strategies Induced by Aphasia

The cognitive-neuropsychological approach has offered a framework for the identification and interpretation of strategies used by individuals with aphasia. The detailed attention to response patterns and subtle manipulations of stimuli inherent in model-based assessments can reveal much about a person's ability to process specific sentence types, and to use strategies when needed. It was a long-standing assumption that strategies were used in aphasia only when processing failed. More recently, research suggests that individuals with aphasic language may regularly avoid aspects of sentence processing, becoming overly dependent on normally influential cues such as word order (Caplan, 1992), verb-specific mapping information (Berndt & Mitchum, 1998), or primitive spatial strategies (Chatterjee, Maher, Gonzalez-Rothi, & Heilman, 1995). Linebarger (1995) suggests that the use of strategies is not compensatory, but rather reflects "normal mechanisms which have come to play an abnormally visible role" (p. 83). This interpretation is supported by evidence that even normal listeners use shallow processing for comprehension that is usually "good enough" to support a correct interpretation (see also Chatterjee, Southwood, & Basilico, 1999; Ferreira, 2003; Ferreira, Bailey, & Ferraro, 2002; Saffran, 2001).

In some cases, strategies are detected in post-therapy assessments. For example, apparent generalization to comprehension of passive sentences has been shown to hinge on

the superficial detection of the "by" phrase in the surface structure (Berndt & Mitchum, 1998; Haendiges et al., 1996). This was revealed only when truncated versions of passive sentences (i.e., passives without the "by" phrase such as "the boy was hit") were not interpreted at the same level as full passive structures. Mitchum and colleagues (2004) demonstrated the clinical utility of identifying response biases in tests of sentence comprehension. Two individuals with aphasia responded to interventions that took their strategic tendencies into account. Of interest was the finding that the person who demonstrated a more superficial strategy was more responsive to intervention, presumably because the strategy represented a "good enough" approach that was easily displaced.

Strategies are also frequently observed in aphasic attempts at verbal sentence production. The use of "light" verbs, or simplified structures, implicates an attempt to produce a syntactically structured proposition in spite of the linguistic limitations imposed by aphasia (Marshall, 1999; Mitchum & Berndt, 1994). One well-developed theory of agrammatic sentence production emphasizes patients' ability to revert to simplified (but normal) elliptical structures when their processing resources become taxed (Kolk, 2005; Kolk & VanGrunsven, 1985). Kolk stresses that these elliptical structures are a type of speech register that may be used by normal speakers in some conditions, such as when talking to a foreign speaker.

A program of production therapy has been devised based on Kolk's hypothesis. Springer and colleagues describe good results for German speakers with aphasia using Reduced Syntax Therapy (REST) (Springer, Huber, Schlenk, & Schlenk, 2000). This intervention is based on the view that severe agrammatism is a compensatory response to the loss of syntactic ability that arises from the nondominant hemisphere (Springer et al., 2000). Like other linguistic approaches, treatment encourages activation of Functional-Level information and the mapping between thematic roles and (simple) syntactic structures. However, the production of morphosyntactic elements is actively *discouraged* in favor of expanding the lexical content of telegraphic-style utterances. The authors suggest that their compensatory approach "frees up capacities for other aspects of the production process, like message planning, word activation and motor speech planning" (Springer et al., 2000).

The consistent use of response strategies by individuals with aphasia should be considered in diagnostic testing to avoid misinterpreting the nature of their language impairment. Such identification typically requires testing the patient with a variety of tasks using different response formats. It is equally important to identify the extent to which changes established with therapy reflect shifts in strategy, or whether they represent a fundamental change in cognitive processing. Although any positive change is a welcomed outcome, a better understanding of how therapy affects cognitive processing

leads to a more efficient basis for matching the treatment candidate to the most effective intervention.

FUTURE TRENDS

Cognitive-neuropsychological studies have contributed to a better understanding of sentence-processing impairments in patients with aphasia. In this chapter, we illustrated how even a single symptom (e.g., impaired verb retrieval) can arise from multiple sources in the sentence-production process, and how such a symptom may be embedded within the unique combination of spared and impaired function of each individual with aphasia. In this respect, cognitive neuropsychology has served to reveal the complexity of the aphasic condition. At the same time, a cognitive-neuropsychological analysis offers a structured means of accounting for the differences in function that may be imposed by brain damage, and it provides a basis for therapy that seeks either to restore normal function, or to find new or compensatory ways to communicate around the impairment.

As models of normal cognition improve, there will be a better account of the flow of information within and across levels of representation. A more detailed understanding of normal cognition will provide a much-needed basis to develop a theory of the therapy process itself. Future research should be directed at refining the basis for selecting a therapy approach, with studies of how treatment effects generalize within and across cognitive domains. A less-developed area that is beginning to receive more attention is how certain cognitive domains (such as memory and perception), traditionally viewed as nonlinguistic functions, serve to support language in various ways and at multiple points in processing.

Increased interest in individual therapy outcomes dictates an individualized approach to therapy. Cognitive-neuropsychological studies of aphasia continue to offer a framework for addressing this challenge by approaching the problem in terms of the difference between normal and aphasic language, and not as an effort to classify individuals under diagnostic “labels” that reiterate the symptoms of impairment.

KEY POINTS

1. Models of normal cognitive function, such as sentence processing, can be used to guide diagnosis and intervention in aphasia. Even underspecified models are useful in this regard. As models are further developed, and theories of normal sentence processing are advanced, the extent to which models of normal cognition can be applied to clinical intervention will improve.
2. The set of symptoms traditionally associated with agrammatism do not always occur together, making it clear that agrammatism does not constitute a clearly defined syndrome. Current approaches to the study of sentence production and comprehension in aphasia seek to explain how a particular symptom (such as poor verb retrieval) contributes to the sentence-processing pattern observed in individual cases, or in groups of individuals who share (at least) the symptom of interest.
3. Treatment studies based on a cognitive-neuropsychological interpretation of aphasic sentence processing are largely conducted as a research endeavor. However, the recent emphasis on evidence-based therapy has forged a more direct and urgent link between research and clinical intervention. Although many of the treatment approaches described here have direct clinical relevance, the goal of such studies is generally not intended to test the efficacy of a particular therapy. Rather, such studies illustrate an *approach* to diagnosis and intervention that evolves from an understanding of the differences between normal and aphasic language.
4. Although the studies cited here describe experimental therapies, some general clinical implications have emerged. An important finding is that the most effective therapies for improving sentence production are those that integrate the full production process. Treatments that isolate later levels of lexical representation (such as traditional “picture-naming” therapies that practice repeated access to phonologic word forms) are effective only in a small percentage of cases. More often, the best outcomes are obtained from therapy that directs attention to the link between conceptual information about an event and the elements that allow for linguistic encoding of the event, such as meaning and thematic relations.
5. An understanding of noun/verb role relations is a critical element of sentence production that can be retrained effectively in aphasia. Therapy that targets this element of production can be limited to single words, with the expectation that therapy may generalize to sentences and narrative contexts (assuming that there are no additional impairments). Such effects are likely, however, to be limited to the production of canonical structures. Improved production of noncanonical structures (passive, object-relative clause), which give production improved flexibility, appears to require specific retraining of those sentence structures.
6. Studies of the manner in which treatment effects generalize within and among cognitive domains have

important implications for aphasia therapy. At the sentence level, recent studies indicate that generalization between production and comprehension of sentences is not equally bi-directional. Rather, current studies indicate that therapy directed at comprehension tends to generalize to production, whereas production therapy has a minimal effect on sentence comprehension. These findings remain preliminary, and are subject to further refinement through research. One of the least-developed aspects of this area of research is with regard to isolating the elements of production and comprehension that are employed *during* intervention.

7. A deficiency of this approach (noted several times in this review) is a lack of specificity about the details of information transmission among levels, and of the temporal and storage requirements that this transmission entails. Current research using implemented computational models of word production are beginning to contribute importantly to our understanding of these issues, and have great potential to “scale up” to incorporate elements that are specific to sentence processing.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. What is the cognitive-neuropsychological approach to assessment and intervention of aphasia? How do the goals of cognitive-neuropsychological assessment differ from more traditional approaches that classify subtypes of aphasia?
2. Use the model of normal sentence production (Fig. 24–2) to describe, in your own words, the major sequence of processing events that leads to the production of a single, well-formed sentence. Use Garrett’s terms to describe each level of representation that is achieved during production (i.e., Message Level, Functional Level, Positional Level, etc.). Use the following example in your description: *The dog is chasing the cat.*
3. Explain the difference between canonical and non-canonical sentence structures (see Figs. 24–1 and 24–7). Why does a “word-order” strategy for sentence processing result in better performance with canonical, and poorer performance with noncanonical, stimuli?
4. Describe how Garrett and other researchers used the errors of normal speakers to develop a model of normal sentence production?
5. How can sequential pictures be used to assess the ability to produce and comprehend grammatical morphemes? (*Hint*: see Fig. 24–6.) Can you think of any other ways to assess the ability to process grammatical morphemes in sentences?
6. What is the ability to construct an “event representation” at the Message Level? How would an impaired ability to construct an event representation result in difficulty producing sentences? (Refer to the aphasic speech samples in the chapter, or try to create your own example.)
7. A major feature of the Functional-Level representation is the selection of a verb to describe the action in the event. How does the choice of verb influence the content and structure of the sentence? Consider different responses that describe the event shown in Figure 24–4. What responses would be produced for the following verbs: (1) burying; (2) pouring; (3) covered; (4) playing. Note what changes occur in the sentence structure based on the choice of verb. Do the thematic roles of the nouns change or remain constant with different verbs? Is it necessary to name the instrument (e.g., “sand”) in some sentences, but not in others? Repeat the exercise with other pictures or stimuli that are used to elicit sentences.
8. Describe the effect of structural priming at the Positional Level of sentence production. How does structural priming differ in normal speakers as opposed to speakers with aphasia, according to the study by Hartsuiker & Kolk (1998)?
9. Why is it difficult to pinpoint the exact location of impaired sentence processing within the model of normal sentence processing?
10. Explain why the following two statements are false: (1) A verb-based approach to therapy is indicated only for speakers with aphasia who show poor verb retrieval in naming action pictures. (2) A verb-based approach to therapy is indicated only for speakers with aphasia who fail to produce any verbs. Consider the following points in your response: Does picture naming have the same task requirements as sentence production? Is it possible to produce some verbs (e.g., have/got, go/went, come) despite having an impaired ability to retrieve lexical verbs? Use some of the speech samples in this chapter to support your response.
11. Upon viewing a picture of a girl kicking a boy in the shin, a speaker with aphasia says “She really got ‘em on the leg.” Describe what the speaker does and does not convey in the response. Did he or she correctly express the thematic roles of the actors (nouns) in the picture? Was a semantically meaningful verb used? Does the speaker seem to use grammatical morphemes effectively? Repeat the exercise with the following responses:
 - “She pushed him right on there” (points to the boy’s leg).

- “He got kicked by the other one.”
- “The girl is . . . doing . . . something to the boy.”
- “Oh, boy got hurt. Ouch!” (speaker grabs his or her own shin).
- “The boy” (gestures kicking) . . . “strike the girl” . . . “the foot, no shin.”
- “The girl is the kick is shin.”

12. Why is it important to be able to produce well-formed sentences? Is improved sentence production a reasonable goal of therapy for some speakers with aphasia?

► *Acknowledgement:* The preparation of this paper, and the conduct of much of the research reviewed here, were supported by grant R01-DC00262 from the National Institute on Deafness and Other Communication Disorders to the University of Maryland School of Medicine. Many people have contributed in various and substantial ways to the research that continues to shape our view of sentence-processing disorders in aphasia. They include our long-time collaborator Anne N. Haendiges, M.S., as well as Sarah Wayland, Ph.D, Margaret Greenwald, Ph.D., and Jennifer Sandson, Ph.D. Of course, our most important contributions are from the individuals with aphasia who tirelessly support our research efforts with their dedicated participation.

Chapter 25

Comprehension and Production of Written Words

Pélagie M. Beeson and
Maya L. Henry

OBJECTIVES

The purpose of this chapter is:

1. To delineate the processes necessary for reading and spelling familiar and unfamiliar words.
2. To describe assessment procedures for the comprehension and production of written words, with particular emphasis on single-word processing.
3. To describe the nature of acquired impairments of reading and spelling.
4. To provide a description of treatment procedures for specific alexia and agraphia profiles.

Despite the fact that most individuals with aphasia have impaired comprehension and production of written words, treatment directed toward the improvement of reading and spelling abilities is often limited. This may reflect the prominence of spoken communication in our daily lives. In today's society, however, face-to-face communication is increasingly replaced by written communication in forms such as electronic mail; automated machines for banking, postage, and airline check-in; and Internet sites for chatting, news and entertainment, managing finances, and purchasing merchandise. Thus, the functional consequences of reading and writing impairments can be quite significant.

The limited attention given to reading and writing rehabilitation may also reflect, in part, limited knowledge of treatment approaches for acquired alexia and agraphia in comparison to the treatment of spoken language. Thus, the purpose of this chapter is to describe numerous approaches that have been shown to be effective for reading and spelling impairments. Our approach to treatment begins with an effort to understand the nature of a patient's impairment by determining what processes and representations necessary for reading and writing are impaired, and what skills are spared. Therefore, in this chapter, we begin with a review of

the component processes that support reading and writing, and then describe how impairments to specified representations and processes result in reading and writing disturbances. We will not review the neural substrates for written language processing, but refer the interested reader to reviews by Hillis and Tuffash (2002) and Rapsak and Beeson (2002). The major focus of this chapter is the review of evidence-based treatments for acquired alexia and agraphia. These impairment-based approaches constitute a central component of treatment plans that have as their ultimate goal the facilitation of meaningful, functional changes in patients' lives.

READING

Reading of familiar words is typically accomplished with relative ease as we recognize a string of letters as a word and comprehend its meaning. Despite the myriad of possible writing styles, we are able to recognize the letter identities that comprise a written word. The word "apple," for example, is activated by any of the following font styles: apple = *apple* = *apple* = **apple** = ***apple***. In each case, the letter combination is recognized as the spelling for a word that we know. Our vocabulary of written words is variously referred to as the *visual input lexicon*, *graphemic input lexicon*, or *orthographic input lexicon* (the term that we will use here, as shown in Fig. 25–1). The orthographic input lexicon is the mental store of letter strings that we recognize as familiar words. In the figures in this chapter, we have depicted the cognitive processes that support reading and spelling with distinct input and output lexicons. We acknowledge, however, that reading and spelling may rely on shared lexical representations (see review in Tainturier & Rapp, 2001).

Under normal circumstances, orthographic representations activate the appropriate word meaning in the semantic system, allowing us to comprehend the words we read. When reading aloud (and often when reading silently), we access the stored representations for word pronunciations in the *phonological output lexicon*. In turn, this activated representation accesses the component phonemes of the word, which are

Figure 25-1. Schematic depiction of the component representations and processes for single-word reading and spelling. The solid lines depict lexical-semantic routes and the dashed lines indicate sublexical routes.

held in a short-term storage mechanism referred to as the *phonological buffer*, while we plan the appropriate articulatory movements. This cascade of events is referred to as reading via the *lexical semantic route*, because we derive semantic meaning by activation of words in the lexicon. In Figure 25-1, this is shown as follows: written word (*apple*) → orthographic input lexicon → semantic system → phonological output lexicon → phonological buffer → spoken word (“apple”).

Although reading typically activates semantic knowledge, it is possible to read without accessing meaning. We can all recall occasions when we are reading aloud without processing the meaning of the words. In that case, the orthographic input lexicon directly addresses the phonological output lexicon, and meaning is bypassed. This is a lexical route because whole words are processed, but it is a *nonsemantic route* because word meanings are not activated. Reading without meaning is a rare occurrence for healthy adults, but is characteristic of some brain-damaged individuals, particularly those with dementia (Greenwald & Berndt, 1998; Schwartz, Saffran, & Marin, 1987).

When we attempt to read unfamiliar words, there is no corresponding representation to access in our orthographic

input lexicon, so we may take advantage of our knowledge of relatively predictable relations between letters and sounds. Letters or letter clusters that correspond to a single phoneme are referred to as *graphemes*; for example, *f* and *ph* are both graphemes for the sound /f/. In this way, we convert letters (or clusters of letters) to the appropriate sounds and assemble them to produce plausible attempts at their pronunciation. This approach is depicted in Figure 25-1 (with dashed lines) as the *letter-to-sound conversion route*; it is also referred to as *grapheme-to-phoneme conversion*, *orthography-to-phonology conversion*, or simply the *phonological reading route*. This reading process is considered a *sublexical*, or *nonlexical, reading route* because it does not depend on activation of words in our lexicon. Although we typically use this sublexical route to read unfamiliar words, it can be used if we are asked to read pronounceable nonwords or pseudowords, like “flig” or “merber.” When brain damage causes reading failure via the lexical-semantic route, patients may rely on this sublexical approach for reading both words and nonwords. An obvious feature of the phonological approach is that it only works well if the letter-to-sound correspondences are predictable. Because there are a large number of irregularly

spelled words in English, the sublexical route is susceptible to error. For example, the word “sword” might be mispronounced because of failure to appreciate the silent “w.” Proper names, like the first names of the authors of this chapter, also present a challenge because the sound-to-letter correspondences may be difficult to predict:

Pelagie = [pe,lq,ʒi]; Maya = /ma'ɪə/

Impairments of Reading

Neurologic damage can disturb the processes necessary for reading in a variety of ways. In order to isolate the source of the reading impairment, it is helpful to examine performance on tasks that are dependent upon specified representations and processes, such as processing of single words presented variously in spoken, written, and pictured forms with spoken, written, or nonverbal (pointing) responses. Some processing components are specific to reading (e.g., visual analysis of letter strings, orthographic input lexicon, and letter-to-sound conversion), whereas other components are shared with other lexical processing tasks. For example, semantic processing is necessary for auditory comprehension tasks, writing, and oral naming, as well as reading. Similarly, the phonologic output lexicon is accessed for both oral naming and oral reading tasks. By contrasting perfor-

mance for single-word comprehension and production in written and spoken modalities, the hypothesized locus (or loci) of impairment may be isolated.

In addition to examining performance across language modalities, it is also informative to determine the influence of various lexical features on reading accuracy (and reading speed, in some cases). Clues regarding the location of damage can be obtained by examining what types of words pose the greatest problem for reading. Carefully constructed word lists that control for lexical features such as word length, part of speech, frequency of use, and concreteness (or imagery) are useful to discern the nature of the impairment, as shown in Table 25-1. Controlled word lists are available in the *Psycholinguistic Assessments of Language Processing in Aphasia* (PALPA; Kay, Lesser, & Coltheart, 1992), the Battery of Adult Reading Function (Rothi, Coslett, & Heilman, 1986), and the Johns Hopkins University (JHU) Dyslexia and Dysgraphia Battery (Goodman & Caramazza, 1986), which is included in Appendix 25-1. The word lists provide contrasts of lexical features that allow examination of various processes for reading single words. The information gained from performance on these controlled word lists will be discussed further in the context of specific reading impairments.

When possible, reading should also be assessed at sentence and paragraph levels. Sentence and paragraph reading can be screened using subtests from standardized aphasia

TABLE 25-1

Summary of the Primary Features of Various Acquired Alexia Profiles

Locus of Damage	Example Syndrome	Clinical Features						
		Word Length Short > Long	Spelling Regularity Reg > Irreg	Frequency HF > LF	Imageability/ Concreteness HI > LI	Word Class N > F	Inability to Read Nonwords	Semantic Errors
Access to orthographic input lexicon	Letter-by-letter reading	√						
Orthographic input lexicon	Surface alexia		√	√				
Sublexical (letter-to-sound) procedures	Phonological alexia			√	√	√	√	
Semantics and letter-to-sound conversion	Deep alexia			√	√	√	√	√
Access to phonological output lexicon	Surface alexia		√	√				

Key: √ = significant disturbance; Reg = regular spelling; Irreg = irregular/exceptional spelling; HF = high frequency; LF = low frequency; HI = high imagery; LI = low imagery; N = nouns; F = functors.

tests including the *Western Aphasia Battery-R* (WAB-R; Kertesz, 2006) and the *Boston Diagnostic Aphasia Examination, Third Edition* (BDAE-3; Goodglass, Kaplan, & Barresi, 2000). The PALPA (Kay et al., 1992) also provides some sentence-comprehension subtests, and the Reading Comprehension Battery for Aphasia-2 (RCBA-2; LaPointe & Horner, 1998) samples reading for single words, sentences, and paragraphs. In the absence of a comprehensive assessment tool for reading at the paragraph level, some of the tests designed for the examination of developmental reading disorders are useful for examining acquired alexia. For example, the *Gray Oral Reading Test, Fourth Edition* (GORT-4; Wiederholt & Bryant, 2001) provides short essays of graded difficulty that can be used to assess reading rate and accuracy, as well as comprehension. The GORT-4 is particularly useful in that alternate forms (A and B) are available.

The pattern of impaired and preserved reading processes will differ among individuals, but there are discernible patterns of impairment that have been recognized as various acquired alexia syndromes (Ellis, 1993; Hillis & Caramazza, 1992; Margolin & Goodman-Schulman, 1992; Rapcsak & Beeson, 2002). Several patterns of acquired reading impairment will be reviewed here, and evidence-based treatment approaches are reported for each of the various patterns. We will show how the hypothesized nature of the impairment can help to guide the treatment approach. Reading impairments will be reviewed in an order that starts at the processing of visual input and ends with impairments in the spoken production of written language.

Impaired Access to the Orthographic Input Lexicon: Pure Alexia

In some cases of neurologic damage, patients fail to recognize strings of letters as familiar words, even though the individual letters are perceived. In its pure form, this disorder is specific to reading, while writing ability remains preserved, so it is referred to as *pure alexia* or *alexia without agraphia*. Many individuals with pure alexia are able to perceive and name the letters of words that they fail to recognize, and if they spell the word letter-by-letter it often helps them identify the word (see papers in Colheart, 1998). For example, a patient may fail to recognize the word *apple* but after spelling it aloud (or subvocally) quickly acknowledges, “oh, apple.”

A schematic depiction of the impaired access to the orthographic input lexicon is shown in Figure 25-2 with *letter-by-letter reading* shown as a compensatory strategy. As indicated, the orthographic input lexicon is not impaired, and letter naming may provide an alternative means of activating the orthographic representations. The deficit is specific to the visual modality, so in most cases, individuals with pure alexia are able to quickly recognize words that are

spelled aloud to them. Once a word is properly identified, its meaning is easily accessed because there is no impairment of the semantic system. There is also no difficulty in saying the word aloud once it has been recognized.

In pure alexia, access to the orthographic input lexicon is disrupted for all types of words, and reading accuracy typically is not strongly affected by features such as word frequency, concreteness (or imageability), grammatical class, or regularity of spelling, as shown in Table 25-1. When words are decoded letter-by-letter, however, there is a marked word-length effect and thus, long words take more time to read and are more prone to errors than short words. In fact, there is often a linear increase in reading time as a function of the number of letters. In some cases, there is also difficulty with letter identification, which limits the effectiveness of letter-by-letter reading even further.

Treatment for Pure Alexia

Several treatment approaches have been shown to improve access to the orthographic input lexicon or to provide compensatory strategies to support reading. The treatments vary with regard to the complexity of the stimuli used for treatment: text, single words, or single letters. The first approach, multiple oral rereading, is thought to strengthen access to the orthographic input lexicon either in a direct manner or via the compensatory letter-naming route. A different treatment approach is appropriate for patients who show impaired letter identification.

Multiple Oral Rereading. Multiple oral rereading (MOR) entails the use of repeated reading aloud of a given text as a means of facilitating whole-word, rather than letter-by-letter, reading. Several researchers have shown this procedure to be effective as a means to increase reading rate in letter-by-letter readers (Beeson, 1998; Beeson, Magloire, & Robey, 2005; Moyer, 1979; Tuomainen & Laine, 1991). It was hypothesized that repeated reading of the same text facilitates a shift from letter-by-letter reading to whole-word reading because of the support provided by sentence context and familiarity with the text. This approach is thought to improve or re-establish access to the orthographic input lexicon so that letter-by-letter reading can decrease. The procedures for implementing MOR are described in Table 25-2. Essentially, the treatment involves structured homework in which selected text is read aloud repeatedly so that reading rate improves and reading errors decrease. When successful, the improved reading for practiced text is accompanied by improvement in reading of novel (i.e., previously unread) text that more closely approximates normal adult oral reading rates, which range from 150 to 200 wpm (Rayner & Pollatsek, 1989).

The text used for MOR treatment should be controlled for length and complexity. In particular, the average word

Figure 25-2. Schematic representation of impaired access to the orthographic input lexicon with strategic compensation in the form of letter-by-letter reading. Bold black hash marks indicate disrupted process.

length will affect reading performance. Treatment studies implementing MOR have used standardized text, such as passages from the Reading Laboratory by Scientific Research Associates (SRA; Parker & Scannell, 1998) because it has graded levels of difficulty. Reading material can also be selected from readily available sources including books, magazines, and the Internet. If the text is in electronic format, the difficulty level can be appraised using readability indices, such as the Flesch-Kincaid grade level (Kincaid, Fishbourne, Rogers, & Chissom, 1975). To do so using Microsoft® Office Word 2003, use the pull-down menu to select tools → options → spelling and grammar, and check the box for “show readability statistics.” Then run the “spelling and grammar” check on the “tools” menu. At the

completion of the spelling and grammar check, a reading grade level (from 1 to 12) according to Flesch-Kincaid is returned.

Although no studies document the ideal intensity and duration of MOR needed to be effective, therapeutic effects have been documented with a homework schedule of at least 30 minutes a day. A criterion rate of 100 words per minute for the practiced text has been used with even the slowest of letter-by-letter readers (10 seconds per word; Beeson, 1998). Once achieved, new passages are introduced for repeated oral reading as homework. To test whether MOR results in generalized improvements, reading rates and accuracy for previously unread passages are sampled during weekly therapy sessions. The expected outcome is a steady improvement in

TABLE 25-2

Steps for Implementing Multiple Oral Rereading (MOR) Treatment Approach*

- A. Initial treatment session(s)
- Step 1. Determine reading rate and accuracy for text-level material.
- Select a passage of appropriate difficulty, e.g., 100-word segment, to be used as practice text.
 - Ask the patient to read the text aloud allowing for letter-by-letter decoding as needed.
 - Calculate reading rate in words per minute and score reading errors in terms of number of deviations from print (self-corrected errors may be tallied separately).
- Step 2. Establish multiple oral rereading procedures.
- Have the patient reread the text, providing assistance as needed to guide correction of reading errors. Multiple repetitions during therapy sessions provide an opportunity to increase familiarity with text, and should result in increased accuracy.
 - Establish homework activity.
 - Provide a copy of the written text for homework.
 - Agree upon daily homework schedule, e.g., 30 minutes of repeated oral reading of specific text once or twice daily.
 - Establish a log for recording completion of homework. Patients may time themselves and record the time taken to read the passage, or simply note completion of homework on a daily basis.
- B. Subsequent therapy sessions
- Step 1. Review patient's log to confirm consistency in completing MOR homework.
- Step 2. Determine rate and accuracy of reading for practiced text.
- Have the patient read practiced text aloud.
 - Keep a graphic plot of reading rate and accuracy.
- Step 3. Determine target rate for practiced text, e.g., to achieve 50 wpm or 100 wpm. When target rate is attained (with acceptable accuracy) for practiced text, provide a new passage for MOR homework.
- Step 4. Determine reading rate and accuracy for new (previously unread) text.
- Provide a new passage (about 100 words) for oral reading to determine whether reading rate or accuracy for new material improves.
 - Calculate and record reading rate and accuracy during each session to determine effectiveness of MOR treatment.

*Rationale: Multiple oral rereading is thought to improve access to the orthographic input lexicon, so that reliance on letter-by-letter reading decreases and whole-word recognition improves.

(After Beeson, P. M. (1998). Treatment for letter-by-letter reading: A case study. In N. Helm-Estabrooks & A. L. Holland (Eds.), *Approaches to the treatment of aphasia* (pp. 153–157). San Diego: Singular Press.

reading rate for new text while maintaining (or improving) the level of accuracy. Slow readers have shown improvement that is two, three, and four times their pre-treatment reading rates.

The MOR protocol can be implemented with relatively infrequent treatment sessions because it is heavily dependent upon the patient's accomplishment of reading homework. Weekly or even biweekly sessions may be adequate. Variations in the protocol might include adjustment of the criterion reading rate for practiced text from 100 wpm to a slower rate, such as 50 wpm, when deemed necessary.

Brief Orthographic Exposure. A different approach to treatment for impaired access to the orthographic input lexicon involves the presentation of written words for brief exposures so that letter-by-letter reading is not possible. The motivation for this treatment came from the observation that some individuals with pure alexia retain an ability to derive some meaning from words that they cannot explicitly name (Coslett & Saffran, 1989; 1994).

Rothi and Moss (1992) proposed that individuals with pure alexia might be stimulated to use this implicit knowledge gained from brief whole-word “reading” to facilitate comprehension and possibly to regain access to the orthographic input lexicon. They used a paradigm in which single words were presented on a computer screen for brief exposures (e.g., 500 msec), and the patient was asked to make a decision about the word, such as, “Is it an animal?” Although the patient often indicated that he had not actually read the word, he was encouraged to guess. Response accuracy was above chance, indicating some ability to apprehend the whole word at an implicit level. This brief exposure procedure resulted in improved reading rate (following 20 treatment sessions) in Rothi and Moss's patient, suggesting that it facilitated recovery of whole-word reading. However, Rothi and colleagues reported failure of this treatment approach with two other patients (Maher, Clayton, Barrett, Schober-Peterson, & Rothi, 1998; Rothi, Greenwald, Maher, & Ochipa, 1998), suggesting that it may be useful for a subset of people with pure alexia.

An adaptation of the brief exposure procedure could be implemented using written words presented on cards and shown for a brief duration rather than by computer presentation. Another variation involves contrasting real words with plausible nonwords for a lexical decision task in response to the question, “Is this a word?” These variations share the common goal of promoting whole-word apprehension rather than letter-by-letter reading.

Cross-Modality Cueing to Enhance Letter Identification. Letter-by-letter reading cannot be accomplished effectively if a significant number of letter identification errors are made. In some patients, letter identification is facilitated when information regarding the letter shape is provided via another modality. For example, some patients perceive a letter when it is traced on their palm, or when they trace the letter themselves (Seki, Yajima, & Sugishita, 1995). Tracing the component letters of a word with one’s finger, or copying the written word, are compensatory strategies that can be used by the patient without assistance. It is assumed that the kinesthetic information about spelling provides access to the orthographic input lexicon, which substitutes for activation of the lexicon via visual input. Thus, the procedure has been referred to as cross-modality cueing.

A positive response to cross-modality cueing was reported by Maher and colleagues (1998) for a patient with pure alexia who had difficulty naming letters, so letter-by-letter decoding of words was not possible. This patient was able to identify letters in a word only after she traced each letter with her finger. Maher documented that treatment using this motor cross-cueing strategy resulted in improved word recognition and increased reading rate. With practice, letter recognition improved, such that simply tracing the first letter or two of a word was adequate to cue word identification.

Reading with Overreliance on Letter-to-Sound Conversion: Surface Alexia

Reading is disrupted when component processes of the lexical-semantic reading route are damaged. This can include impaired representations in the orthographic input lexicon (or impaired access to orthographic representations), as well as damage to the semantic system or the phonologic output lexicon. In the case of orthographic impairment, it appears as though the individual’s vocabulary of written words has eroded, and thus, visually perceived words that were once familiar now appear unfamiliar and their meaning cannot be derived. If the ability to “sound out” words is retained, reading may be accomplished by means of the letter-to-sound conversion procedure (i.e., via the sublexical route), as shown in Figure 25-3. This procedure works well for words that have good letter-to-sound correspondences (i.e., regular words, such as *flake*), but words that have uncommon letter-to-sound correspondences (i.e., irregular words, such as

yacht) pose a problem and are often misread. For example, the word “blood” might be pronounced such that it rhymes with “mood.” Thus, when reading is accomplished via the sublexical rather than the lexical route, performance is characterized by greater difficulty reading irregularly spelled words when compared to regularly spelled words, as indicated in Table 25-1. This reading profile has been referred to as *surface alexia* because reading is accomplished via phonology rather than meaning, so that it might be thought of as reading “on the surface” (see papers in Patterson, Marshall, & Coltheart, 1985). Because reading is accomplished by sounding-out, regularly spelled words and nonwords are read with at least fair accuracy, and phonologically plausible errors for irregularly spelled words are common. A consequence of overreliance on the sublexical route while reading is confusion of words that sound the same but are spelled differently (i.e., homophones, such as “dear” and “deer”), because access to semantics is gained from the oral reading response. Additionally, words that are spelled the same but pronounced differently (i.e., homographs) may be mispronounced for a given context; for example, “lead” might be (incorrectly) pronounced the same in the phrases “the lead pipe” and “I will lead the way.” Typically, individuals with surface alexia also use a phonological strategy for spelling, and phonologically plausible errors are common when spelling irregular words, reflecting a concomitant syndrome referred to as *surface agraphia* (or lexical agraphia) that is discussed below.

In surface alexia, there are no strong effects of lexical-semantic features such as imageability or word class, because reading “bypasses” the semantic system. However, the impairment at the level of the orthographic input lexicon should be more notable on low frequency words compared to high frequency words (see Table 25-1), because high frequency words are thought to be more resistant to damage. Word length may have a negative effect on reading accuracy, because longer words provide more opportunities for errors in letter-to-sound conversion, and it may also take longer to sound out a long word rather than a short word; however, a word-length effect is not an essential feature associated with impaired representations in the orthographic input lexicon.

Lexical Treatment for Surface Alexia

Because surface alexia typically occurs with surface agraphia, treatment for the reading impairment may be addressed in the context of spelling treatment. A lexical approach to treatment involves retraining orthographic knowledge for specific words. Lexical treatment may focus on words that are prone to error, such as homophones and homographs. Hillis (1993) demonstrated successful treatment to increase reliance on lexical-semantic processing for reading and spelling in the context of retraining homographic and homophonic pairs. Each target word was presented in print with its written definition, which was read aloud by the

Figure 25-3. Schematic representation of damage to the orthographic input lexicon (shaded), and reliance on letter-to-sound conversion to decode written words (heavy black lines), resulting in phonologically plausible reading errors typical of surface alexia (on the right side of figure). Surface agraphia is depicted on the left side of the figure.

clinician. The patient was asked to write the target word in a sentence, and corrective feedback was provided. Treatment resulted in improved oral reading, spelling, and comprehension (as assessed by use of the word in sentence contexts) for trained words, as well as improved oral reading for the untrained members of the word pairs. Therefore, the pairing of specific orthographic representations with semantics served to strengthen the patient's ability to read via the lexical-semantic route, allowing him to disambiguate homophones and homographs.

Another approach to enhance reading via the lexical semantic route (and to reduce overreliance on a phonological strategy) involves the presentation of written words for brief exposures in a manner similar to that described by Rothi and colleagues in the case of pure alexia. Rapid visual presentation can force a lexical strategy for word recognition. Hillis (1993) showed that brief exposure to written words with corrective feedback during oral reading resulted in item-

specific learning for trained items. Because there may be limited generalization with this approach, it is important to select words of functional value for the patient.

Reading with Impaired Letter-to-Sound Conversion: Phonologic Alexia and Deep Alexia

When phonological abilities are impaired due to brain damage, patients have difficulty with letter-to-sound conversion, as depicted in Figure 25-4. Reading is accomplished via a lexical-semantic strategy, such that representations in the orthographic input lexicon should activate the semantic system. Impairments of the nonlexical route are clearly evident when the patient is asked to read unfamiliar words or phonologically plausible nonwords that do not have a lexical representation (e.g., "dusp"). The profile of impaired nonword reading relative to real word reading is referred to as *phonological alexia*. It reflects an inability to use sublexical

Figure 25-4. Schematic representation of impairment to letter-to-sound conversion procedures resulting in lexicalization error on nonword reading (“dust” for “dusp”), reflecting phonological alexia (on the right side of figure). Phonological agraphia is depicted on the left side of the figure.

processes to derive the appropriate sound for a given letter. A range of severity is observed in phonological alexia, with mild cases showing relatively preserved reading of real words but difficulty with nonwords. In more severe cases it is evident that the lexical-semantic route is vulnerable to error when deprived of phonological input. In most cases, the weakened lexical-semantic route typically results in a frequency effect, in that high frequency words are read better than low frequency words. There is also a concreteness (or imageability) effect, such that concrete words such as “apple” are read better than abstract words such as “pride.” This profile may reflect the fact that concrete, high frequency nouns have stronger semantic representations and therefore are most resistant to damage. Abstract, low frequency words and grammatical functors have the weakest semantic representations, or have semantic representations that have a great deal of overlap with other words and are thus easily confused. For example, the meaning of “belief” is

difficult to define and overlaps considerably with the meaning of many other words: confidence, conviction, credence, creed, notion, thought, concept, faith, religion, hope, idea, presumption, principle, trust, and so on. In contrast, the meanings of concrete nouns like “fork” do not overlap as much with other meanings. A part-of-speech (or grammatical class) effect is also common in phonological alexia, in that nouns are read better than adjectives and verbs, which are read better than functors.

Because phonology provides little assistance, there is typically no difference in the reading accuracy of regularly spelled words compared to irregular words in phonological and deep alexia. That is, there is no regularity effect as seen in surface alexia. The overreliance on the lexical route often draws patients to misread nonwords as real words (e.g., “dusp” → “dust”), which is referred to as “lexicalization.”

When damage to the sublexical route is accompanied by dysfunction of the lexical-semantic reading route, semantic

Figure 25-5. Schematic representation of impairments to the semantic system and letter-to-sound conversion resulting in a semantic error (“orange” for “apple”), reflecting deep alexia (on the right side of the figure). Deep agraphia is depicted on the left side of the figure.

errors are prevalent, such as reading *woman* as *girl*, or *apple* as *orange*, as shown in Figure 25-5. The presence of semantic errors is the hallmark feature of the acquired alexia syndrome referred to as *deep alexia*, or more commonly, *deep dyslexia* (Coltheart, Patterson, & Marshall, 1987; Newcombe & Marshall, 1984). Although phonological and deep alexia initially were considered to be distinct syndromes, they are currently viewed as points on a continuum, reflecting quantitative rather than qualitative differences (Glosser & Friedman, 1990; Rapcsak & Beeson, 2002). Deep alexia is usually associated with extensive left hemisphere lesions, suggesting that reading in these patients may be mediated by the right hemisphere (Coltheart et al., 1987; Patterson, Vargha-Khadem, & Polkey, 1989).

Treatment for Phonological and Deep Alexia

Treatments for phonological and deep alexia may be directed toward sublexical or lexical reading processes, or both.

Phonological treatments may serve to strengthen letter-to-sound correspondences that supplement lexical reading procedures. Lexical reading treatments typically include spoken production of target words or text-level material, so there is simultaneous stimulation of written and spoken language processes that ideally improves both language modalities. It is worth mentioning again that reading treatment is an inherent component of treatments for spelling, and thus, clinicians may find it efficient to combine the treatments described for phonological/deep alexia with those described for phonological/deep agraphia.

Strengthening Letter-to-Sound Conversion. The training of letter-to-sound correspondences has the potential to be an effective strategy for reading many words (rather than a specific set of words), so it is worthwhile to determine whether a given patient can relearn letter-sound associations. A number of treatment reports have documented

TABLE 25-3

Establishing Key Words That Are Associated with Specific Graphemes

- A. Initial treatment sessions
 - Step 1. Determine what grapheme-phoneme pairs will be targeted for training.
 - a. Select consonants first because they have more consistent letter-to-sound correspondences than vowels.
 - b. Select frequently occurring consonants (see Appendix 25-2); proceed to less frequent consonants and vowels as appropriate for a given patient. For example, train consonants in sets of five at a time:
 - Set 1. r, t, n, s, l
 - Set 2. k, d, m, p, f
 - Set 3. b, sh, v, g, z
 - Step 2. For each target grapheme, assist the patient in identifying a key word that begins with the grapheme.
 - a. If possible, find key words that the patient can consistently say correctly, such as, “Ron” for r.
 - b. If the patient does not have a key word available for a given grapheme, a word should be agreed upon and trained for consistency of production.
 - c. Construct stimulus cards that have a grapheme on one side (e.g., R-r) and the associated key word on the other side (e.g., Ron).
- B. Establish homework procedures
 - a. Using stimulus cards, the patient should look at the grapheme and say the name of the key word. (Look at key word on the back of the card only as necessary for cueing.)
 - b. Optional: Make a videotape of clinician showing the grapheme and asking for production of the key word (with model provided by clinician after a pause so that the patient can evaluate response relative to the model).
 - c. Establish frequency of homework (e.g., daily practice).
- C. Subsequent therapy sessions
 - a. Review the patient’s ability to retrieve the key word for each targeted grapheme.
 - b. Target additional graphemes as appropriate.
- D. Subsequent treatment
 - a. Select (or develop) a subsequent protocol to take advantage of key words for deriving phonology from written words (for reading) or deriving graphemes from phonology (for writing).

*Rationale: to develop a corpus of key words that can be used to assist the patient in retrieving phonology from written words.

success in re-establishing links between orthography and phonology (e.g., de Partz, 1986; Nickels, 1992). A “key word” approach is often used, such as that described in Table 25-3. The training involves establishing at least one key word for each grapheme-phoneme pair targeted for treatment. As indicated in Table 25-3, key words are used to assist a patient in self-cueing the phonology for a given grapheme. The items selected as key words should be ones that the patient can consistently produce. In other words, it is typical that the list of key words is different for each individual, capitalizing on their success with specific words. Key words are typically nouns, and can include proper names that the patient can easily retrieve. Treatment typically begins with higher frequency phonemes, so it is useful to consider frequency of occurrence in English words to guide the choice of targets (see Appendix 25-2; Berndt, Reggia, & Mitchum, 1987; Hanna, Hanna, Hodges, & Rudolf, 1966). Because the predictability of letter-to-sound correspondences is stronger for consonants than vowels, it is most effective to establish key words for consonants first. For some patients, it may be too effortful to train the vowels at all. Although the time required to re-establish the letter-to-sound associations may

be considerable, much of the work can be accomplished by self-drill outside of the therapy session. Videotaped homework is particularly useful to provide articulatory models for practicing letter-to-sound correspondences.

After key words are established, treatment proceeds to phonemic self-cueing, so that the patient can derive the appropriate phoneme from a grapheme. This training may be accomplished by having the patient say the key word with the first sound prolonged, and then say only the first phoneme in isolation (for example, “Sue SSSSue SSSS . . . [s]”). Thus, the key word provides the means to cue placement of the articulators for a given letter. The patient is then trained to produce only the first sound of the key word in response to its associated letter. In many instances, phonological information obtained via letter-to-sound conversion may be adequate to reduce or block phonological and semantic errors in oral reading and to initiate correct production of a word (de Partz, 1986). Training can also proceed to reading three- or four-letter monosyllabic words and nonwords by deriving the component sounds and blending them to produce a word (or nonword). In some patients, mastery of regular letter-to-sound associations

provides the necessary additional information to support the impaired lexical-semantic reading route, such that treatment addressing the nuances of irregular spellings is not necessary.

Treatment for Impaired Semantics. Individuals with impairment of the letter-to-sound conversion mechanism and concomitant damage to semantics may also benefit from treatment to strengthen semantics. Such treatment may include written word-to-picture matching tasks that reinforce the links between word forms and their meanings. Hillis demonstrated the value of this approach with a patient who exhibited impaired semantics affecting his reading as well as written and spoken naming (patient JJ in Hillis & Caramazza; 1991a, 1991b, 1994). The semantic treatment entailed matching written words and their corresponding pictures, with error responses corrected and missed items re-presented after intervening items until a correct response was achieved. Treatment resulted in rapid improvement of oral reading and comprehension of the trained words.

Oral Reading Treatments. In some patients, semantic errors do not reflect a central impairment of semantic knowledge, but rather a failure to activate correct phonological representations. Hillis demonstrated that a cueing hierarchy to elicit correct oral reading of target words was an appropriate intervention approach (patient HW described by Hillis, 1993; Hillis & Caramazza, 1994). In effect, this cued oral reading treatment served to improve access to spoken word forms in an item-specific manner. To do so, written words were presented for oral reading, and phonemic cueing and repetition were provided as needed to elicit correct production. This treatment resulted in item-specific improvement of oral naming and oral reading of targeted items, which confirmed the hypothesized locus of damage to be the phonological output lexicon that is common to both tasks. The success of this procedure is best explained as a lowering of the activation threshold in the phonological output lexicon as a consequence of the increased frequency of production in the training context. This stimulation effect is a familiar result of effective hierarchical cueing and mass-practice effects. Despite the lack of generalization to other words, there can be considerable functional benefit from item-specific improvement of single-word reading and naming.

Oral reading treatments have also been implemented at the text level, with positive treatment outcomes. Cherney, Merbitz, and Grip (1986) documented the value of an approach referred to as Oral Reading for Language in Aphasia (ORLA), which involves oral reading in unison with the clinician. The protocol includes corrective feedback and modeling by the clinician to facilitate accurate oral reading of text-level stimuli. The nature of the reading impairment in the participants was not described from a cognitive perspective; however, spoken language impairment in these individuals suggested impairment to lexical and sublexical

procedures, typical of phonological and deep alexia. Administration of ORLA was associated with improved reading comprehension, as well as improved comprehension and production of spoken language. An adaptation of ORLA, referred to simply as Oral Reading Treatment, demonstrated similar benefits for spoken and written language performance in an individual with aphasia and phonological alexia (Orjada & Beeson, 2005). The outcomes from these studies suggest that reading treatments may stimulate interactive processing of orthography and phonology with benefits to both reading and spoken language in individuals with aphasia.

There is evidence to suggest that oral reading of text can also serve to strengthen access to grammatical words in individuals with relatively mild language impairment. This was demonstrated by Beeson and Insalaco (1998), who showed that the multiple oral rereading (MOR) approach can also benefit individuals who do not fit the classic profile of pure alexia but who appeared to have relatively mild phonological alexia. MOR was implemented with two individuals with anomia who reported slow reading rate as their primary complaint. Both showed a word-length effect for oral reading, slower reading rate for function words in comparison to nouns, and impaired reading of nonwords. Using the MOR approach, both patients were able to more than double their reading rate for new text to about 100 words per minute, an increase that was adequate to support pleasure reading. An examination of their reading rate and accuracy for single words before and after treatment showed the greatest improvement in reading rate for function words, suggesting that for some individuals MOR may be particularly beneficial for improving recognition of function words. These results suggested that the syntactic constraints offered by sentence contexts help to facilitate access to function words, and that repeated oral reading had a durable therapeutic effect.

Unspecified Alexia Profiles

In this chapter, we have taken a cognitive approach to describing the nature and treatment of written language processing. We acknowledge, however, that some treatment studies have shown positive responses to reading treatments for individuals with aphasia and acquired alexia that was unspecified with regard to the specific nature of the impairment. For example, Katz and Wertz (1997) demonstrated significant improvement on standardized aphasia tests in response to a hierarchical reading treatment presented via computer. The treatment provided structured reading tasks from single letters to words to sentences, with corrective feedback and performance-based advancement through the protocol hierarchy. Significant improvement was documented following the computerized reading treatment on measures of overall language performance when compared to conditions with nonlinguistic computer stimulation or no

treatment. These outcomes support the notion that written-language treatments may engage and strengthen spoken-language processes.

Summary of Treatments for Acquired Reading Impairments

Reading disturbances may reflect impairments to the component processes necessary for comprehension and production of written words. Degraded representations (or impaired access to representations) may occur at the level of orthography, semantics, or phonology. Similarly, the sublexical reading route that enables sounding out words may be impaired. These impairments may occur in isolation or in various combinations. Numerous treatment approaches have been shown to be effective in strengthening lexical-semantic representations and processes, and improving letter-to-sound conversion abilities, as well as developing alternative strategies to support reading. Even when reading processes are not fully restored, item-specific improvements and the retrieval of partial information can serve to improve functional reading skills. It is also worth noting that several treatment approaches might be implemented in sequence, so that improved skills are incorporated in successive treatment stages. For example, initial treatment efforts may focus on lexical-semantic processes, whereas a later stage of treatment may include strengthening the sublexical route. In this way, progressive approximation of normal reading processes is achieved, and appropriate strategic compensations are established.

SPELLING

The act of expressing our ideas in writing involves clarifying our thoughts, formulating sentences, and sequentially translating each word to its written form according to the spelling conventions for the language. Writing calls upon a multitude of cognitive, linguistic, and perceptual-motor processes. We will focus here primarily on the processes that are specific to single-word spelling. Under normal circumstances, our semantic representation activates a written word in our mental dictionary. This collection of spellings that we know is referred to as the *orthographic output lexicon* (Fig. 25-1); or it may also be referred to as the *graphemic output lexicon* or the *visual output lexicon* (Ellis, 1993). As we write a word, it is held in short-term storage in the *graphemic output buffer*, which may simply be called the *graphemic buffer*. The information is held in the graphemic buffer as a series of graphemes, which are generic, abstract letter representations (as opposed to specific upper or lowercase exemplars in particular writing styles). The representation in the graphemic buffer allows realization of spelling in several forms—handwriting, typing, or oral spelling. Written spelling requires implementation of peripheral processes whereby

the specific letter forms (referred to as *allographs*) are selected and motor movements are planned and executed. The selection of a particular letter form is referred to as the *allographic conversion process*. Finally, graphic motor programs are implemented to write the component letters of a word.

The motivation to write a word most often reflects self-activation of a semantic concept; but in clinical situations, we may ask a patient to write a word that we dictate (i.e., in response to auditory input), write the name of a pictured item, or even copy a printed word. As is the case with reading, spelling may be accomplished via the lexical-semantic route, but it can also rely on sublexical knowledge of sound-to-letter correspondences, as shown in Figure 25-1. For an unfamiliar word (or a nonword), spelling can be derived by sounding out the word and converting sounds to letters, a process that is also referred to as *phoneme-to-grapheme conversion*. This sound-to-letter conversion is considered a non-lexical or sublexical process, because spellings are assembled rather than retrieved as whole words. Assembled spellings are likely to reflect regular spelling rules, such that irregularly spelled words might be regularized; for example, “cough” might be spelled as *coff*. This sublexical route can provide an important compensatory spelling strategy when the lexical-semantic spelling route is impaired.

Impairments of Spelling

The processes necessary to spell words can be disrupted by damage to central linguistic processes as well as more peripheral components involved in writing (Ellis, 1993; Rapsak & Beeson, 2000; Tainturier & Rapp, 2001). A comprehensive assessment of writing includes examination of spontaneous writing, written naming, writing to dictation, and copying. A sample of spontaneous writing may be obtained by asking a patient to compose a short narrative; however, it may be preferable to request a written description of a standard picture, such as the picnic scene from the *WAB-R* (Kertesz, 2006) or the cookie-theft picture from the *BDAE-3* (Goodglass et al., 2000). The use of a standard stimulus allows for comparison over time and also provides referent information that may be helpful in discerning the intended content and spellings. Written narratives allow for examination of semantic organization, syntactic structure, word choice, and single-word spelling.

There are several sources of standardized stimuli that can be used to assess single-word spelling. Standardized aphasia tests, such as the *WAB-R* and *BDAE-3*, offer a small set of items for initial screening of writing. A comprehensive assessment of single-word writing requires the use of controlled word lists, such as those included in the *PALPA* (Kay et al., 1992) or the *JHU Battery* (Goodman & Caramazza, 1986; Appendix 25-1). Assessment of oral spelling, typing, spelling with anagram letters, and copying may be needed to

TABLE 25-4

Summary of the Primary Features of Various Acquired Agraphias

Locus of Damage	Example Syndrome	Clinical Features						
		Word Length Short > Long	Spelling Regularity Reg > Irreg	Frequency HF > LF	Imageability/ Concreteness HI > LI	Word Class N > F	Inability to Read Nonwords	Semantic Errors
Sublexical (sound-to-letter) procedures	Phonological agraphia			√	√	√	√	
Semantics and sound-to-letter conversion	Deep agraphia			√	√	√	√	√
Orthographic output lexicon	Surface (lexical) agraphia		√	√				
Graphemic buffer	Graphemic buffer agraphia	√						

Key: √ = significant disturbance; Reg = regular spelling; Irreg = irregular/exceptional spelling; HF = high frequency; LF = low frequency; HI = high imagery; LI = low imagery; N = nouns; F = functors.

discern whether central or peripheral spelling processes are impaired. Given that clinical evaluations are typically constrained by time and financial considerations, it is important to select writing subtests that serve to test hypotheses regarding the locus of damage to the spelling system, in order to ensure that an appropriate treatment approach is selected.

As with acquired alexia, characteristic patterns of acquired agraphia may result when certain component processes are disturbed (Table 25-4). In this section of the chapter, several patterns of acquired spelling impairments will be described, with greatest attention given to the central (or linguistically based) writing impairments that often accompany aphasia. Treatment approaches directed toward particular components of the writing process are described, with reference to representative studies.

Spelling with Impaired Sound-to-Letter Conversion: Phonological Agraphia and Deep Agraphia

Selective impairment of sublexical spelling, or sound-to-letter conversion, has been referred to as *phonological agraphia* (Shallice, 1981). The defining feature of phonological agraphia is a disproportionate impairment of sound-to-letter conversion, with relative sparing of lexical-semantic procedures (see Fig. 25-4). Accordingly, individuals with phonological agraphia have a pronounced nonword spelling deficit and show little effect of spelling regularity. A pure form of phonological agraphia is relatively uncommon, and

would only affect spelling of unfamiliar words and nonwords (Alexander, Friedman, Loverso, & Fischer, 1992). In actuality, most individuals with impaired sublexical spelling also have some degree of concomitant lexical-semantic spelling impairment, suggesting that phonological processes are critical for both nonword and real word spelling (Henry, Beeson, Stark, & Rapsak, 2007). Because spelling in these individuals is mediated by the lexical-semantic route, performance tends to be affected by lexical variables such as word frequency (high > low), imageability (high > low), and grammatical class (nouns > functors) (see Table 25-4). Spelling errors are typically not phonologically plausible, and often bear some visual or orthographic similarity to the target (e.g., *flewen* for *flower*). Morphological errors (e.g., *walking* for *walked*) and functor substitutions (e.g., *since* for *about*) are also prevalent.

In some individuals, impaired sound-to-letter conversion is accompanied by deficits at the semantic level. Written semantic errors occur when semantic representations are damaged or in some way underspecified, resulting in the retrieval of the incorrect orthographic representation. For example, a fully elaborated semantic representation of *apple* might include <fruit>, <round>, <red>, <juicy>, <sweet>. If the semantic representation included <fruit>, <round>, <juicy>, <sweet>, but failed to include <red>, then it might activate *orange* as shown in Figure 25-5. Such semantic errors are observed in spelling, but also may be evident in other output modalities, such as spoken production. The combined profile of written semantic errors and poor

sound-to-letter conversion ability has been called *deep dysgraphia*, or *deep agraphia*, which is the analog of deep dyslexia. As with phonological/deep alexia, phonological and deep agraphia were initially considered distinct syndromes but have more recently been described as points along a continuum of increasingly severe phonological and lexical-semantic impairment (Rapcsak & Beeson, 2002). As shown in Table 25-4, these impairments result in spelling that is influenced by the same lexical features that affect performance in phonological agraphia (concreteness/imageability, word class, and frequency). As with phonological agraphia, there is little influence of spelling regularity, and nonword spelling is poor. Patients typically produce error types consistent with those seen in phonological agraphia (morphological errors, functor substitutions, and visually/orthographically similar misspellings) and also produce semantic errors (e.g., *apple* for *orange*) (Rapcsak, Beeson, & Rubens, 1991).

Treatment for Phonological and Deep Agraphia

As with phonological/deep alexia, treatment for individuals with phonological and deep agraphia may be directed toward sublexical and/or lexical processes. Phonological treatment may serve to strengthen sound-letter correspondences so that spellings can be derived phonologically. For individuals with concomitant damage to the lexical-semantic route, treatment may address damage to semantic representations or may focus on rebuilding specific spellings in the orthographic output lexicon.

Strengthening Sound-to-Letter Conversion. If a patient has impairment of sound-to-letter conversion, but has the ability to say words, it may be worthwhile to provide treatment to retrain sublexical spelling procedures (Cardell & Chenery, 1999; Hillis & Caramazza, 1994; Hillis Trupe, 1986). This treatment can be implemented using the same key word approach as used in reading treatment, with the potential for both modalities to be trained simultaneously (see Table 25-3). Once key words are established, training should be implemented to facilitate retrieval of phoneme-grapheme correspondences for spelling, as illustrated in Table 25-5. Hillis described clinical cases in which information derived from the sublexical route in combination with a partially damaged lexical-semantic system provided improved access to single words for written communication (Hillis Trupe, 1986; Hillis & Caramazza, 1994).

In individuals with deep agraphia, strengthening sound-to-letter conversion skills may provide access to initial graphemes, serving to block semantic errors or support activation of the orthographic output lexicon (Bub & Kertesz, 1982). In other words, semantic errors in writing might be avoided or self-corrected if a patient has at least some ability to translate the initial sounds of a word into the correspond-

ing graphemes. For example, if the intended target word is *movie*, but the patient incorrectly writes *TV*, the error might be self-corrected if the initial phoneme /m/ is converted to the grapheme *m*. While retraining sound-to-letter conversion skills may improve spelling in patients with deep agraphia, others require treatment directed toward the semantic system itself.

Treatment for Impaired Semantics. Effective remediation of semantic impairments may result in improved responses on oral naming and repetition tasks, as well as in written naming. For example, in cases where semantic errors suggest an underspecification of the features necessary to distinguish among items in the same semantic category, semantic treatment may be directed toward clarifying the semantic distinctions among written words as they are matched to corresponding pictures (Hillis, 1991). When errors are made, corrective feedback is offered that highlights distinctive features of the target in contrast to other members of the semantic category. For example, if *shirt* is written incorrectly as *pants*, then gestures, pointing, and simple verbal explanation highlight the distinction of *shirt* as clothing for the upper body and *pants* as clothing for the legs. This type of treatment has been shown to be effective in remediation of written naming within trained categories, even for untrained items. This pattern of improvement indicates the development of richer semantic representations, allowing for more accurate distinctions among items in treated categories. Semantic spelling treatment has also resulted in generalized improvement in other modalities, including oral naming and comprehension, again suggesting an improvement at the level of the semantic system (Hillis, 1991).

Lexical Spelling Treatments. As mentioned above, many individuals with damage to sublexical spelling procedures also have damage to the lexical-semantic spelling route. For individuals whose orthographic representations are damaged or unavailable and for whom a sublexical strategy is not feasible, treatment may be administered with the goal of rebuilding specific representations in the orthographic output lexicon. Because many of these individuals also have significant aphasia, item-specific lexical spelling treatment may be used to develop a functional written vocabulary that can augment, or substitute for, spoken language (Beeson, 1999; Clausen & Beeson, 2003; Robson, Marshall, Chiat, & Pring, 2001).

Several effective treatment protocols have been reported that include the task of arranging anagram letters to spell target words (Beeson, 1999; Beeson, Hirsch, & Rewega, 2002; Hillis, 1989). This lexical approach, called Anagram and Copy Treatment (ACT), is depicted in Figure 25-6. The treatment procedure consists of a task hierarchy to elicit correct spelling of the target words through the arrangement

TABLE 25-5

Cueing Hierarchy for Teaching Phoneme-to-Grapheme Conversion**A. Initial treatment sessions**

Step 1. Select target graphemes to be trained; for example, four sets of five graphemes (see Appendix 25-2).

Step 2. Establish one key word that the patient can write for each grapheme (see procedures in Table 25-3).

B. Implement cueing hierarchy to train targeted graphemes

Note that Step 1 is the most difficult task. If the patient cannot respond correctly, proceed to Step 2, then subsequent steps as needed. Follow the instructions to ascend the hierarchy when correct responses are achieved.

Step 1. "Write the letter that makes the sound /phoneme/."

- a. If correct, move on to the next target phoneme.
- b. If in error, proceed to Step 2.

Step 2. Provide an array of letters (five or more) including the correct target and say, "Point to the letter that makes the sound /phoneme/."

- a. If correct, remove array of letters and go to Step 1.
- b. If incorrect, proceed to Step 3.

Step 3. "Think of a word that starts with /phoneme/." or "Think of your key word for /phoneme/."

"Now point to the first letter of your key word" (from array of letters).

- a. If correct, say, "Yes, a word that starts with /phoneme/ is [key word]. [Key word] starts with the letter [target letter]." For example, "Yes, a word that starts with /b/ is baby. Baby starts with the letter B."
Rearrange the letters in the array and go back to Step 2.
- b. If incorrect, go to Step 4.

Step 4. "A word that starts with /phoneme/ is [key word]. Point to the letter that makes the first sound of [key word]."

- a. If correct, rearrange the array of letters and go back to Step 2.
- b. If incorrect, go to Step 5.

Step 5. "Write your key word for /b/. Write [key word]."

"Now point to the letter that makes the first sound of [key word]."

- a. If correct, rearrange letters in the array and go back to Step 2.
- b. If incorrect, go to Step 6.

Step 6. Clinician writes the key word for the target sound /phoneme/, and says, for example, "The letter B makes the first sound of *baby*. /b/ is the first sound of *baby*. B makes the sound /b/. Point to the letter B. Now copy the letter B." Return to Step 2.

C. Repeat the probe and cueing hierarchy for all targeted letters. Record responses only to initial trials of Step 1 to determine progress. Probe each letter at least three to five times per session.**D. Once single letters are reliably written in response to their associated phoneme, provide spoken words and ask the patient to write the first letter of the word.**

For example, "Write the first letter for the word 'basketball.'"

E. Determine next appropriate protocol to develop and take advantage of phoneme-to-grapheme conversion abilities.

*Rationale: to train patients the ability to derive graphemes from their associated phonemes.

(After Hillis Trupe, A. E. (1986). Effectiveness of retraining phoneme to grapheme conversion. In R. H. Brookshire (Ed.), *Clinical aphasiology* (pp. 163-171). Minneapolis: BRK.

of anagram letters, followed by repeated copying of the word. The goal is to strengthen the orthographic representations of specific words. After correct anagram arrangement and copying of the word, recall trials require repeated correct spelling from memory. The ACT approach relies heavily on the completion of homework (at least 30 minutes per day) that involves repeated copying of sets of target words presented with line drawings or photographs.

Another homework-based lexical spelling treatment is Copy and Recall Treatment (CART; Beeson, 1999; Beeson

et al., 2002; Beeson, Rising, & Volk, 2003; Clausen & Beeson, 2003). For this treatment, individuals repeatedly copy target words, then test their memory by covering up the written example and attempting to recall the spelling. During the treatment sessions, patients are trained to appropriately implement CART homework and check the accuracy of their responses. Typically, five words are targeted for treatment at one time, with additional sets of words added sequentially as criterion is met. For individuals who can repeat spoken words, CART can also be implemented with

Figure 25-6. Schematic depiction of Anagram and Copy Treatment (ACT).

verbal repetition of target words in order to improve both written and spoken naming (Beeson & Egnor, 2006). The model for spoken repetition can be provided on videotape, or using a photo album with an audio-recording feature, or one of various augmentative communication devices. Patients are trained to produce both spoken and written responses for each target during their daily homework. This CART plus repetition treatment resulted in positive gains in both written and spoken modalities for two individuals with moderate aphasia and severe spelling impairment (Beeson & Egnor, 2006).

Improvements made using ACT and CART tend to be item-specific but can be highly functional when target words are individually selected and personally relevant. For example, written targets may be proper names, including those of family, friends, and favorite restaurants, allowing for specific, meaningful exchange of information. CART has proven beneficial in individuals with severe aphasia, even those with minimal pre-treatment spelling skills

(Beeson et al., 2003). Words practiced using the CART protocol may also be trained in the context of group-treatment sessions, wherein each individual is given opportunities to communicate using practiced written words (Clausen & Beeson, 2003). This type of treatment has resulted in increased use of written targets in structured group settings and also in the context of conversation with unfamiliar partners.

Spelling with Overreliance on Sound-to-Letter Conversion: Surface (Lexical) Aphasia

In many cases of acquired agraphia, patients appear to have lost the orthographic representations for words, or have degraded representations, such that they show partial knowledge of word forms that they once knew. Low frequency words are typically more vulnerable to impairment than high frequency words. If sound-to-letter conversion abilities are spared, as shown in Figure 25-3, spelling may be

accomplished using the knowledge of sound-to-letter correspondences. This provides a useful strategic compensation; however, overreliance on the sublexical spelling route results in errors on words that have irregular spellings (for example, *knight* and *yacht* might be spelled as *nite* and *yot*). This spelling pattern is referred to as *surface agraphia*, in reference to the pattern of “writing how it sounds” (i.e., “on the surface”); it is also referred to as *lexical agraphia*, in reference to the damaged lexicon for writing (see Table 25-4). Because of patients’ reliance on a sounding-out procedure for spelling, surface agraphia is characterized by poor spelling of homophones (e.g., *suite* and *sweet*) and relative sparing of nonword spelling.

Lexical Spelling Treatment for Surface Agraphia

Several studies have documented the utility of item-specific training for strengthening representations in the orthographic output lexicon. This type of treatment has been used to teach correct spellings for irregularly spelled words (Hillis & Caramazza, 1987) and homophones (Behrmann, 1987) in patients with surface agraphia. Hillis and Caramazza (1987) showed that repeated, corrected practice served to improve spelling of targeted words. Behrmann (1987) used a task that involved matching pictures and written words followed by written naming of the picture. This treatment also used homework that required selection of the appropriate homophone to complete printed sentences. The treatment was successful in improving spelling of homophones and some untreated irregularly spelled words, but did not generalize to untreated items.

The aforementioned lexical spelling treatments, ACT and CART, may be appropriate for individuals with damage to orthographic representations in order to retrain spellings for specific lexical items. In addition, individuals with lexical agraphia, who have relatively spared sublexical spelling, may be trained to take advantage of sound-letter conversion abilities in conjunction with residual lexical knowledge, as described below.

Training a Problem-Solving Approach to Spelling.

Individuals with damage to the lexical-semantic route may demonstrate an overreliance on the sublexical spelling route, resulting in errors on irregularly spelled words and homophones. In some cases, plausible misspellings derived by sound-to-letter conversion may provide written cues that help patients resolve their own spelling errors. A problem-solving approach to spelling is appropriate for individuals who are capable of generating plausible or partial spellings. In this type of treatment, individuals learn to self-correct spelling errors by evaluating their written attempts relative to their lexical knowledge (Beeson, Rewega, Vail, & Rapcsak, 2000). Problem-solving treatment also includes training in the use of an electronic speller that accepts plau-

sible misspellings to help resolve spelling difficulties. For example, an individual might use a sublexical strategy to generate an initial spelling (e.g., *sepost* for “supposed”), then evaluate this spelling relative to residual lexical knowledge for the target (resulting in a closer approximation, such as *suposed*). Finally, the individual is instructed to use the electronic speller to check their spelling or to correct it further, resulting in an accurate spelling of the target. Problem-solving strategies have proven useful for self-correction of spelling errors, and it has been documented that, following the implementation of homework-based writing treatment employing the problem-solving approach, individuals may show generalized improvement in spelling abilities (Beeson et al., 2000).

Impairment of the Graphemic Buffer

The orthographic representation that is derived either from the orthographic output lexicon or via the sublexical sound-to-letter conversion process is held in short-term storage while letter forms are selected and writing is initiated. It has been documented that some patients have an impairment of this graphemic buffer, such that information decays at an abnormally rapid rate (Hillis & Caramazza, 1995; Miceli, Silveri, & Caramazza, 1985). As shown in Figure 25-7, the graphemic buffer receives output from both lexical-semantic and sublexical routes. Therefore, an impairment of the graphemic buffer will affect all writing tasks, including spontaneous writing, written naming, writing to dictation, and delayed copying. Damage to the graphemic buffer affects spelling of all word types, and thus, there are no effects of frequency, imagery, grammatical class, or regularity of spelling (see Table 25-4). In contrast, word length has a significant effect on performance, with a tendency for short words to be more accurately spelled than long words, due to the increased demand on storage capacity for longer words. Damage to the graphemic buffer also tends to result in loss of information about the identity and serial ordering of letters, resulting in spelling errors such as letter omissions (e.g., *sweater* → *sweatr*), substitutions (e.g., *peanut* → *peanul*), transpositions (e.g., *painter* → *painetr*), and additions (e.g., *flower* → *flowaer*). In the case of left hemisphere brain damage, the initial letters of the word are most likely to be correct, with errors occurring in the middle or toward the end of words (Caramazza, Miceli, Villa, & Romani, 1987; Hillis & Caramazza, 1989, 1995; Katz, 1991).

Treatment for Impairment of the Graphemic Buffer

In cases of selective impairment to the graphemic output buffer, the spared cognitive processes for spelling may provide a means to compensate (or self-correct) for spelling errors. For instance, individuals with some degree of preservation of sublexical and lexical-semantic spelling processes

Figure 25-7. Schematic representation of impairment to the graphemic output buffer, resulting in loss of information for the rightmost part of the word.

may be trained to use strategies for self-correction of spellings (Hillis & Caramazza, 1987). Such strategies may include examining spellings to evaluate their accuracy (i.e., comparing to representations in the orthographic lexicon) and also sounding out each word as it is written (to call attention to phonologically implausible misspellings).

Spelling treatments targeting impaired lexical spelling procedures have resulted in improvement for individuals with deficits at the level of the orthographic output lexicon as well as the graphemic buffer, indicating that a single treatment approach may prove beneficial to more than one component of the spelling process. Raymer, Cudworth, and Haley (2003) used a modified version of CART to address a spelling impairment involving both the orthographic output

lexicon and the graphemic buffer, and they documented improvements at both levels of processing in a single patient. Rapp and Kane (2002) used a delayed copy treatment with two individuals, one with a deficit at the level of the orthographic output lexicon and the other with a graphemic buffer impairment. Both individuals demonstrated positive treatment effects for trained items, with the latter showing generalization to untrained items.

Impairment of Allographic Conversion

Writing requires the conversion of each grapheme (i.e., abstract letter identity) into a particular letter shape, or allograph, in order to form the string of letters for a word.

Figure 25-8. Schematic representation of impairment to the allographic conversion mechanism, resulting in errors of letter selection in writing. Preserved ability to perform oral naming is indicated.

There are many ways to write a given grapheme, including upper or lowercase, print or cursive, and individual variations in writing style. Therefore, each time a word is written, the appropriate letter shape must be selected for that instance. This stage of writing, the allographic conversion process, is specific to written spelling, and is not required for oral spelling (Fig. 25-8). Some patients show a selective impairment of the allographic conversion process. These patients can spell aloud but are impaired in the selection and generation of the correct letter shapes in handwriting (Margolin, 1984; Ramage, Beeson, & Rapcsak, 1998). This impairment may be specific to letter case (upper or lowercase; De Bastiani & Barry, 1986; Kartsounis, 1992) or style (print vs. cursive; Hanley & Peters, 1996). The characteristic features include incorrect letter selection, resulting in

well-formed but incorrect letters, and also in disturbed letter formation. In either case, the writing errors are accompanied by preserved oral spelling.

When examining allographic conversion processes, it is useful to ask patients to transcode printed words from lower to uppercase and vice versa (see Appendix 25-1). Performance on this task may be compared to direct copy of single words. If graphomotor skills appear preserved for copy, but performance on the transcoding task is impaired, the profile is suggestive of impairment at the level of allographic conversion.

Treatment for Allographic-Conversion Impairment

It makes sense that treatment for individuals with impaired allographic conversion processes should attempt to take

advantage of superior oral spelling abilities. Self-dictation procedures have proven beneficial in improving spelling in individuals with preserved oral relative to written spelling (Pound, 1996; Ramage et al., 1998). Pound (1996) instructed a patient with impaired allographic conversion to engage in the following steps during treatment: orally spell each target word before attempting to write it; self-dictate each letter while writing one letter at a time; examine the written word one letter at a time while orally spelling the word again; self-correct any noted errors, using an alphabet card if a model is needed; finally, inspect the entire word to check it against the orthographic representation for the word. While spelling accuracy was not perfect post-treatment, this procedure proved successful in improving the patient's written spelling to a level commensurate with performance in oral spelling.

Summary of Treatment for Spelling Impairments

Spelling impairments can result from damage to one or more of the critical components of the cognitive processes that support written spelling. Treatment studies demonstrate that therapy directed toward lexical-semantic and sublexical spelling processes can improve spelling abilities of individuals with acquired writing impairments. In some cases, treatments serve to strengthen damaged or degraded representations, including semantic knowledge or orthographic word forms (i.e., spellings), as well as access to those representations. In other cases, the sublexical sound-to-letter conversion processes are strengthened. Finally, other treatments improve the operation of the graphemic buffer or allographic conversion processes that ultimately initiate the graphic motor plans for writing. The more peripheral sensorimotor impairments of writing (such as those resulting from cerebellar damage, subcortical lesions, and disorders of praxis) were not discussed here because they are less likely to accompany aphasia, but these disorders are reviewed elsewhere (Rapsack & Beeson, 2000).

CLOSING COMMENTS

In this chapter, we sought to provide a framework for assessing reading and spelling and using the assessment findings to select or design treatments. The treatment approaches focused on those components of the reading or spelling process that are impaired or can be used more efficiently to compensate for damaged components. The illustrative evaluation and therapy methods we have described surely do not exhaust the possibilities for improving processing at each level. However, the general approach to identifying, in each patient, which processes are impaired and which processes are spared in the tasks of reading or spelling should provide a springboard for designing other focused treatments. In practice, sequential treatment approaches may be warranted

to develop and take full advantage of improved skills and compensatory strategies in a given individual. We caution that it is essential to monitor a patient's progress carefully so that only effective interventions are pursued. Additionally, specific treatment approaches should be tailored appropriately to meet the functional needs of the patient.

FUTURE TRENDS

We expect that advances in our understanding of the cognitive processes and neural substrates that support reading and spelling will continue to influence treatment approaches for acquired alexia and agraphia. In the past decade, a number of interdisciplinary efforts have contributed to the knowledge base, and reflect complementary perspectives from speech-language pathology, neuropsychology, behavioral neurology, cognitive science, and psycholinguistics (e.g., Funnell, 2000; Hillis, 2002; Nadeau, Gonzalez Rothi, & Crosson, 2000; Rapp, 2001). We expect knowledge gained from behavioral research to be complemented by research using functional neuroimaging and computational modeling of normal and disordered language processes. Functional neuroimaging has the potential to clarify the neural substrates of recovery and the response to behavioral interventions (see, for example, Crosson et al., 2005; Marsh & Hillis, 2005). Computational modeling can be implemented to simulate the effects of brain damage and test different treatment approaches (see, for example, Houghton & Zorzi, 2003; Plaut, 1996). Advances in these endeavors may provide insights that improve our understanding of the nature of reading and spelling impairments, as well as maximize the effectiveness and efficiency of behavioral treatments.

Finally, the increased attention to evidence-based practice in speech-language pathology has promoted increased rigor in the experimental designs used to examine treatment outcomes. In particular, the quantification of treatment outcomes using standardized effect sizes should facilitate a better understanding of the therapeutic effects of different treatments (see, for example, Beeson & Robey, 2006). Ideally, treatment research should serve to clarify who are the ideal candidates for particular treatment approaches, and provide an estimate of treatment effect size for such individuals. This information can serve to guide clinicians as they select treatment for a particular individual.

Hillis, M.D. for her significant contributions to the previous edition of this chapter. We also thank Roberta Goodman-Schulman and Alfonso Caramazza for generously sharing the Johns Hopkins Dyslexia and Dysgraphia Batteries.

KEY POINTS

1. Neurologic damage can disturb the processes necessary for reading and writing in a variety of ways. Careful examination of the component processes for reading and writing can serve to isolate the locus (or loci) of impairment and thus guide the treatment approaches.
2. Treatment for acquired reading and writing impairments include approaches that strengthen weakened processes and representations, as well as those that encourage the development and use of strategies to compensate for impaired processes.
3. Reading impairments can result from impairment to any or all of the following processes or representations: visual processing of written words, the orthographic input lexicon (the store of known written words), the semantic system, the phonological processes necessary for speech production (for oral reading), and the processes necessary to convert letters to the corresponding sounds.
4. Treatment for acquired reading impairments may be directed toward lexical-semantic processes, so that the links between written words and their meanings are strengthened. Conversely, treatment may be directed toward strengthening the sublexical route for reading, whereby letters are converted to their associated sounds and word pronunciations are assembled.
5. Writing impairments can result from impairment to any or all of the following processes or representations: the semantic system, the orthographic output lexicon (the store of spellings), the graphemic buffer that temporarily holds graphemic information for writing, the conversion processes necessary to select and form specific letters, and the graphic motor processes necessary for the implementation of writing.
6. Similar to reading, treatment for writing impairments may be directed toward lexical-semantic processes, sublexical spelling processes, or both.
7. Some treatment approaches result in item-specific improvements, whereas other approaches result in the development of strategies that are of general benefit. Both approaches are valid.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. What are the components of the lexical-semantic route for reading?
2. Why do you always read “apple” as “apple,” regardless of the style of the font?
3. Why is letter-by-letter reading a successful strategy for pure alexia, but not a useful strategy for surface or deep alexia?
4. When might you work on reading at the text level in a patient who has trouble reading single words?
5. What is the benefit of training a “key word” approach for alexia or agraphia?
6. Individuals with surface agraphia nearly always demonstrate surface alexia, but it is not uncommon to observe surface agraphia without surface alexia. Discuss why that is the case.
7. Describe an example of a lexical treatment for spelling.
8. What alexia syndrome is characterized by a word-length effect?
9. What agraphia syndrome is characterized by a word-length effect?
10. What is meant by an interactive, problem-solving approach to spelling treatment?
11. Deep alexia and deep agraphia are characterized by what hallmark feature?
12. What is meant by the statement that phonological and deep alexia/agraphia represent the ends of a severity continuum?
13. How might you combine treatment for spoken and written language at the same time? Give an example in the context of reading treatment, and an example in the context of spelling treatment.

APPENDIX 25.1

Johns Hopkins University Dyslexia and Dysgraphia Batteries

The following word lists are controlled for lexical features including grammatical word class, frequency of occurrence in written English, concreteness, regularity of spelling based on sound-to-letter correspondences, and word length. Nonwords are also provided that are pseudohomophones (i.e., nonword spellings that are homophones with real words) and nonhomophones (i.e., pronounceable nonwords derived by altering real words by one grapheme). The words are grouped on the basis of their relevant features, so that the contrasts are apparent; however, items within a given list should be presented in random order during test administration. In many cases, the same word lists can be used to assess reading and writing, but as indicated below, some lists are specific to the dyslexia or dysgraphia batteries.

The dyslexia battery consists of oral reading of words and nonwords. The dysgraphia battery includes writing to dictation, written naming of pictures, transcoding by letter case (e.g., upper to lowercase), and copying of single words. Writing to dictation is accomplished by presenting a word or nonword auditorily and asking the patient to first repeat the stimulus aloud and then write it.

1. Grammatical Word Class

List composition: 104 words (28 nouns, 28 adjectives, 28 verbs, 20 functors)

a. Dyslexia Battery

Task: oral reading

b. Dysgraphia Battery

Task: writing to dictation

<u>Word</u>	<u>Class</u>	<u>Frequency</u>	<u># Letters</u>	<u>Word</u>	<u>Class</u>	<u>Frequency</u>	<u># Letters</u>

3. Word Frequency

List composition: Use responses from any or all of the following lists

Grammatical Class List (nouns, adjectives, verbs only) = 42 HF and 42 LF

Word Concreteness List (concrete and abstract) = 14 HF, 14 MF, and 14 LF

Word Length List = 35 HF and 35 LF

a. Dyslexia Battery

Task: oral reading

b. Dysgraphia Battery

Task: writing to dictation

4. Nonwords

a. Dyslexia Battery

Task: oral reading

List composition: 34 pseudohomophones and 34 nonhomophones

b. Dysgraphia Battery

Task: writing to dictation

List composition: 34 nonhomophones (* indicates 20 nonwords to be used for oral spelling task with real words in list 7)

7. Oral Spelling and Copy Tasks—Dysgraphia Battery Only

Task composition: 42 words (21 HF and 21 LF including nouns, adjectives, verbs, functors)

a. Oral spelling—ask the patient to spell the word aloud

b. Copy

1) Cross-case transcoding—present written words in uppercase and ask patient to copy in lowercase

2) Direct copy—present written words in lowercase and ask patient to copy in lowercase

<u>Word</u>	<u>Class</u>	<u>Frequency</u>	<u># Letters</u>	<u>Word</u>	<u>Class</u>	<u>Frequency</u>	<u># Letters</u>

APPENDIX 25.2

Rank Order of Phoneme Occurrences in Word Corpus and the Common Associated Graphemic Representations

<u>Rank of Occurrence</u> ¹	<u>International Phonetic Alphabet</u>	<u>Compatible Representation</u>	<u>Keyboard Probable Grapheme</u> ²	<u>Example</u>
1	/r/	r	r	<u>rat</u>
2	/t/	t	t	<u>tea</u>
3	/n/	n	n	<u>no</u>
4	/s/	s	s	<u>sun</u>
5	/ɪ/	ih	i	<u>pill</u>
6	/ə/	uh-	o, a	<u>button</u> , <u>about</u>
7	/l/	l	l	<u>lake</u>
8	/k/	k	k, c	<u>key</u> , <u>cat</u>
9	/i/	ee	ee, ea	<u>bee</u> , <u>eat</u>
10	/æ/	ae	a	<u>apple</u>
11	/ɛ/	eh	e	<u>egg</u>
12	/d/	d	d	<u>dog</u>
13	/m/	m	m	<u>man</u>
14	/p/	p	p	<u>pen</u>
15	/ə/	er	er	<u>mother</u>
16	/o/	o	oa, o	<u>boat</u> , <u>open</u>
17	/b/	b	b	<u>book</u>
18	/e/	ay	a-e	<u>ape</u>
19	/a/	ah	a	<u>father</u>
20	/f/	f	f	<u>fan</u>
21	/ʃ/	sh	sh	<u>shoe</u>
22	/v/	v	v	<u>van</u>
23	/ai/	ai	i, i-e	<u>find</u> , <u>ice</u>
24	/ʌ/	uh+	u	<u>up</u>
25	/g/	g	g	<u>goat</u>
26	/z/	z	z	<u>zebra</u>
27	/dʒ/	dj	j	<u>joke</u>
28	/ɔ/	aw	aw, o	<u>saw</u> , <u>soft</u>
29	/h/	h	h	<u>hat</u>
30	/w/	w	w	<u>window</u>
31	/ŋ/	ng	ng	<u>ring</u>
32	/tʃ/	tch	ch	<u>chin</u>
33	/u/	oo	oo	<u>food</u>
34	/ð/	th-	th	<u>then</u>
35	/aʊ/	au	ou, ow	<u>house</u> , <u>owl</u>
36	/ʊ/	u	oo	<u>book</u>
37	/ɔɪ/	oy	oy	<u>boy</u>
38	/θ/	th+	th	<u>thin</u>
39	/j/	y	y	<u>yellow</u>
40	/ʒ/	zh	g	<u>rouge</u>

¹Rank of occurrence was calculated from a corpus of 17,310 English words by Hanna, Hanna, Hodges, & Rudorf (1966) with modifications made by Berndt, Reggia, & Mitchum (1987).

²Phoneme-to-grapheme correspondences were taken from Berndt, et al. (1987) who used the Hanna, et al. (1966) data to calculate probability estimates for pronunciation of particular graphemes. The graphemes presented here reflect only the most probable spellings (see Berndt, et al. for a complete listing of graphemes for each phoneme).

APPENDIX 25.3

Glossary

Alexia without agraphia—An acquired reading impairment that is not accompanied by an impairment of writing; also called pure alexia. It is often characterized by a letter-by-letter reading approach.

Allographic conversion—The process whereby an abstract orthographic representation is converted to a specific physical manifestation of a given grapheme.

Allographs—The different forms that a grapheme can take, that is, the various ways one can write a given letter by varying, for example, font, case, script, and handwriting styles.

Deep agraphia (Deep dysgraphia)—An acquired writing impairment that is characterized by the presence of written semantic errors, as well as effects of word frequency (high better than low), imagery (high better than low), and grammatical class (nouns better than functors).

Deep alexia (Deep dyslexia)—An acquired reading impairment that is characterized by the presence of semantic errors in reading, as well as reading performance that is better for high-frequency, concrete nouns in comparison to low-frequency, abstract words.

Global agraphia—An acquired impairment of writing that disrupts lexical and sublexical spelling processes to such an extent that few words are spelled correctly and it is difficult to detect lexical influences on spelling accuracy.

Grapheme—The abstract representation of a letter's identity, e.g., *F* and *f* are letters that both represent the grapheme *f*. A grapheme is a letter or letter cluster (like *sh*) that corresponds to a single phoneme.

Grapheme-to-phoneme conversion mechanism—A mental process whereby a written word is sounded out by associating each letter identity with its corresponding sound.

Graphemic input lexicon—The corpus of written words that one recognizes.

Graphemic output buffer—The short-term storage mechanism for holding graphemes as one selects the specific allographs (letter form and style) and implements graphic motor programs.

Graphemic output lexicon—The corpus of words that one knows how to spell.

Homographs—Words that are spelled the same but pronounced differently; for example, the adjective *lead* as in “a lead pipe” and the verb *lead* as in “lead the group.”

Letter-by-letter reading—An approach to reading whereby letters are identified in serial order; typically observed as a compensatory reading approach in individuals with pure alexia.

Letter-to-sound conversion—The process of reading aloud by converting a letter (or letter cluster) to the corresponding sound.

Lexical agraphia (Surface agraphia)—An acquired writing impairment that is characterized by an overreliance on sound-to-letter conversion processes; typical errors include regularization of irregularly spelled words (e.g., *yot* for *yacht*).

Lexical-semantic route—A means of processing information whereby lexical entries for words are activated along with their corresponding meanings.

Nonlexical route—A means of information processing that does not rely on activation of lexical representations; for example, non-

lexical reading can be accomplished by converting letters to their corresponding sounds and nonlexical writing can be accomplished by converting sounds to their corresponding letters.

Orthographic input lexicon—The collection of mental representations for written words that one recognizes; also called the visual-input lexicon or the graphemic-input lexicon.

Orthographic output lexicon—The collection of mental representations for spellings that one knows; also called the graphemic-output lexicon.

Orthography-to-phonology conversion—The process of reading aloud by converting a letter (or letter cluster) to the corresponding sound; also referred to as letter-to-sound conversion.

Phoneme-to-Grapheme Conversion—The process of writing by means of deriving spelling based on knowledge of sound-to-letter correspondences.

Phonological agraphia—An acquired impairment of spelling that is characterized by the inability to write nonwords due to impairment of the sublexical sound-to-letter conversion processes.

Phonological alexia—An acquired impairment of reading that is characterized by an inability to read nonwords due to impairment to the sublexical letter-to-sound conversion processes.

Phonological buffer—The short-term storage mechanism whereby phonemes are held while articulatory planning for speech production is accomplished.

Phonological output lexicon—The collection of phonologic representations for words that one can produce.

Pure alexia—An acquired reading impairment that is not accompanied by an impairment of writing. It results from a disruption of visual input from the appropriate abstract word-form representation, so that words are visually perceived, but not recognized.

Semantic paralexias—Reading errors that are semantic in nature; for example, reading *bus* as “car.”

Sublexical route—A means of information processing that does not rely on activation of lexical representations; for example, reading that is accomplished by converting letters to their corresponding sounds or writing that is accomplished by converting sounds to their corresponding letters.

Surface agraphia (Lexical agraphia)—An acquired writing impairment that is characterized by an overreliance on sound-to-letter conversion processes; typical errors include regularization of irregularly spelled words (e.g., *yot* for *yacht*).

Surface alexia (Surface dyslexia)—An acquired reading impairment characterized by reading according to letter-to-sound correspondence rules so that irregularly spelled words (such as *yacht*) tend to be mispronounced.

Visual input lexicon—The collection of mental representations for written words that one recognizes; also called orthographic-input lexicon or graphemic input lexicon.

Visual output lexicon—The collection of mental representations for spellings that one knows; also called orthographic output lexicon or graphemic output lexicon.

C. Cognitive Neurolinguistic Approaches to the Treatment of Language Disorders

Chapter 26

Language Rehabilitation from a Neural Perspective

Stephen E. Nadeau, Leslie J. Gonzalez
Rothi, and Jay Rosenbek

OBJECTIVES

The objectives of this chapter are to detail a neural network model of language function that incorporates phonologic, semantic, lexical-semantic, and grammatical function; to discuss cerebral memory mechanisms in relation to the acquisition of knowledge and skills during language therapy; to define mechanisms by which knowledge and skills gained during therapy might generalize in ways that will enhance daily communicative function; to consider the implications of education psychology research for the structure, context, and temporal spacing of therapy, the nature of stimuli presented in therapy, and the nature of feedback delivered during therapy; and to review several specific therapies (including phonologic, semantic, and grammatical therapies; constraint-induced language therapy, and errorless learning) to illustrate the applications of neural principles to treatment and the potential opportunities for generalization.

Rehabilitation after brain injury depends on two processes: (1) the endogenous responses of neural tissues (reactive plasticity), which include reactive neurogenesis, neural migration, axonal sprouting and extension to target structures, and synaptogenesis (Kolb, 2004; Kolb & Cioe, 2004); and (2) the replacement of knowledge lost as a result of injury through behavioral therapy. Although we are at the scientific threshold of manipulating reactive plasticity

to therapeutic advantage, the clinical data so far are inconclusive and do not yet bear on rehabilitation of language processes. Therefore, the principal focus of this chapter will be on behavioral therapies.

The efficacy of behavioral therapies for language impairment has been demonstrated in a large number of studies, some providing level I evidence. These are reviewed at length in this text. In this chapter, we focus on the treatment of aphasia not from the perspective of clinical trials but, rather, from the perspective of neural science. We will begin with a very brief review of relevant aspects of neuroscience (see also Nadeau et al., 2004).

The brain contains 100 billion neurons. Half of these are located in the cerebrum. Any given neuron sends output, through its axon, to thousands or tens of thousands of other neurons, and any given neuron receives synaptic contacts providing input from up to tens of thousands of neurons. Neurons, through their connections, are organized into networks. These networks provide the basis for the representation of knowledge and for transforming knowledge in one domain (e.g., written language) into another domain (e.g., spoken language). For these reasons, neural networks (as opposed to neurons) have been identified as the essential unit of brain function (Buonomano & Merzenich, 1998). The brain is best viewed as webs of connected neural processes, including axons and dendrites, in which the neurons themselves serve mainly to provide metabolic support, structural maintenance, and the currency of neural processing (firing rates), and the knowledge is represented in synaptic connection strengths.

The state of the brain at any given moment (the substrate for conscious awareness) largely is defined by the pattern of neural activity in all its neural networks. Because active perceptions, thoughts, and plans correspond to patterns of spatially disseminated neural activity, we refer to their neural

representations as being distributed.¹ When an excitatory neuron fires, it elicits firing in many of the neurons to which it is connected. In this way, neural activity can spread from a few neurons to many neurons within a network and from one network to another.

Information is not sent from one part of the brain to another (this is a digital computer concept); rather, a sustained pattern of neural firing in one network eventually elicits a sustained pattern of firing in another network. Most neural efferent (output) projections are reciprocated by returning (afferent) projections from the target networks. Thus, the transmission of information in the brain corresponds to an ongoing, two-way dialogue between a sending network and a receiving network in which the two networks ultimately settle into a steady state. The time to settle largely defines behavioral response latency. This dynamic additionally provides the neural basis for bottom-up/top-down processing effects. In practice, information transmission typically involves a large number of connected networks, each contributing its particular knowledge and expertise to the final steady-state pattern. In this way, the brain is able to meet multiple different constraints simultaneously—an emergent property of connected neural networks referred to as “parallel constraint satisfaction.” Nowhere is parallel constraint satisfaction better illustrated than in the case of language, in which what we ultimately say reflects perceptual input (e.g., auditory); knowledge latent in our semantic networks; processing by neural networks supporting grammar, the translation of concepts into phonologic sequences, implicit rules governing phonologic sequences, and implicit rules governing modifications of phonologic sequences as language is produced (phonetic modifications); and constraints imposed by neural networks driving respiratory and pharyngeal musculature in actually producing sound.

A given neural network supports knowledge (long-term memory, represented in neural connection strengths), working memory (the pattern of neural activity in the network at any given time), and processing (the transformation of input patterns into output patterns). Learning corresponds to changes in connection strengths in the network. Knowledge includes facts and skills. Acquisition of declarative knowledge (fact memory) requires the participation of a unique ancillary processor (the hippocampal system). The acquisition of nondeclarative knowledge (e.g., procedural or skill memory) can be achieved through the incremental adjustment of neural connection strengths that may occur during

neural network processing activities. Rules can be learned explicitly (e.g., “i” before “e” except after “c”). In general, however, such rules are best viewed as metamemory, and in the extremely rapid online processing that underlies language comprehension and production, rules are reflected as implicit knowledge of regularities in a network’s experience.

There has been a long-standing debate in the linguistic and neuropsychological literatures as to whether deficits observed after brain damage reflect loss of knowledge or loss of access to knowledge. The fact that even subjects with severe impairment may demonstrate residual knowledge often is cited as support for the loss-of-access theory (e.g., subjects with agrammatical aphasia often display considerable ability in make judgments regarding grammar; semantic paraphasic errors tend to be near-misses, and phonemic paraphasic errors typically bear a semantic and/or phonologic relationship to the target). The neural network understanding of brain operations that we have achieved (summarized above) leads us to more nuanced conclusions. Because knowledge is distributed as connection strengths throughout a neural network, damage to a network may lead to a substantial probability of output error, but it does not eliminate all knowledge unless the network is completely destroyed, a phenomenon referred to as “graceful degradation.” Thus, evidence of residual knowledge is perfectly consistent with partial loss of knowledge as a result of network damage. On the other hand, certain types of brain damage, particularly those involving major white matter pathways, may destroy connections between networks, leading to cognitive dysfunction that truly reflects loss of access to intact knowledge representations—that is, true disconnection syndromes (Geschwind, 1965). For example, following transection of the corpus callosum to treat refractory generalized epilepsy, the right hemisphere generally cannot express itself verbally, because it has no access to left hemisphere language networks and the left hemisphere cannot speak about right hemisphere perceptions, thoughts, and plans because it has no way of accessing these representations. Subjects with posterior cerebral infarcts that destroy the left occipital cortex and the splenium of the corpus callosum cannot read, because even though the right occipital cortex can see the printed words, it cannot relay this orthographic information to the left hemisphere for linguistic processing. In the final analysis, most aberrant behavior observed after brain damage likely reflects a mix of loss of knowledge as a result of destruction of neural networks and loss of access to knowledge as a result of damage to white matter pathways or intervening gray matter “relay stations.” Even in the case of callosal section, arguably the purest disconnection syndrome, the involved interhemispheric axons support synaptic connections that represent knowledge—connections that are lost with the surgery. In the domain of language, conduction aphasia has long been viewed as a disconnection syndrome caused by damage to the arcuate

¹ Local representations—that is, information defined at a single discrete locus—are not found in the central nervous system. They are present only peripherally, such as when a photon of light stimulates a single retinal rod or cone or when the firing of a single muscle fiber is elicited by the firing of the terminal of its afferent axon.

fasciculus (and, perhaps, other anteroposterior white matter pathways). It certainly is true that a discontinuity exists between language zones in the posterior perisylvian region and Broca's area, and to this extent, the result of a lesion of the connecting white matter can be viewed as a disconnection syndrome. Abundant evidence, however, exists that conduction aphasia also reflects damage to the neural networks supporting phonologic sequence knowledge.

A fully neuroscientific approach to behavioral therapy for language impairment must ask what types of knowledge need to be replaced, how are they represented in the brain, and how can the brain best be coaxed into reacquiring this knowledge? The answers to these questions are not known with certainty in any cognitive domain, but we probably know more about language than about any other cognitive function. In fact, we have sufficient knowledge about the neural basis of language processes to propose some reasonable hypotheses regarding therapeutic strategies. We currently have no ability to treat components of aphasia related to disconnection (loss of access to knowledge) other than through training of networks that are still connected and have some capability for acquiring the requisite linguistic knowledge. For example, in the subject with conduction aphasia, it may be possible to enhance phonologic sequence knowledge in networks in the nondominant hemisphere, effectively bypassing the disconnection in the dominant hemisphere (see *Phonologic, Semantic, and Lexical-Semantic Processing* under *A Parallel Distributed Processing Model of Language* below).

Although a number of approaches have been taken to explain language processing (e.g., linguistic and cognitive neuropsychological), this chapter will focus heavily (but not exclusively) on parallel distributed processing models, also known as connectionist models, both because they enable us to link neural network architecture directly to complex behavior and because they incorporate many of the properties of neural systems discussed above. A specific PDP model of language will be discussed to introduce the basic concepts and to frame some later hypotheses about the domains of knowledge represented. A brief review of the unique properties and particular strengths of PDP models will follow. Subsequently, we will have cause to refer back frequently to PDP models, but we will also rely on other sources of information about the neural basis of language as it relates to speech-language therapy.

A PARALLEL DISTRIBUTED PROCESSING MODEL OF LANGUAGE

Phonological, Semantic, and Lexical-Semantic Processing

The Wernicke-Lichtheim information processing model of language function has played a dominant role in understanding aphasic syndromes (Lichtheim, 1885) and has stood

the test of time in defining the topographical relationship between the modular domains (acoustic representations, articulatory-motor representations, and concept representations) underlying spoken language function. Unfortunately, the Wernicke-Lichtheim information processing model does not specify the characteristics of the representations within these domains and how they might be stored in the brain. It also does not address the means by which these domains might interact. We have proposed a parallel distributed processing (PDP) model that uses the same general topography as the Wernicke-Lichtheim model (Nadeau, 2001; Roth, Nadeau, Hollingsworth, Cimino-Knight, & Heilman, 2006), but this PDP model also specifies how representations are generated in the modular domains and how knowledge is represented in the links between these domains (Fig. 26-1). Although not tested through simulations, this model is neurally plausible and provides a cogent explanation for a broad range of psycholinguistic phenomena. More generally, connectionist concepts now are deeply embedded in—and receive enormous support from—mainstream neuroscientific research (see, e.g., Rolls & Deco, 2002; Rolls & Treves, 1998).

The PDP modification of the Wernicke-Lichtheim model posits that the acoustic domain (akin to Wernicke's area) contains large numbers of units located in auditory association cortices that represent acoustic features of

Figure 26-1. Proposed parallel distributed processing model of language. (From Roth, H. L., Nadeau, S. E., Hollingsworth, A. L., Cimino-Knight, A. M., Heilman, K. M. (2006). Naming concepts: Evidence of two routes. *Neurocase*, 12, 61–70; with permission.)

phonemes.² The articulatory domain (analogous to Broca's area) contains units located predominantly in the dominant frontal operculum that represent discrete articulatory features of speech, as opposed to continuously variable motor programs (e.g., phonemic distinctive features). The semantic or conceptual domain contains an array of units distributed throughout unimodal, polymodal, and supramodal association cortices that represent semantic features of concepts. For example, the representation of the concept of "house" might correspond to activation of units representing features of houses, such as visual attributes, construction materials, contents (physical and human), and so on. Each unit within a given domain is connected to many, if not most, of the other units in that same domain (symbolized by the small looping arrow appended to each domain in Fig. 26-1). Knowledge within each domain is represented as connection strengths between the units. Thus, semantic knowledge is represented as the pattern of connection strengths throughout the association cortices supporting this knowledge. Within any domain, a representation corresponds to a specific pattern of activity of all the units, hence the term "distributed representation." Each unit within each of these domains is connected via interposed hidden units to many, if not most, of the units in the other domains. During learning of a language, the strengths of the connections between the units are gradually adjusted so that a pattern of activity involving the units in one domain elicits the correct pattern of activity in the units of another domain. The entire set of connections between any two domains forms a pattern associator network. The hidden unit regions, in conjunction with nonlinear unit properties, enable the systematic association of representations in two connected domains that are arbitrarily related to one another (e.g., word sound and word meaning). The model employs left-right position in acoustic and articulatory motor representations as a surrogate for temporal order in precisely the same way as the reading model of Plaut, McClelland, Seidenberg, and Patterson (1996). Thus, acoustic-articulatory motor representations would feature positions for each output phoneme or distinctive feature, ordered as they are in the phonologic word

form. The use of left-to-right sequential order in lieu of temporal order is a device of convenience, but evidence exists for this temporal-geographic transform in the brain (Cheung, Bedenbaugh, Nagarajan, & Schreiner, 2001). During any type of language processing, initiated by input to any domain of the network, almost instantaneous engagement of all domains of the network will occur. Thus, linguistic behavior is best viewed as the emergent product of the *entire* network.

We will now focus on particular components of the network to provide a more detailed understanding of how they work and the nature of the knowledge they support.

Concepts Representations

As we have noted, the Wernicke-Lichtheim information processing model provides no insight regarding the nature of the representations in the various domains. The nature of concept representations (depicted in Fig. 26-1) can be best illustrated using a particular model developed by David Rumelhart and his colleagues (Rumelhart, Smolensky, McClelland, & Hinton, 1986). This "rooms in a house" model is comprised of 40 "feature" units, each corresponding to an article typically found in particular rooms or an aspect of particular rooms. Each unit is connected with all the other units in the network—an attribute that defines the model as an *auto-associator network*. Auto-associator networks have the capacity for "settling" into a particular state that defines a representation. Connection strengths are defined by the likelihood that any two features might appear in conjunction in a typical house. When one or more units are clamped into the "on" state (as if the network has been shown these particular features or articles), activation spreads throughout the model, and the model eventually settles into a steady state that implicitly defines a particular room in a house. Thus, clamping "oven" ultimately results in activation of all the items one would expect to find in a kitchen and thereby *implicitly* defines, via a *distributed representation*, the concept of a kitchen (Fig. 26-2). No kitchen unit *per se* is turned on. Rather, "kitchen" is defined by the pattern of feature units that are activated. The network contains the knowledge, in the totality of its connections, that enables this representation to be generated. The 40-unit model actually has the capability of generating distributed representations of a number of different rooms in a house (e.g., bathroom, bedroom, living room, or study), subcomponents of rooms (e.g., easy chair and floor lamp, desk and desk-chair, or window and drapes), and blends of rooms not anticipated in the programming of the model (e.g., clamping both bed and sofa leads to a distributed representation of a large, fancy bedroom replete with a fireplace, television, and sofa).

This auto-associator model, simple though it is, has the essential attributes of a network that might be capable of generating the distributed representations of meaning underlying semantics. The brain's semantic auto-associator obviously is comprised of vastly more than 40 features, and it

² A "unit" is the smallest functional entity within a connectionist model. It has a level of activation that is defined as a nonlinear mathematical function of its combined inputs at any one time (in many models, a sigmoidal curve that asymptotically approaches a minimum value of zero or a maximum value of one). It has an output that is a nonlinear mathematical function of its level of activation, often incorporating a threshold such that for activation levels below the threshold, no output occurs. Each unit is connected to a very large number of other units. The patterns of connectivity within a network define its functional capacity. The precise neural counterpart of a unit is uncertain and may vary from region to region. Thus, it is not implausible that single neurons function as units in the superior colliculus, whereas in the cortex, it is possible that a cortical column comes closer to meeting our definition of a unit. The neurobiology of cortical neural network function is currently understood only at the most rudimentary level.

Figure 26-2. Evolution of the pattern of activation in the “rooms-in-a-house” model when the units “ceiling” and “oven” are clamped in the “on” position. Time elapses from left to right. The size of each square indicates the degree of activation of that particular feature unit. (From Rumelhart, D. E., Smolensky, P., McClelland, J. L., & Hinton, G. E. (1986). Schemata and sequential thought processes in PDP models. In J. L. McClelland, D. E. Rumelhart, & the PDP Research Group (Eds.), *Parallel distributed processing* (Vol. 2, pp. 7–57). Cambridge, Massachusetts: MIT Press; with permission.)

enables an enormous repertoire of distributed representations corresponding to the vast number of concepts we are capable of representing. This particular model network is not compartmentalized, but nothing inherent in PDP models precludes a semantic representation comprised of two or more subnetworks (see, e.g., Farah and McClelland, 1991). Good evidence suggests that in the brain, the meaning of a given word is distributed over a host of networks, depending in part on the semantic features that are most essential to that meaning. For example, visual information makes a particularly large contribution to the meaning of living things; consequently, subjects with damage to visual association cortex as a result of herpes simplex encephalitis

exhibit category-specific naming and recognition deficits for living things (Forde & Humphreys, 1999; Warrington & Shallice, 1984).

The concept of a fractionated, multi-network distributed representation of meaning is illustrated in Figure 26-3. The distributed representation of the concept “dog” has a major component in visual association cortices corresponding to knowledge of the visual appearance of dogs in general, as well as to that of particular dogs; a major component in auditory association cortices corresponding to the sounds that dogs characteristically make; a major component in the limbic system corresponding to one’s feelings about dogs in general and about specific dogs; a component in somatosensory cortex corresponding to the feel of dog fur or wet tongue or cold nose; a predicative component, presumably involving the frontal cortex, corresponding to our knowledge of what dogs are likely to do; a component in the olfactory cortex corresponding to the odors of dogs; and components in the perisylvian language cortex that enable us to translate the semantic representation of “dog” into an articulatory motor representation (so we can say /dog/) or an acoustic representation (so we can understand another person saying /dog/). Not all of these subnetworks will be activated every time or in exactly the same way by everyone. Thus, we can speak in terms of *working memory*—in this case, a pattern of activity in particular subnetworks corresponding to “dog”—and we can speak in terms of *working associations*, meaning the elicitation of distributed concept representations in other connected subnetworks, either automatically or volitionally. Thus, nearly everyone would, when hearing /dog/, develop visual and limbic distributed representations, each constituting a working memory, with the two together comprising an automatic working association. The average person, however, might need to volitionally develop the working association that brings in the olfactory component of the meaning of “dog.”

Figure 26-3. The full, multi-component, distributed representation of the concept “dog.” (See text for explanation.)

The Acoustic-Articulatory Motor Pattern Associator Network

The knowledge that allows a person to translate heard sound sequences into articulatory-motor sequences and, thereby, mediates repetition of both real words and nonwords is contained in the network that connects the acoustic domain to the articulatory motor domain (the acoustic-articulatory motor pattern associator; see Fig. 26-1, pathway 7-3). Because this network has acquired, through experience, knowledge of the systematic relationships between acoustic sequences and articulatory sequences, it has learned the sound sequence regularities of the language: the phonemic sequences of joint phonemes, rhymes, syllables, affixes, morphemes, and words characteristic of the language (Nadeau, 2001). Consideration of the reading model developed by Plaut and colleagues (1996) will help to make this more transparent (see also Seidenberg & McClelland, 1989).

This reading model fundamentally recapitulates the acoustic-articulatory motor pathway of Figure 26-1, the major difference (inconsequential to this discussion) being that in place of acoustic representations, it incorporated orthographic (printed letter) representations. The model (Fig. 26-4) was composed of three layers:

1. An input layer of 105 grapheme units grouped into clusters, the first cluster including all possibilities for the one or more consonants of the onset, the second cluster including all the possible vowels in the nucleus, and the third cluster including all possibilities for the one or more consonants in the coda.
2. A hidden unit layer of 100 units.
3. An output layer of 61 phoneme units grouped into clusters, including all the possibilities for onset, nucleus, and coda, respectively (as for the graphemes).

Figure 26-4. One version of the parallel distributed processing (PDP) reading model developed by Plaut and colleagues. (From Plaut, D. C., McClelland, J. L., Seidenberg, M. S., & Patterson, K. (1996). Understanding normal and impaired word reading: Computational principles in quasi-regular domains. *Psychological Review*, 103, 56-115; with permission.)

Local representations were used for the graphemes and phonemes. One-way connections from each of the grapheme input units exist to each of the hidden units, and two-way connections exist between each of the hidden units and each of the phoneme output units. Every output unit was connected to every other output unit, providing the network with the auto-associator capability for “settling into” the best solution (as opposed to its own approximate solution). The model was trained using a mathematical algorithm that incrementally alters the strengths of connections that make the biggest contribution to error, which was computed as the difference between the actual product of the network and the desired product of the network.³ The orthographic representation of 3,000 English, single-syllable words and the corresponding phonologic forms was presented, one pair at a time, cycling repeatedly through the entire corpus. In this way, the model ultimately learned to produce the correct pronunciation of all the words it had read. One of the most striking things about the trained model is that it also was able to produce correct pronunciations of plausible English nonwords (i.e., orthographic sequences it had never encountered). How was this possible?

One might have inferred that the model was simply learning the pronunciation of all the words by rote. If this had been the case, however, the model would have been incapable of applying what it had learned to novel words. In fact, what the model learned was the relationships between *sequences* of graphemes and *sequences* of phonemes that are characteristic of the English language. To the extent that a limited repertoire of sequence types exists, the model was able to learn it and then apply that knowledge to novel forms that incorporated some of the sequential relationships in this repertoire. The information the model acquired through its long experience with English orthographic-phonologic sequential relationships, however, went considerably beyond this. Certain sequences (i.e., those most commonly found in English, single-syllable words) were more thoroughly etched in network connectivity. Thus, it was very fast with high-frequency words. It also was very fast with words having an absolutely consistent orthographic-phonologic sequence relationship (e.g., words ending in “-ust,” which are always pronounced /ʌst/ [e.g., must, bust, trust, lust, or crust]). The model encountered difficulty (reflected in prolonged reading latency) only with low-frequency words, and only to the extent that it had learned different, competing pronunciations of the same orthographic sequence. Thus, it was slow to read “pint,” because in every case but “pint,” the sequence

³ This is a highly effective but entirely heuristic means of training PDP networks. Real neural networks learn by completely different mechanisms, some of which will be discussed later in this chapter. Understanding the details of mechanisms underlying knowledge acquisition by the cerebral cortex currently poses one of our greatest neuroscientific challenges.

“int” is pronounced /*Int*/ (e.g., mint, tint, flint, or lint). It also was slow (but not quite so slow) to read words like “shown,” because two equally frequent alternatives exist to the pronunciation of “own” (e.g., gown, down, and town vs. shown, blown, and flown). It was very slow with words that are unique in their orthographic-phonologic sequence relationship (e.g., aisle, guide, and fugue). These behaviors precisely recapitulate the behavior of normal human subjects given reading tasks.

To be more precise, the knowledge the model acquires reflects competing effects of type frequency and token frequency. If a single word is sufficiently common (high token frequency), the model acquires enough experience with it that competing orthographic-phonologic sequential relationships have a negligible impact on naming latency. If a word is relatively uncommon (e.g., pint), however, its naming latency will be significantly affected by the knowledge of other words that, although equally uncommon, together belong to a competing type (e.g., mint, flint, tint, or sprint).

The capacity of the model to read nonwords reflects its ability to capture patterns in the sequential relationships between orthographic and articulatory word forms and to apply this knowledge to novel word forms. Plaut and colleagues (1996), as well as Seidenberg and McClelland (1989) in their earlier work on this reading model, focused on differences in rhyme components of single-syllable words (the nucleus plus the coda [e.g., *bat*]), because these are the major determinants of whether a word is orthographically regular (e.g., mint) or irregular (e.g., pint). As Seidenberg and McClelland point out, however, the network architecture in these models is capable of capturing any kind of regularity in the orthographic and phonologic sequences to which it is exposed, limited only by the extent of exposure. Such regularities would include joint phonemes other than rhymes (e.g., “str-” of stream, street, stray, and strum) and, in a multi-syllabic version, syllables and morphemes (affixes and the root forms of nouns and verbs as well as functors [e.g., articles, auxiliary verbs, conjunctions, and certain prepositions]).

The acoustic-articulatory motor pathway in the model of Figure 26-1 would capture analogous patterns in the sequential relationships between acoustic and articulatory word forms (actually somewhat more redundant, because in English, acoustic-articulatory correspondences are substantially more consistent than are orthographic-articulatory correspondences). These sequential relationship patterns potentially involve sequences of varying length, from phoneme pairs (joint phonemes) and syllables up to and including whole words and, possibly, multi-word compounds. These patterns represent the repository of knowledge about subword (sublexical) entities in general as well as our knowledge of phonotactic constraints (the rules that determine whether a given phonologic sequence is permissible in a particular language). This repository of

sequence knowledge also provides the basis for “neighborhood” effects (Vitevitch, 1997), which reflect the influence of variously competing pieces of sequence knowledge on the ultimate phonologic sequence selection and are demonstrated in the tendency to produce near-miss phonologic sequence errors that correspond to one of the close neighbors.

Lexicons

Understanding the meaning of a word that is heard is achieved through the connections between the domain that contains the sound features of language and the domain that contains concept features (the acoustic-concepts representations pattern associator; see Fig. 26-1, pathway 6-5). This pattern associator network corresponds to the cognitive neuropsychological concept of a phonologic input lexicon (Ellis & Young, 1988). It contains neither knowledge of acoustics nor knowledge of semantics—it serves only to translate a representation in the acoustic domain into a representation in the concepts/semantics domain, where meaning is instantiated. This conceptualization of a lexicon as a vast number of connections between two network domains, although well accepted in the connectionist literature, is not intuitive and, in fact, is strongly at odds with traditional conceptualizations of lexicons as repositories of abstract local representations of single words. It begins to make sense, however, when one recalls that all representations in the central nervous system are distributed (e.g., the “kitchen” representation), not local, and that the knowledge underlying the capacity to generate a representation lies in connection strengths and is not a piece of data at a memory location (as in a digital computer).

The knowledge that enables a person to translate a concept into a spoken word (the phonologic output lexicon) (Ellis & Young, 1988) is contained in two different pattern associator networks that connect the concept representations domain to the articulatory motor domain (Fig. 26-1, pathways 1-2 and 4-3). These two pattern associator networks support different forms of knowledge. The indirect concept representations–articulatory motor pathway (Fig. 26-1, pathway 4-3) provides a robust basis for knowledge of sequences and sublexical entities because of the sequence knowledge stored in the acoustic-articulatory motor pattern associator. The direct concept representations–articulatory motor pattern associator (Fig. 26-1, pathway 1-2) does not, however, contain much knowledge of sequences and sublexical entities, because it translates spatially distributed patterns of activity corresponding to concepts into temporally distributed sequences of activity corresponding to articulated words. This spatial-temporal translation precludes significant acquisition of sequence knowledge and makes this fundamentally a whole-word pathway. The existence of this direct, whole-word naming route finds support in studies of

subjects with repetition conduction aphasia⁴; some appear to have lost most phonologic sequence knowledge (Fig. 26–1, pathways 3, 4, and 7), resulting in a severe deficit in auditory verbal short-term memory, but can speak quite well, producing few, if any, phonologic paraphasic errors; can repeat real words (with evidence of influence by semantic attributes but little influence of word length); and are severely impaired in repeating nonwords and functors (Caramazza, Basili, Koller, & Berndt, 1981; Friedrich, Glenn, & Marin, 1984; Saffran & Marin, 1975; Warrington & Shallice, 1969). It also finds some support in reports of subjects with conduction aphasia who are able to repeat words better than nonwords (Caramazza, Miceli, & Villa, 1986; Friedrich et al., 1984; McCarthy & Warrington, 1984; Saffran & Marin, 1975) and who are able to repeat words better when they are given in a sentence context than when given as a single word, thereby increasing the likelihood of engaging concept representations (McCarthy & Warrington, 1984). A model in which the only link from the concept representations domain to the articulatory motor domain is the direct one (Fig. 26–1, pathway 1-2) cannot account for observations that normal subjects exhibit phonologic slips of the tongue, and subjects with aphasia produce phonemic paraphasias in naming and internally generated spoken language quite comparable to those produced during repetition. To explain these observations, one must posit access from concept representations to phonologic sequence knowledge, as indicated in pathway 4-3 of the model (Fig. 26–1). Thus, this PDP model predicts that two pathways should be enabling the naming of concepts.

Further evidence of two pathways supporting naming of concepts has been provided by a subject who, depending on the type of verbal cue provided, could be induced to use either the whole-word (direct) naming route or the phonologic (indirect) naming route (Roth et al., 2006). This left-handed subject had a Broca's aphasia stemming from a massive infarct involving the entire left middle cerebral artery territory. His language was largely limited to single words, which he produced quite readily and with good articulation. He tended to pursue a semantic *conduite d'approche*, which, however, was successful only approximately 10% of the time. He made very rare phonologic paraphasic errors. When asked to name an object, such as a faucet, and given either no cue or a semantic cue, a typical response would be "dishes . . . chairs . . . dishwasher . . . shut . . . water . . . ready to go . . . water . . . shut . . . hot . . . old . . . sink . . . water . . . heavy . . . water . . . heavy . . . washer . . . tub." When given the phonemic cue "faus," however, he replied "fauwash . . . fau . . . fau . . . fauswah . . . thafaush . . . fallshine . . . fallsha . . .

fallshvine . . . fallswash . . . fallsh." These patterns of response to bedside testing suggested that he normally used a whole-word route to confrontation naming (as well as in internally generated language; see Fig. 26–1, pathway 1-2) but that by providing him with a phonemic cue, we could induce him to employ a phonologic route—a route that engaged sublexical representations implicit in his stores of phonologic sequence knowledge (Fig. 26–1, pathway 4-3). He actually was able to successfully name objects 30% of the time using this pathway, but at the cost of producing large numbers of relatively undesirable nonword errors. The dual-route naming hypothesis was further tested and validated with systematic cued naming studies.

Lexical-Semantic and Phonologic Impairment in Aphasias

At this point, we have fleshed out the essential components of the model. One might reasonably ask, how can this model account for the lexical-semantic and phonologic features of subjects with various types of aphasia and, in turn, how can the model be reconciled with what is known about correlations between lesion locus and aphasia type?

Phonologic Paraphasic Errors

Phonologic paraphasic errors generally are thought to reflect damage to dominant hemisphere networks supporting phonologic processing. In our model, this would correspond to the dominant hemisphere acoustic-articulatory motor pattern associator network (Fig. 26–1, pathway 7-3)—the repository of phonologic sequence knowledge. Nonpropositional spoken language, which often is supported by the nondominant hemisphere (Speedie, Wertman, Ta'ir, & Heilman, 1993), does reflect sequence knowledge, but discrete phrasal, lexical, or sublexical elements of this knowledge cannot be selected at will, however, as they can in propositional language processing. The subject described in the foregoing (Roth et al., 2006), who could be cued to use one or the other of the two concept-naming routes (Fig. 26–1, pathways 1-2 or 4-3), provides new insight regarding the neural basis of phonologic paraphasic errors. His left hemisphere was nearly completely destroyed. Thus, he must have been speaking with his right hemisphere, which was undamaged, and his performance when naming after phonemic cueing suggests that he was using discretely accessible phonologic sequence knowledge represented in his right hemisphere. This suggests, in turn, that deficient development of networks instantiating this knowledge (as contrasted to damage to fully developed networks) can provide an alternative basis for phonologic paraphasic errors.

Factors Influencing the Pattern of Errors in Internally Generated Language

In the two-route naming model we have introduced, three factors may influence the pattern of errors observed in internally generated spoken language in perisylvian aphasias (and

⁴A conduction aphasia, originally described by Warrington and Shallice (1969), in which subjects have very limited ability to repeat, have severe impairment in auditory verbal short-term memory, and make few, if any, phonologic paraphasic errors. It can be contrasted with reproduction conduction aphasia, in which subjects often make profuse phonologic paraphasic errors in repetition and, usually, in production and have variable but sometime negligible deficits in auditory verbal short-term memory.

whether this pattern is marked exclusively by impaired word retrieval or, additionally, by phonemic paraphasic errors). First, given the likely anatomical representation of the network shown in Figure 26–1, most dominant perisylvian lesions probably damage both the whole word and the phonologic output routes (Fig. 26–5), and the pattern of spoken output may reflect the relative degree to which these two-pattern associator networks are affected. This would explain why subjects with Wernicke’s or conduction aphasia apparently do not have the option of relying entirely on the whole-word route. Second, these two output pattern associator networks likely are differentially represented in the two hemispheres, with the phonologic pathway being more frequently better developed in the dominant hemisphere and the whole-word path-

Figure 26–5. Cartoon depicting the network of Figure 26–1 mapped onto the brain. Color coding is the same as in Figure 26–1. Concept representations are assumed to be widely distributed across association cortices throughout the brain. In this cartoon, only the region of presumed interface between concept representations and the remainder of the model is depicted. Given the paucity of information about the anatomical organization of the human perisylvian region, the mapping depicted here is, at best, approximate; our goal is primarily to demonstrate the feasibility of mapping a connectionist architecture of phonologic processing to cortical anatomy. Recent magnetic resonance imaging–diffusion tensor imaging tractographic studies of deep white matter pathways, however, are shedding some light on the anatomical details. Catani, Jones, & Fytche (2005) have delineated two dominant perisylvian pathways linking Wernicke’s and Broca’s areas: a direct one, corresponding to the arcuate fasciculus (possibly corresponding to pathway 3 in our model), and an indirect one, projecting from Wernicke’s area to the inferior parietal cortex (Brodmann’s areas 39 and 40), with apparent relay to Broca’s area via what likely is component III of the superior longitudinal fasciculus (Makris et al., 2005) (possibly corresponding to pathway 1-2 in our model). They concluded that the broad extent of origin and termination of these pathways and their large cross-sections favored a connectionist account. (From Roth, H. L., Nadeau, S. E., Hollingsworth, A. L., Cimino-Knight, A. M., Heilman, K. M. (2006). Naming concepts: Evidence of two routes. *Neurocase*, 12, 61–70; with permission.)

way more equally developed in the two hemispheres. Subjects with dominant hemisphere lesions almost invariably demonstrate impaired—if not completely absent—phonologic sequence knowledge but often exhibit partial sparing of lexical-semantic knowledge. Studies of subjects with callosal disconnection demonstrate that the disconnected right hemisphere has a phonologic input lexicon and conceptual semantic knowledge but impoverished phonologic processing (Zaidel, Iacoboni, Zaidel, & Bogen, 2003). Third, there may be individual variability in the degree to which connectivity is developed in these two output routes, and this individual variability may vary as a function of hemisphere. Thus, to understand fully language production following a left hemisphere lesion, a bihemispheric language model that incorporates both developmental attributes and the impact of the lesion must be considered (Fig. 26–6).

As the case of Roth et al. (2006) suggests, in the presence of an extensive left hemisphere perisylvian lesion, deficient development of connectivity in nondominant hemisphere concept representations may lead to the generation of anomia and semantic paraphasic errors, and deficient development of connectivity in the nondominant hemisphere phonologic route may lead to the generation of phonemic paraphasic errors. The deficient development of both systems, particularly the phonologic one, may be a general characteristic of the right hemisphere, but deficient development of the phonologic

Figure 26–6. Cartoon depicting mapping of a bi-hemispheric model to the brain. This provides the basis for a fuller explanation of the results of left hemisphere lesions on language output in terms of bi-hemispheric contributions, the effect of the lesion, and the degree to which various networks are developed in each hemisphere. Color coding is the same as in Figures 26–1 and 26–5. HU = hidden units. (From Roth, H. L., Nadeau, S. E., Hollingsworth, A. L., Cimino-Knight, A. M., Heilman, K. M. (2006). Naming concepts: Evidence of two routes. *Neurocase*, 12, 61–70; with permission.)

route also may occur, to one degree or another, in the left hemisphere as a result of normal variability in phonologic network ontogenesis (Goodglass, 1993; Plaut et al., 1996).

In summary, with any given left hemisphere lesion, the actual pattern of internally generated spoken language may reflect three factors:

1. The effects of the lesion on the two output routes (phonologic and whole word).
2. The degree to which one or both of these routes is represented in the right hemisphere.
3. The degree of development of connectivity in each of the two routes in the two hemispheres.

If both naming routes are involved and the combined effect of the three factors differentially impacts the phonologic routes, the net result will be output marked predominantly by word retrieval deficits (with or without semantic paraphasic errors) as whole-word routes become the predominant means of language production (as in repetition conduction aphasia). If whole-word routes are differentially impacted, the net result will be output marked by word retrieval deficits and a substantial incidence of phonemic paraphasic errors as damaged or inadequately developed phonologic routes become the predominant means of language production.

Subjects with reproduction conduction or Wernicke's aphasia predominantly use damaged or inadequately developed phonologic pathways. Wernicke's aphasia may reflect more severe impairment and, hence, greater difficulty with word retrieval and more profuse phonemic paraphasic errors than with conduction aphasia. Subjects with Wernicke's aphasia also may have damage to acoustic representations or the acoustic representations–concept representations pathways that enable verbal comprehension. Naming difficulty may arise through mechanisms discussed in the preceding paragraph or in two additional ways. First, damage to Brodmann's areas 37 and 39 in the dominant hemisphere may be associated with word retrieval deficits (Chertkow, Bub, Deaudon, & Whitehead, 1997; Hart & Gordon, 1990; Raymer et al., 1997; Whatmough, Chaertkow, Murtha, & Hanratty, 2002). These areas may constitute the interface between association cortices throughout the brain supporting concept representations and the core language apparatus (proximal to the point at which the phonologic route provides differential access to sequence knowledge). Second, dysfunction of conceptual (semantic) networks because of left hemisphere damage and deficient development of right hemisphere networks, as in our subject, would be expected to yield naming difficulty with production of semantic paraphasic errors.

Processes Occurring During Recovery

The dual-route naming model, as elaborated in the foregoing, also can account for the patterns of evolution of internally generated spoken language observed during recovery.

First, recovery of connectivity in the dominant hemisphere phonologic route (or enhancement of deficient connectivity in phonologic routes in either hemisphere) would lead to increased naming success and a reduction in phonemic paraphasic errors. Second, because articulatory motor representations normally depend on input from both the whole-word and phonologic routes for activation, damage to either route could lead to anomia as representations fail to reach threshold for activation (a diaschisis effect).⁵ Changes may occur in the connectivity within articulatory representations or in surviving connectivity within the two naming routes such that this diaschisis effect diminishes with time. Third, in normal brain development, neural network connectivity in the two hemispheres presumably evolves such that transcallosal pathways facilitate coordinated bihemispheric activity and do not impede independent unihemispheric activity. A lesion may disrupt this precise inter-hemispheric coordination (another form of diaschisis), potentially rendering transcallosal input dysfunctional until appropriate readjustment of connectivity within and between hemispheres occurs in the course of recovery. With such readjustment, word retrieval may improve as the nondominant whole-word route achieves a progressively greater transcallosal impact on dominant hemisphere spoken language output. Finally, because phonemic paraphasias have such an invidious effect on communication, subjects like the one described by Roth et al. (2006), to make themselves more readily understood, may be able to learn a strategy of using only the whole-word route and of semantically “boxing in” the concept they are trying to convey.

Why PDP Models?

Below, we will extend the model to account for grammatical function. Before doing so, however, we will briefly review particularly important features of PDP models in general and the model of phonologic, semantic, and lexical-semantic function that we have developed, because these have strong implications for the function of the model and provide major support for the application of PDP models to the under-

⁵ Diaschisis, a concept first elaborated by von Monakow (1914), constitutes transient dysfunction of undamaged brain regions that are connected to the focus of brain damage. For example, subjects with acute middle cerebral artery (MCA) distribution strokes affecting a large extent of the dorsolateral frontal lobe often will exhibit an overwhelming tendency to direct their eyes (gaze) toward the side of the lesion and cannot be induced to look toward the opposite side. This reflects dysfunction of the frontal eye field because of diaschisis. The frontal eye field rarely is damaged by MCA distribution infarcts; however, it receives enormous, mainly excitatory input from brain regions supplied by the MCA. With the acute stroke, it no longer receives this excitatory input. Consequently, no input from other brain regions can bring the neurons in the frontal eye field up to the firing threshold. With time and neuroplasticity, these neurons adjust, and gaze substantially normalizes, typically within days.

standing of language and aphasia. Having fleshed out a concrete example of a PDP model of language, it is reasonable to take a moment to ask, why this particular approach?

Limitations of Existing Theories

Linguistic theories have not yet provided a satisfactory account for the language errors made by normal subjects or the language disorders observed in subjects with aphasia. Three major reasons can be identified:

1. Linguistic theories have been founded on the concept of serial processing, whereas abundant data suggest that language production incorporates parallel processing (Stemberger, 1985).

2. These serial processing-based theories of linguistic function have difficulty capturing effects that are easily explained by bottom-up and top-down processing interactions (Table 26-1) that are an intrinsic attribute of many PDP models (including ours), such as the occurrence of paraphasias (speech errors) that have both semantic and phonologic similarity to the target (Dell & Reich, 1981; Dell, Schwartz, Martin, Saffran, & Gagnon, 1997; Harley, 1984).
3. Linguistic theories have failed to account for how linguistic behavior might emerge from neural structure.

Cognitive neuropsychological theories incorporate, to one extent or another, information processing models—the “box and arrow” models that date back to Wernicke and

TABLE 26-1

Properties of Parallel Distributed Processing (PDP) Networks

The knowledge is in the connections.

In simulated PDP models, knowledge is represented as the strength of the connections between units. In the brain, knowledge is represented as the strength of synaptic connections between neurons.

A network supports processing, working, and long-term memory.

Like neural networks in the brain, PDP networks support the processes underlying all cognition and behavior. In both PDP and neural networks, working memory corresponds to a transient network pattern of unit/neural activity or partial neural depolarization (a mechanism not yet tested in PDP research). Long-term memory (i.e., knowledge) is represented as the sum total of unit or neural connection strengths in the network.

Hidden units plus non-linearity support associations between orthogonal representations.

Both PDP and neural networks can translate representations in one domain into arbitrarily related representations in another, connected domain. For example, concept representations, corresponding to knowledge of word meaning, can be translated into spoken word representations.

Distributed representations bring with them several powerful emergent features.

Content-addressable memory

With distributed representations, engagement of a feature of a particular memory can generate the distributed representation of the entire memory. In contrast, in digital computer models, the address of a memory must be known to retrieve that memory.

Graceful degradation

Both PDP and neural networks can perform at close to normal levels with substantially degraded input, in part because of their ability to settle into attractor states and in part because of bottom-up/top-down processing effects (see below). Both PDP and neural networks demonstrate the same general patterns of performance even when damaged, because knowledge is represented throughout the network and because partial damage only reduces the redundancy of the knowledge and increases the probability of error or non-response.

Inference, generalization, and confabulation

Both PDP and neural networks naturally encode the commonalities and patterns that are implicit in the information to which they are exposed during training, thereby instantiating implicit rules. These rules can then be usefully applied to situations that have never been encountered before but that bear a resemblance to what has been experienced. The knowledge gained during training thereby generalizes. Performance based on the acquisition of implicit rules reflects the inference that the rules apply in a new, yet-to-be-experienced situation. If the rules do not apply, then the response can be characterized as confabulation.

Bottom-up and top-down processing.

Through repeated upward and downward flow of unit/neural activity between input networks and higher-order networks (e.g., from networks supporting visual representations of orthographic input to networks supporting semantic representations), neural network systems settle into states that represent the optimal amalgamation of incoming information and existing knowledge. This enables simultaneous (but likely compromised) satisfaction of constraints provided by a multitude of different neural networks (e.g., phonologic, lexical-semantic, semantic, and syntactic—a process called parallel constraint satisfaction). It enables valid perception despite very noisy input. It also, however, carries the risk of misperception of a near-miss input as the correct input (leading, e.g., to our tendency to overlook editorial errors when proofreading).

Lichtheim. As we have seen, PDP models may be entirely consistent with information processing models with respect to the topography of processes involved—in this case, language. What PDP models provide as an added value is specificity regarding the nature of the representations in the boxes and the nature of the processes symbolized by the arrows, about which information processing models are agnostic.

PDP Models Emulate Brain

PDP models are “neural-like” in that they incorporate large arrays of simple units that are heavily interconnected with each other to form networks, like neurons in the brain (McClelland, Rumelhart, & PDP Research Group, 1986; Nadeau, 2000). Their processing sophistication stems from the simultaneous interaction of the large numbers of units (hundreds or even thousands) in these arrays. In PDP models, memories are represented as connection strengths in the same networks that support processing, just as in the brain. Thus, in PDP models of language, memories of language units (e.g., stored knowledge of phonemes, joint phonemes, syllables, words, and sentence constituents) are represented in the same neural networks that support linguistic processing. In PDP models, working memory also is represented in the same networks that support processing, as transient patterns of neural bias or firing (again, just as in the brain). The incorporation of working- and long-term memory in the same neural networks that are responsible for processing, in conjunction with processes underlying the engagement of working memory (Goldman-Rakic, 1990), eliminates the need to posit separate buffers, which are a digital computer concept. PDP models are particularly appealing in the context of language processing, because they involve simultaneous processing at a number of levels and locations, apparently mimicking what is going on in the brain (something that will become more apparent when we consider grammatical function). Finally, pure PDP models (models without incorporated digital devices), endowed with learning algorithms, can implicitly learn the rules governing the data they process in the course of their experience with that data (see, e.g., Plaut et al., 1996). In fact, they are nonpareil in extracting commonalities and patterns in the data, which form the basis for implicit rules. Thus, for example, a pure PDP model of phonology has no need to build in specific structures to account for specific phonologic phenomena. The structure of the model is defined entirely in terms of the domains of information accessible to it and the necessary topographical relationship of these domains to each other. The model learns the rest. The absence of specific, ad hoc devices motivated by models (e.g., linguistic) designed to account for particular phonologic phenomena in an orderly fashion also is crucial to the maintenance of neurologic plausibility (architectural faithfulness to neural structure). In humans, as in neurally plausible PDP models, the linguistic

phenomena we observe reflect entirely the emergent behavior of the networks.

PDP models can easily be endowed specifically with properties that emulate brain structure and function. For example, the model shown in Figure 26–1 incorporates two-way connections (the general pattern in the cerebrum), and this two-way connectivity is what enables top-down/bottom up interaction effects. These effects are enormously beneficial in enabling us to extract meaning from extraordinarily degraded input (e.g., much of the spoken language that we hear), because the input only has to be sufficiently informative to partially activate the correct target distributed representation. This target then provides top-down activation of lower-level units contributing to its activation, which, in turn, amplifies the bottom-up activation of the target. Of course, this feature can have invidious effects as well. Our great difficulty in eliminating all typographical errors from manuscripts stems from the fact that bottom-up/top-down interaction effects are quite literally leading us to see what we intended rather than what is actually there. Bottom-up/down-down interaction effects provide a powerful explanatory mechanism for many linguistic phenomenon (Dell, 1986; Dell et al., 1997; McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982).

Another useful property that can be built into PDP models is recurrent connections (as in the model shown in Fig. 26–1, symbolized by the loops at concept, articulatory motor, and acoustic representations). This feature, which also is neurologically plausible, enables the network to deal with the situation that arises when a pattern of input does not precisely correspond to one of the patterns on which the model was trained, either because the input pattern is novel or because the input is noisy. In such circumstances, a model without recurrent connections might generate a pattern of activity in the output representational field that does not correspond to any recognizable entity. Clearly, the brain has the capability for creating meaning for novel distributed representations. Equally clearly, however, we derive great advantage from the ability to translate very noisy and degraded input into something we recognize, as discussed in the context of bottom-up/top-down processing effects. This ability corresponds to a network capacity for adjusting near-miss distributed representations until they correspond to the nearest meaningful representation.⁶ This capacity is achieved by creating connections between every unit within the representational field and every other unit in that field. The field is thereby transformed into what is referred to as an “auto-associator network,” which is a network that tends to settle into stable states corresponding to meaningful dis-

⁶ “Nearest” corresponds literally to the distance in n -dimensional space between the near-miss and the closest meaningful distributed representation, where n is the number of units in the representational field and “meaningfulness” is defined by the knowledge structure, latent in the network, that was acquired during the training period.

tributed representations as defined during the training period (Rumelhart et al., 1986). This feature gives the entire network what are called “attractor” properties, referring to the tendency of the network to settle into or be “attracted to” particular stable states. Attractor properties convey another very useful property in computer simulations of network behavior—that is, the time that it takes a network to “settle” into an attractor state corresponds to the response latency of that network. In this way, the attractor feature endows the network with a performance measure—namely, response latency—that precisely coincides with one of the most common dependent variables used in behavioral studies of human subjects.

PDP models provide us with the means to understand how complex behavior might emerge from neural networks, which now are accepted as the fundamental unit of cortical function (Buonomano & Merzenich, 1998). Before this approach to understanding the brain was developed, behavioral neurologists, cognitive neuropsychologists, and linguists had to accept as a matter of faith that someday, somehow, the discoveries they were making could be linked directly to neural structure. For many of us, it is stunning that this dream has been realized in our lifetime. No model represents a final answer to how the brain handles a domain of cognitive function. Rather, a particular model represents a specific hypothesis about the topographic organization of neural processes underlying a given function and the mathematical properties of the units and connections comprising the neural networks involved. It presumes the now well-established faithfulness of the PDP concept to the essential features of neural network processing, and to the extent that it successfully replicates behavior of human subjects in health and disease, it accommodates empirical data on brain function. The dialectic in the PDP literature between principles of neural network topography and mathematical function on the one hand and empirical data on language behavior on the other has proven to be a particularly fruitful one in advancing the science of language and the brain.

The Heuristic Value of PDP Modeling

The appeal of PDP modeling also derives from the fact that simulations of particular models can be run on computers, leading to the generation of vast amounts of data that can then be compared with data derived from experimental studies in animals and human subjects. It is even possible to systematically vary one or more parameters in a particular model and, thereby, generate a population of PDP “individuals” who can be simulated, thus providing a foundation for group statistics. PDP simulations have been extraordinarily successful in replicating the behavior of normal human subjects, as in the PDP reading model of Plaut and colleagues (1996; see also Seidenberg & McClelland, 1989). Simulations involving “lesioned” PDP models also have been extraordinarily successful in emulating the behavior of human subjects with

brain injury (Cohen, Johnston, & Plunkett, 2000) and even in simulating the effects of rehabilitation (Plaut, 1996).

A Paradigm Shift

PDP models invoke a scientific and philosophical paradigm shift in that they reflect chaotic order rather than deterministic order. Chaotic order (Gleick, 1987) is system order deriving from the orderly behavior of the individual units of the system, whereas deterministic order reflects the impact of an overall guiding force or principle.⁷ Neural network brains, whether in *Drosophila* (100,000 neurons) or in human beings (100 billion neurons), also operate by chaotic principles. Because in PDP order emerges naturally from network properties and topography rather than being defined primarily by the structure of the model, neurologic plausibility replaces the goal of choosing the simplest of competing theories (i.e., Occam’s razor) as the guiding force in the design of these models (see O’Reilly, 1998). Although the precise details of the organization of neural networks in the brain still largely elude us, it now is quite clear and well accepted that the brain incorporates PDP principles, and the related scientific field, computational neuroscience, is burgeoning (Rolls & Deco, 2002; Rolls & Treves, 1998).⁸

⁷ Examples of chaotic order include the ornate structure of a flower and the marvelous computational machine that is the human brain; they reflect the order that emerges from the precise behavior of individual cells interacting with each other. Deterministic order is exemplified by the movement of planets in the solar system (and the satellites that we send to them), which can be explained entirely by equations that characterize the force of gravity and its effect on mass.

⁸ The only major departure of neural network theory from PDP theory is that the former seeks to apply exclusively local learning processes, whereas PDP simulations employ predominantly heuristic devices that are, for the most part, not local. The prototypic example of a local learning process is Hebbian learning, named after Donald Hebb, who first elucidated the concept (Hebb, 1949). Hebb postulated that to the extent that two connected neurons are simultaneously active, the strength of the synaptic connection between them will increase. This concept has since been validated in extensive research on long-term potentiation (Buonomano & Merzenich, 1998). This work has also revealed evidence of a reciprocal process, long-term depression, which occurs to the extent that the activity of connected neurons is discrepant. Hebbian learning is intrinsically local and therefore eminently plausible neuroscientifically. It requires only a peculiar neurotransmitter receptor such as the NMDA-glutamate receptor, which functions as a detector of the coincidence of high activity of the post-synaptic neurons (reflected in a depression in membrane voltage) and high activity of the presynaptic neuron (reflected in large amounts of glutamate released from the presynaptic axon terminal). In contrast, the most common learning algorithm employed in PDP simulations is back propagation, which requires a change in the strength of inter-unit connections based upon events occurring at the output end of the network, which could be many synapses away. This intrinsically non-local learning algorithm is biologically implausible but it remains possible that some non-local learning processes are instantiated in the brain (O’Reilly, 1996). Nevertheless, there do not appear to be any fundamental scientific impediments to the realization of the language model we develop incorporating a local learning process.

Grammar

We now resume our discussion of PDP and language, extending the model to incorporate a basis for grammatical function. For purposes of discussion, we will break grammatical function down into syntax and grammatical morphology. Syntax is knowledge of acceptable word order and sentence structure. Grammatical morphology refers both to the modifications of words that are made in their use in sentences (bound grammatical morphology [e.g., affixes conveying case, number, or tense]) and to the use of individual words that, at least superficially, appear to primarily serve sentence composition rather than meaning (free grammatical morphemes [e.g., articles, auxiliary verbs, conjunctions, and certain prepositions]). We will break syntax down into (1) *sentence organization*, which encompasses such things as the necessary relationships between verbs and nouns or noun phrases in a sentence (verb argument relationships; see below), embedded clauses, and passive voice constructions and (2) *phrase structure rules*, which constrain word order at the local level (e.g., the rule that constrains articles to precede nouns). In Chomskian thinking, both of these components of syntax are thought to arise from the operational principles of a grammar generator. In contrast, we will argue that principles of sentence organization follow directly from the way in which the brain manipulates concept representations and that phrase structure rules and rules of grammatical morphology are an emergent property of the pattern associator networks responsible for articulatory and inscrip-tional (written) output.⁹

Syntax: Sentence Organization

It is easy to conceive of spoken, concrete nouns as being the product of distributed representations of concepts that are linked, through pattern associator networks (Fig. 26-1, pathways 1-2 and 4-3), to articulatory motor representations and, ultimately, to networks that support the sequences of oropharyngeal movements that actually produce the speech sounds of the noun, as discussed in the section on phonology. The same cannot be said about other types of words, most particularly adjectives, verbs, and abstract nouns.

Adjectives represent the simplest case and, therefore, are a reasonable place to start. In principle, the distributed representations corresponding to noun concepts are infinitely malleable. We can easily modify the general distributed representation of “dog” to capture any species of dog or any particular dog we have personally known. We can easily

contemplate the most complicated and arbitrary of distributed representations, such as “the obese, pockmarked, oily-haired, slovenly, unctuous, check-shirted, plaid-jacketed man with the striped pants, food-stained paisley tie, goatee, wire-rimmed glasses, bundle of pens in his pocket, and clip board in his hand”—a sort of Uriah Heep cum used-car salesman. The process of pairing one or more adjectives or adjectival phrases with a noun corresponds to a particular modification of the distributed representation of the noun.

Verbs are viewed as the work masters in traditional linguistic formulations, because they specify the major participants in the action that is described by the verb, thereby defining sentence structure. These participants are called the arguments of the verb. Arguments usually are noun phrases but also may be prepositional phrases, adjectival phrases, and sentential clauses. They fill argument positions (e.g., subject, object, and indirect object positions). Each argument is assigned a purpose in the sentence by the verb, referred to as its “thematic role.” For example, the agent is the perpetrator of the action (“The *man* gave flowers to Mary”), the theme is the object of the verb’s action (“flowers” in the preceding sentence), and the goal is the recipient of the action (Mary). Verbs differ with respect to the arguments they specify—some require only an agent; some an agent and a theme; others an agent, theme, and goal—and many verbs allow some freedom in choosing whether to include a certain argument. They also differ with respect to the nature of the arguments they can specify (e.g., “knew” easily accommodates a sentential clause in the predicate, e.g., “He knew Mary would arrive soon,” whereas “hit” does not).

Does the argument specification property of verbs provide direct insight regarding the cerebral processing of verbs? To date, no one has succeeded in answering this question using a traditional linguistic formulation. How might a verb be represented in PDP terms? First, consider what might be the distributed representation of a verb, such as the verb “to shoot.” What features underlie this distributed representation? A problem is immediately apparent. Our conceptualization of “shooting” actually consists of the juxtaposition of two distributed concept representations: a person who is the shooter, and a person who has been shot or is about to be shot. The sentence “the old man shot the burglar” generates two distributed concept representations: one of an old man appropriately altered to incorporate the act of shooting, and the second of a burglar appropriately altered to incorporate the fact of having been shot. Thus, “shot” achieves its meaning not through the generation of its own distributed representation but, rather, through the elicitation of two reciprocally modified distributed representations (“old man shooter” and “shot burglar”) that, in addition, are meaningfully linked, in effect constituting a composite, “super-distributed” representation that incorporates the entire shooting scene. The two components of this composite representation are implicitly linked by their complementarity (shooter and

⁹ Although the ideas proposed here are fundamentally at odds with traditional linguistic formulations, any consideration of language and the brain, including PDP, must rely heavily on the extraordinarily rich and detailed information that linguistic studies have provided about regularities in the phenomenology of languages.

shot) and their simultaneity. They become explicitly linked when this particular reciprocal pair of distributed representations generates a pattern of activation in articulatory motor cortex that will produce the sound sequence corresponding to the sentence. They also may become explicitly linked when a pattern of activity in acoustic cortex, generated by the sound of the sentence being produced by a speaker, leads to production of the reciprocal pair of distributed concept representations underlying “old man shooter” and “shot burglar.”

Intransitive verbs function in a fashion essentially identical to adjectives (e.g., “the soldier salutes”). A transitive verb functions as a sort of super-adjective, reciprocally modifying the distributed representations of the concepts underlying the two or three noun phrases in the sentence and at the same time, linking them to form a new, super-distributed representation. Thus, in our new conceptualization, verbs are defined exclusively by the effect that they have on the distributed representations of the nouns they constrain, which constitutes both their grammatical and their semantic roles, and on the pattern of activity in the phonologic processing network, which constitutes their lexical-semantic role.

Any volitional alteration in distributed concept representations constitutes *concept manipulation*. Thus, even use of adjectives or intransitive verbs, which serve to modify a single distributed concept representation, can be usefully viewed as concept manipulation and, as will be discussed below, will tend to be impaired in subjects with aphasia (e.g., Broca’s aphasia) that are associated with deficits in transitive verb use and argument structure. Production of the sentence “the old man shot the burglar” requires fairly symmetric manipulations of two distributed concept representations. Sentences employing adjunctive phrases, however, such as “Jones slept in the park,” may demand highly asymmetric manipulation of the two distributed concept representations. In this sentence, the “Jones” concept is the object of most of the modification, and the “park” concept is only very subtly modified. This asymmetry could be dramatically altered, however, by additional information neurally defined as additional distributed concept representations—for example, “Jones was apprehended as the murderer of nighttime joggers. He slept in the park during the day.”—in which case the distributed concept representation of park is substantially modified by its association with Jones the murderer.

The auto-associator network representation of a concept can be translated by the concept-articulatory motor pattern associator networks into any one of a number of different word sequences. The actual word sequence chosen will depend on several factors, including (1) the modifiability of the core distributed representation of the concept, (2) whether the modification occurs nearly simultaneously with the generation of the core distributed representation or at some later time, and (3) the availability of words to be elicited by the auto-associator network representation of the concept. To provide a sense of the concept manipulation

demands that are met by the normal brain, we will consider each of these possibilities in some detail.

Modifiability of the Core Representation

Consider the core representation of “burglar” in our previous example. “Old man shot burglar” is not likely to be a modification of the distributed representation of burglar that is readily available to us. Thus, we are forced to use a super-distributed representation to capture this concept—namely, a representation that therefore engages a verb (e.g., “The burglar that had been shot by the old man”). On the other hand, consider the concept of streets wet with rain. Here, the concept of “rain-wet streets” falls well within the various modifications of street that are readily available to us. Thus, we have a choice in expressing this idea. We can employ a single distributed representation, modified by an adjective, yielding “rain-wet streets,” or we can employ a super-distributed representation, thus engaging a verb (e.g., “The streets made wet by the rain”).

Simultaneous Versus Sequential Modification

Whether a modification of the distributed representation underlying a concept occurs as the concept is formed or sometime later is likely to influence the word sequence corresponding to that concept. Thus, someone viewing a romantic Parisian street in her mind’s eye might incorporate “rain-wet” from the beginning, favoring the verbal product “rain-wet streets.” On the other hand, the wetness modification might be conceptualized only after the street concept has been realized and verbalization has been initiated, hence “the car skidded on the street that was still wet from the rain,” “the car skidded on the street because the street was still wet from the rain,” or “The car skidded on the street. The street was still wet from the rain.” The way the sequence of conceptual development happens to emerge probably is not the only factor at play here. We may have the luxury of shaping the conceptual stream according to our intent to place emphasis or imply causality. On the other hand, working memory capacity may limit the number and complexity of modifications we can make in a distributed representation at one time, forcing us to use a narrative stream employing multiple clauses or sentences, each further modifying the original distributed concept representation.

The Availability of Words

Word representations corresponding to certain distributed concept representations may be completely unavailable, available but inappropriate to the context, or temporarily unavailable. Each of these circumstances would necessitate a clause construction in lieu of an adjectival construction. Thus, “rain-wet” might simply not be in a person’s vocabulary. Alternatively, it might be available but carry with it a

sense of inappropriateness to the context (possibly a limbic component to the distributed representation generated by the word in this context). Thus, “rain-wet” is satisfactory in a novel but would sound contrived in ordinary conversation and inappropriate in formal discourse. Finally, the word may be transiently unavailable because of the “tip-of-the-tongue” phenomenon, necessitating a circumlocutory clause or sentence to convey the concept.

In this way, the aspect of syntax that we have defined as sentence organization depends not on the machinations of a sophisticated language processor but, rather, constitutes an emergent property of the distributed representations of concepts, the modification of concepts, the linking of concepts into super-distributed representations, and the interaction of network systems defining concepts with the pattern associator networks defining language output. Concept representations and their manipulations invoke association cortices throughout the brain as well as subcortical structures, such as the amygdala. Therefore, the ways in which concepts are handled provide a window on the fundamental properties of higher brain function. The grammatical properties that are common to the vast number of languages spoken on our planet (the “universal grammar”) reflect the fact that, as a first approximation, the basic structure and function of the entire brain is the same in all human beings. On the other hand, because language production is a direct reflection of patterns of distributed concept manipulation, grammatical differences in language production may provide a window on cultural, genetic, and even individual differences in the way people think.

Disorders of Syntax

Two aspects of a common aphasia, Broca’s aphasia, are explainable on the basis of a breakdown in the processes we have just outlined. Broca’s aphasia commonly is characterized by two grammatical attributes: simplification of syntax, and a characteristic abnormality of grammatical morphology known as agrammatism—that is, the propensity for leaving out words of primarily grammatical importance, such as articles, auxiliary verbs, conjunctions, and to some extent, prepositions. These two aspects of Broca’s aphasia may be dissociated: A number of cases of morphologic agrammatism without simplification of syntax have been reported, and several cases of simplification of syntax without morphologic agrammatism have been reported (Nadeau, 1988; Nadeau & Gonzalez-Rothi, 1993). As we have noted, sentence production reflects the flexible modification and manipulation of the distributed representations underlying concepts. The simplification of syntax seen with Broca’s aphasia, including a paucity of embedded clauses and inability to use strings of adjectives (e.g., “big barn” or “red barn,” but not “big, red barn”), can be accounted for in terms of a defect in the ability to alter the distributed representations of single or

multiple concepts at will. This may be caused by a general inability to maintain selective engagement of the specific neural networks incorporating the featural basis for the concepts and their intended nuances. Consistent with this interpretation is the fact that subjects with Broca’s aphasia exhibit limited lexical priming (Prather, Zurif, Stern, & Rosen, 1992). By *selective engagement*, we mean the bringing online of selected representations in selected neural networks, either by eliciting sustained neural activity in those networks or altering the state of polarization of the neurons such that they are more susceptible to firing by other afferent input (see Chapter 19). Selective engagement is a general term that embraces the many processes by which the brain allocates resources, and it includes processes commonly referred to as working memory—the specific type of selective engagement we refer to here—as well as attention (Nadeau & Crosson, 1997). In normal subjects engaged in a lexical decision task, preceding a lexical target with a semantically related word reduces the time that is needed to determine whether the target is a word or a nonword. Seeing the semantically related word has led to the selective engagement of a number of semantically related distributed concept representations and their associated articulatory motor representations, one of which is the target. In subjects with Broca’s aphasia, the range and number of the distributed concept representations selectively engaged appears to be limited, with the result that speeding of lexical decision by semantic priming is less likely to occur.

Generating verbs also normally invokes a particular form of selective engagement to modify two or more distributed representations in reciprocal fashion and link them to form a super-distributed representation. It thus makes special demands on selective engagement mechanisms. Subjects with Broca’s aphasia exhibit relatively greater difficulty accessing verbs than nouns, and their production of verbs with complex argument structures is more impaired than their production of simple verbs (e.g., intransitive verbs) (Thompson, Lange, Schneider, & Shapiro, 1997)—further evidence of impairment in ability to simultaneously manipulate multiple distributed representations. Notably, the ability of subjects with Broca’s aphasia to produce verbs in tasks of picture naming, whether naturally or as a result of treatment (in our nomenclature, to use verbs as adjectives), does not translate into the ability to use verbs in sentences (i.e., to link and reciprocally modify distributed concept representations), a far more demanding skill (Mitchum & Berndt, 2001).

One of the most widely accepted theories regarding the fundamental deficit in Broca’s aphasia is referred to as the Mapping Deficit Hypothesis (Saffran & Schwartz, 1988; Saffran, Schwartz, & Marin, 1980; Schwartz, Linebarger, Saffran, & Pate, 1987). This hypothesis characterizes the deficit as an inability to produce ordered sentence components (e.g., noun phrase–verb–noun phrase) that reflect the underlying thematic roles (e.g., agent, theme, or goal) to

link sentence structure to meaning. Two components are identified: lexical, referring to argument information specified by verbs; and procedural, referring to operations governing thematic role assignment for sentences that require interpretation of structural cues (e.g., word order or verb morphology) to relate noun phrases as they literally appear in the sentence to underlying sentence meaning. For example, to understand who did what to whom in the passive-voice sentence “Joe was hit by John,” one must cue not just on word order but also on the auxiliary verb “was” and the preposition “by” (we will have more to say about such words below). These mapping capacities correspond quite directly to the capacities for distributed concept manipulation and association discussed in the foregoing. The advantage of the sentence organization hypothesis we have introduced is that it relates these functions directly to neural network processes.

Syntax: Phrase Structure Rules

One of the most remarkable attributes of words in spoken language is their consistent respect for phrase structure rules (e.g., articles always precede and never follow nouns). Only in the occasional patient with jargon aphasia does this rule seem to be broken, and even then, it is far from clear whether inappropriate sequences emerge in continuous discourse or result just by happenstance, from the juxtaposition of phrase fragments. Clearly, these immutable phrase structure rules reflect some very fundamental and redundantly represented attributes of cerebral language networks that govern word sequence. To gain some insight regarding such network properties, we return to the pattern associator model of single-syllable word reading developed by Plaut and colleagues (1996; see also Seidenberg & McClelland, 1989). Had the model been designed to accommodate multi-syllable words rather than only single-syllable words, we would have seen it acquire, simply from its experience with English vocabulary, sequence knowledge about syllables, polysyllables, root forms, and affixes as they combine to form words. This sequence knowledge incorporates the sequential relationship of these various sublexical phoneme clumps to each other—the lexical equivalent of phrase structure rules.

The inferential leap we make at this point is that sequential relationships *between words* also are represented in various neural pattern associator networks in the same way that sequential relationships between phonemes *within* words are represented. Most specifically, we need to posit that, for phrase structure rules to be represented in oral language output, there needs to be a pattern associator network encoding word sequence knowledge that parallels the acoustic-articulatory motor pattern associator supporting sublexical sequence knowledge, or that a single pattern associator network incorporates sequential knowledge of both sublexical entities and short phrases. This additional pattern associator

provides the basis for a link between distributed representations of concepts underlying words, characterized by the properties of their network representation (e.g., nouns, adjectives, or verbs, as we have discussed), with distributed representations of the articulatory forms of these words in proper sequence. In effect, it is a property-sequence transducer in which the systematic relationships between concept representation properties and articulatory sequences emerge as implicit knowledge through extended experience with heard and spoken language. At first, one is inclined to protest that, because the number of possible word sequences is virtually infinite, no system, even one comprised of tens of billions of units and involving combinatorial mathematics, could possibly represent all the possibilities. The actual amount of information relevant to word sequence that is implicit in all the allowable word sequences, however, is actually much less than it seems and quite plausibly is incorporated within neural connectivity. This is because word sequence information implicitly incorporates rules governing the order of *classes* of words, precisely as a multi-syllabic phonemic processor would implicitly incorporate rules about the placement of suffixes and prefixes. Thus, in English, words that have the attribute of modifying the distributed representation of a concept (adjectives) uniformly precede nouns and knowledge about the proper order of adjective-noun sequences simply emerges from the network’s experience with heard and written English. PDP networks can learn specific exceptional representations as well as patterns that are common to many representations. Thus, the reading model of Plaut and colleagues (1996) was able to learn to read such extremely exceptional words as “aisle,” “guide,” and “fugue.” By the same token, a word sequence network should be able to learn certain sequences with very few exemplars, such as those involving the placement of articles. In fact, because articles are among the most commonly encountered words in the language, the network would be expected to instantiate the sequential relationship between articles and nouns with particular redundancy.

How long are the word sequences that are likely to be entrained by the pattern associator network contemplated here? The answer is not known. Some evidence suggests that the length of commonly used sequences grows with practice through the life span. Elderly people are relatively more likely than younger people to develop Wernicke’s aphasia and relatively less likely than younger people to develop Broca’s aphasia, whether the lesion is caused by stroke, neoplasm, or trauma (Basso, Bracchi, Capitani, Laiacina, & Zanobio, 1987; Brown & Grober, 1983; Kertesz & Sheppard, 1981; Miceli et al., 1981). One possible explanation for this is that elderly people are able to maintain reasonable fluency given a frontal lobe lesion because of the repertoire of word sequence knowledge that they retain in the predominantly posteriorly located pattern associator network we have described. Only when the lesion directly

affects this pattern associator and/or its related phonologic pattern associator does aphasia result, and then it is a Wernicke's aphasia or a conduction aphasia, directly reflecting the impairment in sequence knowledge. This explanation does not presume superior syntactic capability by elderly subjects (in fact, the evidence is to the contrary), only greater reliance on a particular repository of knowledge than in the young.

Grammatical Morphology

Grammatical morphology refers to the use of words (free grammatical morphemes [e.g., articles, auxiliary verbs, conjunctions, and some prepositions]) and suffixes (bound grammatical morphemes [e.g., affixes specifying case, number, or tense]), the role of which appears to be primarily grammatical. The distinctiveness of these free grammatical morphemes and the apparently fundamental differences between them and major lexical items (nouns and main verbs) is further conveyed in the other terms by which they are known: functors, and closed-class words.

This way of classifying these words has a certain appeal if one posits the existence of a grammatical processor, such as that proposed by Chomsky and others. As we have noted, however, there has not been a successful effort to account for a grammatical processor in terms of known principles of neural network function. Therefore, in this section, we will continue the approach taken earlier, assuming that all aspects of language can be understood in terms of (1) the properties of distributed representations, (2) the mechanisms that manipulate distributed representations, and (3) the interface of the auto-associator network supporting semantic distributed representations with pattern associator networks that translate these semantic distributed representations into alternate forms (e.g. acoustic, orthographic, articulatory, and inscriptional) that are represented in networks supporting sequence knowledge. The essential currency of semantic distributed representations is meaning. Constraints on sequence in spoken language are provided primarily by implicit sequence rules latent in the connectivity of the acoustic-articulatory pattern associator network. We will attempt to approach the problem of grammatical morphology from the perspective of meaning constrained by sequence.

Articles

We have already noted (in the section on phrase structure rules) that representations of articles such as "the" probably are engaged, to some degree, by virtue of their incorporation in multi-word sequence knowledge. In addition, although articles have minimal meaning, they cannot be characterized as having no meaning whatsoever—they do indicate definite or indefinite. As modifiers in noun phrases, however, they differ from adjectives in that their meaning is contextual, whereas the meaning of adjectives is absolute. That is,

whether the article "a" or "the" is used depends on the preceding discourse; in contrast, the use of an adjective, such as "big," depends only on the attributes of the noun distributed representation to which it is linked. Thus, the use of articles depends, in part, on the maintenance of some working memory of what has already been said (i.e., sustained selective engagement of immediately preceding distributed concept representations and their relationship to each other). To the extent that working memory (selective engagement) mechanisms are defective, we might expect the impetus to article use from this source to be reduced. In English-speaking subjects with Broca's aphasia, as we have noted, some evidence of such a defect exists. As predicted by our hypothesis of defective selective engagement, these subjects tend to omit articles (agrammatism). In other languages (e.g., German), articles are marked for case, gender, and number—additional meaningful information that derives from the semantic representation of the nouns with which they are associated. Apparently because of these additional contributors to engagement of article representations, German subjects with Broca's aphasia are much more likely to produce incorrect articles (para-grammatisms) than to omit articles (Bates, Friederici, & Wulfeck, 1987); these substitutions can be viewed as the equivalent of syllabic sequence errors.

The essential lesion for producing agrammatism in spontaneous language appears to involve dominant postcentral perisylvian cortex (Nadeau, 1988). If our hypothesis regarding the contextual and, hence, working memory dependence of article use is correct, however, we should see some evidence of article omission in English speakers with dominant frontal lobe convexity cortex lesions. The fact that subjects with frontal lesions with sparing of postcentral perisylvian cortex are not conspicuously agrammatical may reflect two things: (1) that frontal systems engaged in working memory processes underlying article use are highly distributed, and (2) that frontal lesions spare the neural network representation of multi-word sequence knowledge (e.g., phrase structure rules). Thus, a modest lesion in postcentral perisylvian cortex may produce agrammatism (Kolk & Friederici, 1985), both because it is at the point where frontal projections converge on the pattern associator networks producing language output and because it is the locus of relevant sequence knowledge.

Auxiliary Verbs

Four attributes of auxiliary verbs (e.g., "The boy was fishing") might make them particularly prone to omission by subjects with Broca's aphasia given the model we have been considering. First, they are linked to the main verb. We have reasoned that main verbs function by simultaneously reciprocally modifying and linking as many as three distributed representations corresponding to the verb arguments in the sentence, a process particularly demanding of selective

engagement mechanisms. Although auxiliary verbs have been consigned to the class of functors, in their use they typically act like main verbs in an adjectival way to modify distributed concept representations. For example, consider the two sentences “Mary hides the candy” and “Mary had hidden the candy.” In the first, Mary is in motion, busily secreting the candy in an obscure place. In the second, Mary is static, but she has the attribute of responsibility for the current state of the candy. In the first, the candy is being carried about; in the second, the candy is still. We have already identified this process of volitional modification of distributed concept representations as one requiring frontal systems, which are consistently impaired in subjects with Broca’s aphasia.

Second, the purpose of an auxiliary verb often is to convey tense. Frontal systems may provide the chief substrate for the neural instantiation of the time concept by virtue of their primary role in planning. Time-tagging of memories is impaired in subjects with frontal lobe lesions. Third, auxiliary verbs often are used only to reconcile the tense of the sentence with the tense of the preceding narrative, such as “She has a headache now. She has been having headaches for six months.” That is, the inclusion and choice of auxiliary verbs are based, like those of articles, on narrative context and, hence, on working memory. Finally, auxiliary verbs may be linked to main verbs within the domain of sequence knowledge. The fact that the neural mechanisms underlying all four of these are impaired in subjects with Broca’s aphasia may account for the tendency of these subjects to omit these words.

Articles and Auxiliary Verbs as Syntactic Elements

Some circumstances exist in which articles and auxiliary verbs appear to play a truly syntactic role, in which case the knowledge that supports them could be characterized as lexical-syntactic. Consider first the two dative sentences: (1) “The teacher showed the parents the student’s desk,” and (2) “The teacher showed the parent’s student the desk.” Here, the placement of the article “the” and the possessive “-s” is critical to the meaning of the sentence. In passive-voice sentences, the presence of the “was . . . by” combination is equally essential to the meaning of the sentence.

Prepositions

Although many types of prepositions exist, we will focus only on locative prepositions (e.g., “The book is *on* the table”). These words strongly resemble main verbs in that they are the product of reciprocal alterations in the distributed representations of the concepts underlying the nouns on which they operate, coupled with linkage of these noun concepts. On this basis alone, we might expect them to be differentially affected by brain lesions that impair the selective engagement processes necessary for this to happen, as in the case of verbs.

Pronouns

Because they derive their meaning only through reference to antecedent nouns, pronouns depend on sustained engagement (working memory) of the noun representations that have been used recently. Again, to the extent that such sustained selective engagement mechanisms are impaired, one would expect defective use of pronouns. Indeed, this is the case in subjects with Broca’s aphasia. By contrast, people with aphasia resulting from more posterior lesions, which leave frontally mediated selective engagement mechanisms intact, use pronouns to excess as a device to deal with their problems with lexical-semantic access.

Grammar: A Synthesis

Lexical-semantic function is based primarily on three domains of knowledge: semantic, sequence, and the pattern associators linking semantic and sequence knowledge, which provide the basis for the phonologic lexicons. In addition, it may require frontal systems involved in selective engagement (working memory) and frontal systems involved in manipulation of distributed concept representations to volitionally modify distributed concept representations corresponding to nouns.

Grammatical expression demands:

1. An elaboration of sequence knowledge to the extent that word stems may attach free-standing and bound grammatical morphemes and multi-word sequences are governed by phrase structure rules.
2. Engagement and reciprocal modification of two or more distributed concept representations employing procedures that correspond to rules of verb argument structure, further modified in a way that will support engagement of modifying auxiliary verbs.
3. Engagement by the super-distributed concept representations that instantiate verb argument structure of phonologic sequences in the acoustic-articulatory motor pattern associator that will instantiate the lexical form of the verb, with or without auxiliaries.
4. Engagement by certain super-distributed concept representations of articles and auxiliary verbs that are essential to syntax and can usefully be viewed as lexical-syntactic in nature.
5. The operation of volitional selective engagement mechanisms that will support the working memory of the modified distributed concept representations currently in play as well as recent modified representations, the recall of which is essential to correct production of articles, pronouns, and some auxiliary verbs.

Because all of the systems supporting these various aspects of grammatical function impose constraints, the process of sentence production involves parallel constraint satisfaction, a particular strength of PDP systems (Nadeau, 2000).

In this conceptualization, anomia for nouns reflects a breakdown in semantic or lexical-semantic knowledge. Curiously, difficulty modifying nouns (e.g., with adjectives) could be caused, in part, by a breakdown in syntactic function, because it also involves volitional modification of distributed concept representations. Anomia for verbs may reflect, in part, a form of breakdown in lexical-semantic knowledge in which super-distributed representations fail to elicit a pattern of activity in articulatory motor representations corresponding to the spoken form of the verb. Impaired ability to generate the super-distributed concept representations that are essential to verb production, however, also may cause difficulty with verb production as well as violation of rules of verb argument structure. Even when syntactically impaired subjects produce a relatively normal number of verbs, their verb use tends to ignore argument structure (Thompson, Shapiro, Kiran, & Sobecks, 1997). The production of articles and auxiliary verbs usually depends, in part, on the integrity of sequence knowledge but also on capacity for further, often subtle refinement of distributed or super-distributed concept representations and the engagement of working memory of recent sentences spoken or heard.

These general principles will apply to all languages. Languages differ, however, in the degree to which they rely on particular domains of knowledge, the specific content of these domains of knowledge, and the particular acquired skills in distributed concept manipulation.

MEMORY

Any behavioral therapy—language therapy included—involves the addition of new knowledge to the brain to replace that lost as a result of brain injury or disease. Because the properties of the neural systems that incorporate new knowledge have major implications for the therapeutic strategies employed in presenting that information, we will address this topic in some detail.

Language processes explicitly involve two well-known types of memory, procedural and declarative (Squire & Knowlton, 2000), and may involve other as-yet-unrecognized types of memory.

Procedural Memory

Procedural memories, often referred to as skill memories, are acquired incrementally by the neural systems representing the skills as they are practiced. For example, skill in playing tennis is enhanced gradually through extended practice as connectivity in the premotor and motor cortices, basal ganglia, cerebellum, brain stem, and spinal motor systems is incrementally modified. In language, the neural network knowledge that enables translation of continuous incoming sound into the acoustic representation of phonemes, which are discrete (i.e., not continuous), probably represents a

form of procedural knowledge. By the same token, the neural network knowledge that enables the translation of the articulatory representation of phonemes, which also are discrete, into continuous programs of movement involving pharyngeal and respiratory musculature also probably represents a form of procedural knowledge. It also seems likely that knowledge of the phonemic sequence repertoire of a given language is procedural, at least insofar as this knowledge is actually used in speech. For example, subjects with amnesia resulting from mesial temporal lobe lesions are not impaired in learning artificial “grammars” characterized by rule-bound letter strings (Squire & Knowlton, 2000). The development of phonologic awareness—that is, awareness of the discrete phoneme structure of words—may correspond to the addition of a declarative form of this knowledge.

Declarative Memory

Declarative memories, or memories for discrete facts, are acquired all at once in approximately 1 second in a process that is thought to involve fast Hebbian learning (see footnote 18) within Ammon’s horn (the “cornu Ammonis”) of the hippocampus (Alvarez & Squire, 1994; McClelland, McNaughton, & O’Reilly, 1995; Rolls & Treves, 1998; Squire & Zola-Morgan, 1991). Subsequently, some fairly rapid decay occurs, even in normal individuals.

This nearly instantaneous establishment of new connections between active neurons within the hippocampus serves to close long loops linking neural networks in the cerebral cortex. Cerebral association cortices project to the parahippocampal gyrus and perirhinal cortex, which, in turn, project to the entorhinal cortex and then to the dentate gyrus of the hippocampus. Dentate neurons project to the pyramidal neurons in the cornu Ammonis (CA3 and CA1 fields) of the hippocampus. The pyramidal neurons then project via the subiculum to the entorhinal cortex, which then projects back to cerebral association cortices. These circuitous new connections instantiate new knowledge. Initially, this new knowledge constitutes episodic memory in that it is memory of a particular aspect of a particular event at a particular place and time. Eventually, to one extent or another, this new knowledge may be incorporated into neural network connectivity in the cerebral cortex in a process referred to as consolidation. The process of declarative memory consolidation is not completely understood and currently is somewhat controversial. It appears that memories most likely are incorporated into cortical network connectivity to the extent they share features with knowledge already represented in the cortex. In this process of consolidation, the hippocampus appears to serve as a teacher to the cortex, repeatedly subjecting the cortex to patterns of activation congruent with the new information the hippocampus has incorporated. Growing evidence suggests that this process occurs during sleep (Power, 2004). If this theory of consolidation is

correct, then it follows that memories that cannot be readily incorporated into the cortex, because they share few features with existent cortical knowledge, will remain permanently dependent on connections within the hippocampus and its immediately adjacent neural structures. This appears to be the case: Autobiographical memories generally share few features with knowledge represented in the cortex (they represent knowledge of particular places and times that are of only personal significance), and autobiographical memories are highly susceptible to disruption by lesions of the hippocampus and its associated structures.

It currently is thought that the hippocampal system is required, because in neural network simulations, the sustained presentation of new information to networks results in replacement of old knowledge already represented in the network by the new knowledge; in other words, catastrophic degradation of the old information occurs (McClelland et al., 1995; McCloskey & Cohen, 1989). If presentation of new information is interleaved with rehearsal of the old information, however, then a network is capable of instantiating both old and new knowledge simultaneously. It is thought that the hippocampal system provides the brain with a means to circumvent this impasse: It serves both as a repository of newly acquired declarative knowledge and as a teacher to the cortex that, during sleep, serves to interleave the new knowledge with rehearsal of old, related knowledge. The new knowledge is added gradually to the old knowledge, and because the changes in neural connections are made incrementally and the new is interleaved with the old, catastrophic degradation of old knowledge does not occur.

Lexical-Semantic Memory

In our discussion so far, we have suggested that knowledge underlying translation of sound sequences into phonemic acoustic representations, knowledge underlying translation of phonemic articulatory representations into motor sequences, and phonologic sequence knowledge all may constitute varieties of procedural memory. In contrast, knowledge of concepts, by virtue of being discrete and consciously accessible, is prototypic declarative knowledge. What about knowledge linking distributed concept representations to phonemic sequences or to articulatory or acoustic representations? This, the basis for lexical-semantic knowledge, spans the declarative-procedural divide. Is this knowledge declarative or procedural?

A famous paper by Vargha-Khadem and colleagues (1997) provides some hints. They reported three subjects who, early in life, had experienced severe bilateral damage to the hippocampus as a result of anoxic insults. During subsequent intensive neuropsychological testing, these subjects demonstrated expectable severe deficits in episodic memory acquisition. All three, however, had acquired language function that appeared to be nearly normal. There had been similar reports

of this phenomenon in previous case studies, but none nearly as compelling as the paper by Vargha-Khadem and colleagues. The nearly normal language function and the remarkably good general knowledge acquisition of these subjects, in conjunction with the results of studies in nonhuman primates, suggested to the authors that two separate declarative memory acquisition systems exist: one resident in the hippocampus that is essential to acquisition of episodic memories, and one in entorhinal/perirhinal cortex (relatively spared in the three subjects reported) that suffices for declarative semantic memory acquisition. This hypothesis remains to be fully tested. Furthermore, the evidence that the hippocampus and adjacent cortices are anatomically and functionally organized as a cascade system, not a binary system (McClelland et al., 1995; Rolls & Treves, 1998), as discussed in an earlier section, weighs strongly against this interpretation.

The importance of this issue for speech-language therapy is that lexical-semantic dysfunction constitutes one of the most common and disabling aspects of aphasia. Direct approaches to this problem—that is, “naming” therapies—tend to be extraordinarily inefficient. The observations of Vargha-Khadem and colleagues raise the possibility of a completely different declarative memory-like brain mechanism underlying the acquisition of lexical-semantic knowledge. If only we better understood this principle, we might be able to substantially improve the efficiency of naming therapies. The observations of Vargha-Khadem and colleagues also suggest that naming therapies might be successful even in subjects with substantial hippocampal dysfunction (e.g., because of traumatic brain injury).

Properties of Procedural and Declarative Memory Systems Relevant to Therapy for Aphasia

Both procedural and declarative memory systems have characteristic strengths and weaknesses relevant to their recruitment in therapy for aphasia. One major advantage of procedural knowledge underlying language is that it generalizes widely. For example, the acquisition of skills in decoding of sound sequences into phonemic acoustic representations (rarely a source of difficulty), of skills in translating phonemic articulatory representations into motor programs, and of a critical mass of phonemic sequence knowledge will provide the procedural knowledge basis for decoding and producing all words in the native vocabulary. Acquisition of certain skills in manipulating distributed concept representations should generalize to all distributed concept representations susceptible to those manipulations. A second major advantage is that achieving an adequate foundation of procedural language skills potentially gives the subject the tools to continue growth of language capacity on his or her own in the course of routine conversation—in direct analogy to the normal process of language acquisition in early childhood. We will discuss some specific examples of such therapies later in this chapter.

The major disadvantage of procedural knowledge acquisition is that it is incremental; therefore, the ultimate development of a useful level of skill will require extensive practice. Specific domains of procedural memory underlying language also pose their own particular problems. Successful procedural linguistic memory acquisition in the domain of phonologic knowledge would only build the phonemic/articulatory foundation for acquisition of lexical-semantic knowledge. The actual links between distributed concept representations (semantic knowledge) and phonemic/articulatory sequences that would enable naming would still have to be developed, either through further therapy or by the subject in the course of daily use of language. Fortunately, even in the context of extensive brain damage, the language brain likely is not a *tabula rasa*: There exist extensive remnants of previous knowledge (Plaut, 1996), and the therapist's task is to develop these remnants until they reach the critical mass needed for daily spoken communication. Acquisition of grammatical skills in distributed concept manipulation may require such extensive practice that only a very limited repertoire of such skills can be trained.

The advantage of declarative knowledge underlying language is that it can potentially be acquired all at once, but two major disadvantages also exist. First, acquisition of declarative memory is considerably less than 100% efficient in normal subjects (else all attentive students would score 100% on tests of knowledge), and its efficiency drops substantially in the face of extensive damage to cortices supporting declarative memories. Second, the potential for generalization is limited. This limitation is most serious for lexical-semantic knowledge, because little relationship exists between the meaning of a word and its sound: When you have learned one word, you have learned one word. Thus, for any therapeutic strategy that depends on acquisition of lexical-semantic knowledge to achieve practical value, the learning process must be extended to incorporate a full, useful working vocabulary for the subject—something that, remarkably, has been achieved, but only in a very unusual individual (Basso, 2003). The number of words that would be necessary for this, the demographic and cultural modifications in this vocabulary that would be needed, and the practical means for training subjects in this extended vocabulary are largely unknown. The potential for generalization of semantic knowledge may be considerably greater, because many concepts share features and, to the extent that they share features, training of one concept may benefit the ability to generate a distributed representation of another concept. We have not remotely plumbed all the possibilities for engaging shared semantic features to best advantage in therapy for aphasia.

GENERALIZATION

Generalization is the process by which the effects of therapy extend to material or circumstances not explicitly taught

during speech-language therapy sessions. Generalization is essential if speech-language therapy is to have an important impact on the daily communicative lives of subjects. To date, however, evidence from clinical trials has only provided glimpses of generalization effects, and the mechanisms remain poorly understood. In the preceding section on memory, we introduced the concept of generalization in several specific contexts. In this section, we briefly consider the full spectrum of mechanisms that might underlie generalization. Seven (listed in Table 26–2) are posited:

1. **Intrinsic** Application of knowledge acquired in therapy (e.g., semantic features, phonologic sequences, phonetic sounds, or syntactic techniques) to other knowledge that shares these features or sequences or to situations that allow application of the acquired techniques (Kiran & Thompson, 2003; Thompson et al., 2003; Wambaugh, Kalinyak-Fliszar, West, & Doyle, 1998; Weinrich, Whelton, Cox, & McCall, 1997). We touched on this principle in the section on memory. Because knowledge gained about phonetics, phonologic sequences, and syntactic techniques can, in principle, be applied regardless of the subject of communication, therapies that develop this knowledge have the potential for extensive generalization. On the other hand, generalization from semantic therapy will be limited to concepts that share semantic features with the concepts actually trained. These various types of generalization stem directly from the knowledge gained in therapy.
2. **Cross-function** Development of knowledge during therapy that can be applied to multiple tasks. For example, semantic therapy could benefit oral word production, written word production, oral word comprehension, and written word comprehension, because all four capacities involve pattern associator networks linked to association cortices supporting concept representations (in traditional terms, all four capacities depend on the integrity of the semantic field).
3. **Extrinsic** Development during therapy of a knowledge acquisition/skill learning technique that subjects with motivation—and who are capable of engaging motivation to employ the technique—can use during and outside of therapy to rebuild language function (e.g., semantic therapy, phonologic sequence therapy, or syntactic therapy). Here, it is not the substantive material learned in therapy that is crucial to ongoing progress outside of therapy (although a critical mass of substantive knowledge may be necessary)—it is the acquisition of a therapeutic technique that the subject, perhaps with help from family, can continue to apply in the months and years outside of therapy. (This will be further elucidated in some of the specific examples that are discussed in the section on specific rehabilitative strategies.) For

TABLE 26-2

Mechanisms of Generalization

Mechanism	Description
Intrinsic	Application of knowledge acquired in therapy (e.g., semantic features, phonologic sequences, phonetic sounds, and syntactic techniques) to other knowledge that shares these features or sequences or to situations that allow application of the acquired techniques.
Cross-function	Development of knowledge during therapy (e.g., semantic) that can be applied to multiple functions (e.g., comprehension and production) involving verbal and orthographic modalities, because all these functions depend on the integrity of the core domain (in this case, semantics).
Extrinsic	Development during therapy of a knowledge acquisition/skill learning technique that subjects with motivation, and who are capable of engaging motivation to employ the technique, can use during and outside of therapy to rebuild language function.
Mechanistic	Development of a nonlinguistic brain resource (e.g., working memory), ability to endogenously generate distributed concept representations, or intentional bias to use language that is essential to language function.
Substrate mediated	Development of the critical mass of language skill needed to enable conversation at home and elsewhere and, thereby, further the therapeutic process.
Contextual	Acquisition of knowledge, predominantly contextual, during speech-language therapy that aids in retrieval of knowledge outside of therapy by establishing additional commonality between the training situation and the retrieval situation.
Socially mediated	Change in the perception of the subject and his or her family regarding his or her role in the family unit, with the adoption of a new/revised role that subsumes more expectation of speech, more pressure to speak, and greater language production.

example, a subject who has received semantic therapy could continue to use the techniques acquired during therapy for systematically identifying the semantic attributes of concepts, both those that can be named and those that cannot, provided that he or she has the motivation and the capacity for translating motivation into action, thereby continuing to develop the semantic field long after the conclusion of therapy. Even lexical-semantic therapy can make use of this generalization mechanism, as demonstrated by Basso (2003): Exceptionally capable subjects can be given the guidance and techniques to practice naming of the thousands of words needed to communicate in daily life. For extrinsic generalization to occur, subjects must be motivated to continue to use therapeutic techniques learned during therapy after completion of therapy, and they must have the brain mechanisms (which presumably depend, in part, on frontal systems) to translate this motivation into effective post-therapeutic practice. We have preliminary evidence from a study of semantic therapy that only subjects who demonstrate intact frontal function show widespread generalization that also impacts daily communicative behavior (Nadeau & Kendall, 2006).

4. **Mechanistic** Training of a key brain resource, essential to language processing but not fundamentally linguistic, that enables improvement in language function. Three subtypes can be postulated:

- a. Development of working memory capacity needed for language, as discussed, is likely to be particularly important for normal grammatical function, in which multiple distributed concept representations need to be maintained simultaneously for sufficient time for appropriate modifications to be made, and some grammatical functions dependent on reference (e.g., articles, auxiliary verbs, or pronouns) require some recollection of what has recently been said, some of which may be represented as working memory.
- b. Development of the ability to endogenously generate distributed concept representations, which is most impaired in adynamic aphasia¹⁰ (Gold et al., 1997), may be the same as 4.a. The differences between adynamic aphasia (in which there is difficulty generating the representations) and Broca's aphasia (in which there appears to be particular difficulty in

¹⁰ Subjects with adynamic aphasia characteristically are extremely non-fluent in internally generated language and, in extreme cases, may be incapable of more than occasional single-word production. In picture description tasks, however, they may perform almost normally. This suggests that when called on to generate their own distributed concept representations, they have great difficulty, but when distributed concept representations are "planted" in their brain by showing them a picture, they are capable of substantially normal language production.

modifying and manipulating the representations), however, suggest an important difference.

- c. Development of a new intentional bias that favors language use over either non-use or gestural communication, the cardinal example being constraint-induced language therapy (Maher et al., 2003; Meinzer, Djundja, Barthel, Elbert, & Rockstroh, 2005; Pulvermüller et al., 2001). The idea here is that because of frustration with language impairment that is particularly severe in the months immediately following stroke, patients develop an intentional habit of minimal effort to communicate or a habit that leads to alternative communicative modes, such as gesture. This intentional bias then persists despite substantial improvement in capacity for language and, thereby, actually inhibits linguistic communication in the long run. Training that alters the bias can enable the subject to take full advantage of partially recovered language function. There may be other mechanisms at play in mediating the effects of constraint-induced language therapy (e.g., see 7 below), but this particular one (i.e., modification of intentional bias) is the one that has motivated the development of this therapy and appears to be most responsible for the gains associated with the previously developed constraint-induced movement therapy.
5. **Substrate mediated** Development of the critical mass of language skill needed to enable conversation at home and elsewhere and, thereby, further the therapeutic process. It probably is necessary to enable intrinsic and extrinsic generalization mechanisms to operate. For example, below we will discuss our experience in using training in phonemic awareness, phoneme production, and phonologic sequence knowledge to ameliorate impairment of lexical access in aphasia. The therapy does not include training in the ability to link phonemic sequences to concepts—this must occur outside the treatment session. We presume that it can only occur if subjects have acquired a repertoire of phoneme sequence knowledge that covers most words encountered in their daily communication. Under these circumstances, the production of most words, with or without caregiver help, will provide an opportunity for strengthening connectivity between concept representations and corresponding phonemic sequences.
6. **Contextual** Acquisition of knowledge, predominantly contextual, during speech-language therapy that aids retrieval of knowledge outside of therapy (detailed in the next section). In essence, the principle is that when we learn, the knowledge acquired includes not only the intended material but also knowledge about the context. This knowledge may include attributes of other stimuli introduced during a treatment session. It also may include more general attributes of the situation (e.g.,

where the treatment was provided, characteristics of the treatment room and the therapist, who else was present, the mood of the participant, participant attitudes to the stroke experience and associated disability, and the strategies the participant brings to therapy). The greater the resemblance between context in the learning environment and context in the retrieval environment, the higher the likelihood of success in retrieval. Most of us have encountered the negative effects of absence of contextual similarity when we try to remember the name of a professional acquaintance during a chance encounter outside our professional environment.

7. **Socially mediated** Change in the perception of the subject and her or his family regarding his or her role in the family unit, with the adoption of a new/revised role that subsumes more expectation of speech, more pressure to speak, and greater language production (Blonder, 2000). As Blonder has shown, the alterations in lives produced by aphasia may be profound, and even if patients with stroke do not become socially isolated, the value of language facility may be fundamentally reduced. Thus, to varying degrees, restoration of daily communicative ability may require some restoration of the social context that will promote language use as an instrumental measure.

TEMPORAL SPACING, STRUCTURE, AND CONTEXT, STIMULUS PROPERTIES, AND FEEDBACK DURING THERAPY

The focus of clinical research on treatment of aphasia has overwhelmingly been on the substance of that treatment, and very little attention has been devoted to factors that might influence the acquisition of knowledge by the brain during therapy and the retention of that knowledge after the conclusion of therapy. Because, in the subject with chronic stroke, therapy for aphasia is likely to produce its effects by engaging normal learning mechanisms, the educational psychology literature can provide evidence that may be useful in the treatment of aphasia. The discoveries in this research can be related, in a cogent way, to brain structure and function. We will focus on three topics: (1) the distribution of aphasia treatment over time, (2) the structure and context of therapy for aphasia, and (3) feedback during treatment.

Distribution of Aphasia Treatment over Time

Condensed Versus Distributed Practice

The predominant focus in neurorehabilitation in general has been on knowledge or skill acquisition—in other words, the difference between performance at the end of treatment and performance at baseline. Most, however, would agree

that the real measure of treatment efficacy is the knowledge and skills acquired during treatment that the subject retains through the months and years after the conclusion of treatment, which are likely to be considerably less than those acquired by the end of treatment. Only changes retained by the brain over the long run can have a lasting impact on daily performance, activity, participation, and quality of life. This suggests that our primary focus in treatment studies should be on long-term outcome—that is, the difference between performance long after the conclusion of treatment and performance at baseline—rather than on acquisition. It also poses the challenge of understanding the neural mechanisms underlying the relationship between retention and acquisition. The degree to which practice is more or less temporally condensed is very much germane to this issue.

“Massed practice” traditionally is defined as continuous practice conducted over a single day in which the stimuli or skills to be remembered are presented without any intervening irrelevant stimuli or activities. “Distributed practice” traditionally is defined as practice that is broken up into two or more sessions, each separated by an interlude of minutes, hours, or days, or a single session in which repetitions of target stimuli are separated by one or more nontarget stimuli. In speech-language therapy, target stimulus repetitions typically are separated by many intervening, nontarget stimuli, and the limits of human endurance dictate that sessions be conducted over multiple days. Thus, no speech-language therapy conforms to traditional definitions of massed practice, and our major focus here will be on evidence bearing on the impact of more or less temporally distributed therapy.

Studies of constraint-induced movement therapy for upper extremity paresis following stroke may have cultivated the notion that the case for large amounts of highly condensed practice, by virtue of the dramatic impact on outcome measures, has largely been proven (Taub, Uswatte, & Pidikiti, 1999; Taub et al., 2006). Studies have consistently demonstrated, however, a dramatic loss of constraint-induced movement therapy-associated gains over the weeks and months following treatment. Relatively little attention has been devoted to treatments after constraint-induced movement therapy that might help to sustain gains, and to our knowledge, no study has been conducted regarding the relative impact of more versus less distributed constraint-induced movement therapy schedules on long-term retention. Thus, treatment schedule density remains a matter of great scientific and clinical interest in all fields of rehabilitation, and no study that we are aware of provides definitive answers.

Studies contrasting the relative impact of massed practice and distributed practice on learning rate and knowledge retention date back to 1885 (Dempster, 1996; Donovan & Radosevich, 1999; Ebbinghaus, 1885). Literally hundreds of investigations have been conducted involving a wide range of knowledge and skill types. With very few exceptions, distributed practice has been found to be superior to massed

Figure 26-7. Cartoon illustrating the trajectory of skill/knowledge as a function of time with more and less condensed learning regimens. More condensed (less distributed) regimens commonly achieve greater acquisition of knowledge and skill by the end of training, but this is then followed by a higher rate of loss, with the net result that long-term retention typically is greater with less condensed (more distributed) regimens.

practice in its effects on knowledge retention, whether the training involves factual knowledge, simple motor skills, or more complex tasks involving acquisition of factual knowledge, advanced motor skills, and the development of strategies. This superiority has come to be known as the “spacing effect.” Often, recall is greater at the end of the acquisition phase of more condensed training than it is after more distributed training. This superior acquisition efficacy is offset by relatively greater forgetting, however, such that long-term retention usually ends up being greater with more distributed training (Fig. 26-7).

Although these studies provide strong evidence for the superiority of modest temporal distribution of short-duration task practice on retention of knowledge and skill, they do not provide data regarding training, such as rehabilitation therapy, that must be sustained over days, weeks, or months. Unfortunately, very few studies have directly compared the impact of different degrees of distribution of practice over these more extended periods of time. Pyle (1913) compared the impact of an addition drill given to third-grade students twice a day for 5 days with the same drill given once a day for 10 days. The more distributed drill was more effective. Murphy (1916) found that training schoolgirls in a left-handed javelin throw produced a higher rate of learning if done one or three times weekly than if done daily. Shea, Lai, Black, & Park (2000) studied training on two tasks, a dynamic balance task and a calibrated sequential key-press

timing task; for both tasks, training over 2 or 3 days proved to be more efficacious than distributed training over 1 day. Shebilske, Goettl, Corrington, and Day (1999) compared training distributed over 2 days with equal training distributed over 10 days on Space Fortress, a complex task involving acquisition of factual knowledge, motor skills, and strategy. Subjects trained over 10 days performed better on both acquisition and retention measures. Childers and Tomasello (2002) trained 2-year-old children on novel nouns and verbs (i.e., lexical-semantic training bridging a declarative-procedural divide). They found that production performance was better when training was distributed over 4 days compared to 1, 2, or 3 days. Two-day gaps between training sessions did not impair performance, but gaps between training sessions of 5 or 10 days were associated with poorer performance. Bahrick and Phelps (1987) found that among subjects trained on 50 English-Spanish word pairs tested 8 years later, recall was 15% among those trained with a 30-day intersession training schedule, 8% among those on a 1-day intersession interval, and 6% among those with no spacing between sessions. Baddeley and Longman (1978) trained British postal workers to type. Learning was more effective (as defined by retention up to 9 months later) when training was given 1 hour per day over 60 days than when given in two 2-hour sessions per day over 15 days. The task involves training of typographical-semantic knowledge, which is directly analogous to lexical-semantic knowledge in that it involves linking declarative knowledge to procedural knowledge. These various studies suggest that when training must be sustained over extended periods of time, very substantial degrees of temporal distribution of practice may yield superior long-term retention of knowledge and skill.

No studies provide definitive data regarding the impact of degree of distribution on training programs like speech-language therapy that involve intensive, cumulative treatment conducted up to hours at a time over many days, nor to our knowledge have any studies examined the effect of differing degrees of distribution of speech-language therapy. A recent review concluded that more concentrated therapy probably was superior, but degree of distribution was confounded with dose (shorter studies typically involved more hours of therapy) (Bhagal, Teasell, & Speechley, 2003). Thus, both studies of the impact of variable distribution of speech-language therapy over days as a function of domain of knowledge being trained as well as studies of the distribution of therapy within day are needed.

Potential Mechanisms Underlying the Spacing Effect

Many theories have been offered to account for the relative superiority of distributed practice (Greene, 1989; Hintzman, 1974; Shebilske et al., 1999). Although no theory has been shown to account for all experimental results, including both declarative and procedural knowledge, and to fully accommo-

date our current understanding of the neurobiologic bases of memory, the component-levels theory of Glenberg (Glenberg, 1979; Glenberg & Lehmann, 1980) comes closest. Glenberg considered only declarative memory experiments, his own and other's, largely involving free recall of words from word lists and cued recall from word pair learning tasks. This work finds its origins in encoding variability theory (Bower, 1972; Estes, 1955; Melton, 1970). Three principles are essential to his theory. First, in a conceptualization that fully anticipates current concepts of episodic memory, Glenberg posited that when an item to be remembered is learned, three attributes of that item are encoded: (1) its *semantic attributes*; (2) attributes of the neighboring task stimuli (e.g., the neighboring words in the word list), within which it is embedded, as they are perceived and organized by the subject (*structural context*); and (3) the *general context* of the experiment (e.g., the testing environment, the cognitive and affective state and degree of fatigue of the subject, and in complex tasks, the inter-trial reminiscence of salient stimuli and strategy formation). General and structural context exert their impact by modifying the semantic representation. Thus, spacing effects in the declarative domain are attenuated with stimuli being processed only at more superficial levels (e.g., perceptual) (Craig & Lockhart, 1972). Second, a repetition is potentially effective to the degree that the second presentation allows the storage of information distinct from that stored at the first presentation. In massed practice, general and structural context are very nearly identical for every presentation of the item to be remembered. Distributed presentations generally produce differences in general and structural context. Third, the realization of the potential effect of repetition is controlled by the conditions at the time of the memory test—that is, the retrieval environment (i.e., *the spacing effect reflects a storage-retrieval context interaction effect*). Repetition will contribute to recall to the extent that structural and general context attributes associated with *each* presentation of the item to be remembered add together to increase the likelihood that some of these same attributes will be present in the recall environment, thereby increasing the probability of recall. If structural and general context are nearly identical, as in massed practice, repetition confers minimal advantage. If structural and general context differ but recall is requested shortly after the item is repeated, no spacing effect will occur, both because the general context at the time of repetition and at the time of recall are similar and because both are different from the general context at the time of the first presentation of the item (thereby largely eliminating its contribution to recall). Glenberg and Lehmann (1980) have shown that these principles apply not just to learning studies/retention probes that occur within a single day but also to learning epochs that take place a week apart with tests for retention a week later. Studies by Glenberg and others support a proportionality rule: When the retention interval is short relative to spacing intervals, performance is inversely related to spacing, and when the retention interval is long

relative to spacing intervals, performance is directly related to spacing—hence the value of highly distributed training on long-term retention.

It seems likely that treatment of aphasia after stroke engages normal learning mechanisms, both declarative and procedural, even as the relative contributions of each of these two learning mechanisms to training effects in various types of therapy for various types of impairment remain uncertain. Therefore, it is worth asking whether the principles proposed by Glenberg to account for the spacing effect in declarative learning might apply to procedural learning as well. Very little data regarding this are available. The most salient difference between declarative and procedural memory that we need to contend with is that general context attributes are unlikely to be encoded as part of the procedural memory trace (because the hippocampus is not involved). Thus, there likely will be no benefit from the long spacing intervals that enhance the likelihood of change in general context attributes, a major contributor to spacing effects on declarative memory recall. Only structural context attributes are important to the spacing effect on procedural memory retention. Thus, if a particular skill to be learned can be repeated within each one of a full spectrum of *skill contexts* within a short period of time, there should be no advantage to distributing training over a longer period. Evidence suggests that procedural memory acquisition involves a consolidation phase that takes place over several hours (Brashers-Krug, Shadmehr, & Bizzi, 1996). A flurry of recent studies, however, has demonstrated a complex of further consolidative and re-consolidative processes that take place during sleep (Stickgold & Walker, 2005; Walker & Stickgold, 2004). Thus, distribution of procedural training could provide a relative advantage in retention, both because it provides a greater opportunity to train individual skills in a variety of action contexts and because it allows more occasions for sleep-associated consolidative processes to occur. The advantage of distributed over massed practice also can be seen in the superiority of “random” over blocked practice in skill learning (Schmidt & Bjork, 1992).

In the domain of procedural memory is an alternative, connectionist account for the superior retention of knowledge acquired through distributed practice (Sejnowski & Rosenberg, 1988). This account is compatible with the component-levels theory of Glenberg. A pattern associator network employing distributed representations in which extensive knowledge is already stored in its connections can readily, through massed practice, learn to achieve high performance on a particular new skill (e.g., converting a novel acoustic sequence into a novel articulatory motor sequence). When tested immediately after training, performance of the new skill will be excellent. When the network subsequently receives “refresher training” in its old knowledge repertoire, however, performance of the new skill will rapidly decline (catastrophic degradation) (McClelland et al., 1995). On the

other hand, with distributed practice, during which training in the new skill is interleaved with retraining of old skills, the new skill is retained. The explanation is this: With massed practice, connection strengths are altered in a relatively limited part of the network and in a way that supports the new skill at the expense of the old skills. With distributed practice, connection strengths are altered throughout the network in a way that optimizes encoding of attributes that both new and old skills have in common. Thus, distributed practice optimizes compatibility between new and old by distributing connection strength changes more widely through the network. This connectionist conceptualization can be viewed as the neural network embodiment of the structural context knowledge discussed above. The more widely disseminated instantiation of network knowledge of the new skill achieved with distributed practice enables better recall of the new skill under a variety of situations that do not exactly match the training situation. In a sense, with distributed practice, the network implicitly learns the rules underlying the new skill, whereas with massed practice, it learns the new skill by rote. Thus, this connectionist account also suggests that some distribution of procedural training may be superior to massed practice as traditionally defined.

Glenberg’s theory also can be logically reconciled with current knowledge of the neurobiology of declarative (fact) memory acquisition. Declarative memory is acquired as episodic memory all at once, albeit with variable efficiency, through fast Hebbian learning in the hippocampus. Over time, to the extent that this knowledge has features in common with knowledge already represented in the cerebral cortex, it apparently is introduced gradually into cortical connectivity and, eventually, becomes hippocampally independent, a process referred to as “memory consolidation” (Alvarez & Squire, 1994; McClelland et al., 1995; Rolls & Treves, 1998; Squire & Zola-Morgan, 1991). Evidence is accumulating that the process of consolidation also occurs substantially during sleep (Stickgold & Walker, 2005; Walker & Stickgold, 2004). Thus, we can posit two mechanisms by which highly distributed training in declarative memory domains may enhance the likelihood of successful retrieval during retention testing: (1) It enhances the likelihood that structural and general context conditions at the time of test will share attributes with conditions at the time of learning, and (2) it increases the opportunity for memory consolidation (i.e., the conversion of episodic memory into semantic memory that is substantially independent of context effects). Because declarative memory acquisition is far less than 100% efficient, particularly in face of damaged cortical repositories for long-term memory, more paired exposure-consolidation events and more than one night of consolidation per exposure may achieve superior efficacy.

The spacing effect, reflected in the superiority of distributed over fully massed practice in inducing long-term memory, also has been observed in a number of relatively primitive

organisms, such as the sea snail *Aplysia*, goldfish, *Drosophila*, crabs, a nudibranch, and honeybees (Sutton, Ide, Masters, & Carew, 2002). In many of these experimental models, the spacing effect appears to reflect the differential impact of spacing on molecular mechanisms of synaptic change, including induction of cAMP-response element-binding protein, MAP kinase, and subsequent RNA and protein synthesis. Presently, it seems unlikely that such mechanisms underlie the differential effects of more versus less distributed training over days in humans, but this possibility cannot be ruled out entirely.

The Spacing Effect: Summary

A large body of evidence regarding the psychology and neurobiology of learning, as well as connectionist work, strongly supports the superiority of more over less distributed practice in promoting long-term retention. This spacing effect appears to apply to both declarative and procedural memory retention, but for somewhat different reasons and in incompletely understood ways. Distribution of training that engages declarative (but not procedural) memory mechanisms provides the opportunity to benefit from variation in general context attributes during the course of training, and it takes full advantage of hippocampal consolidation processes that are known to continue for years. The emerging importance of brain processes occurring during sleep for memory consolidation, however, both declarative and procedural, could indicate that distribution effects will turn out to be just as important for procedural memory retention.

Very few studies have examined the spacing effect in subjects with brain damage, however, and their results have been inconclusive. A number of other factors need to be considered in this population as well. Hillary and colleagues (2003) found a significant spacing effect on a word list-learning task in subjects with traumatic brain injury. Hochhalter, Overmier, Gasper, Bakke, and Holub (2005) found no such effect on either a pill name or a nonverbal sequence-learning task in subjects with dementia. Subjects with brain injury typically have a heterogeneous mix of deficits, variability in motivation and fatigability, and uneven support systems. The effect size of greater distribution of training thus may be too small to be of importance in the clinical population, and greater distribution may lead to greater long-term attenuation of gain than expected with less distributed practice. The potential advantages of more distributed practice may be outweighed by the effects of reduced concentration on therapy, loss of continuity, reduced practice between sessions, reduced involvement by caregivers, and reduced motivation. These factors may lead to a greater-than-expected disparity between outcomes at the end of the acquisition phase that mitigates the potential long-term advantage of more distributed practice. Only empirical studies can address these questions.

Structure and Context of Aphasia Therapy

In our preceding discussion of the spacing effect, we noted two major factors that might contribute to the relative advantage of more distributed training: (1) time for the evolution of neurobiologic processes, and (2) time for broadening of structural and general context. We have no good ideas for how to manipulate the neurobiologic processes. The broadening of structural and general context need not be left to time and accident, however; we could deliberately alter therapeutic programs in a way that will enhance structural and general context.

Structural context pertains to the content of individual therapy sessions. The spacing effect literature suggests that the richer and more variable the language contexts in a therapy session, the greater the variety of contexts in which any one fact or skill will be acquired and, therefore, the greater the likelihood of similarities between the language environment in one or more training sessions and the language environment at the time of recall, with an attendant increase in the probability of recall. We can therefore ask whether the typical current speech-language therapy session is as rich and varied as it could be, and whether we could achieve some benefits of the spacing effect by enhancing intra-session linguistic richness and variability without increasing the temporal distribution of therapy sessions.

General context pertains to the conditions of individual therapy sessions. The spacing effect literature suggests that the more variability in the general conditions in which individual therapy sessions are held, the greater will be the variety of conditions in which any one fact or skill is acquired and, therefore, the greater will be the likelihood of similarities between the therapy environment in one or more training sessions and the general environment at the time of recall, with an attendant increase in the probability of recall. We can therefore ask how much resemblance exists between the routine speech-language therapy environment and the environments in which the subject ultimately will be struggling day to day to use language to communicate. The physical environs, the people present, the mood of the subject, and strategizing by subject and caregivers between sessions all are factors to be considered. If greater similarity between general context conditions during therapy and during recall can be achieved, the need to distribute therapy over time possibly will be reduced at the same time that retention is enhanced. It also is worth noting that every successful recall by the subject that is overtly recognized by the subject and caregivers constitutes a continuation of the training process outside of therapy.

Stimulus Properties

More than 30 years ago, in a landmark paper, Craik and Lockhart (1972) argued from extensive experimental data that memory retention was strongly influenced by depth of

processing of the material presented. For example, a subject who is asked to count vowels in each of a series of presented words is likely to exhibit far poorer recall of these words than if he or she is asked to make a judgment about the meaning of each word. The concepts elaborated in this chapter enable us to define depth of processing in neural network terms. Counting vowels would require a distributed representation of the orthographic form of the word in a relatively restricted part of visual association cortices. Making a judgment about the meaning of a word is more likely to engage the full, multi-component distributed representation of the word (Fig. 26–3). This would set the stage for closure of long-loop cortical–hippocampal–cortical loops involving association cortices throughout the brain, not just those involving a limited portion of visual association cortices. The much larger number of connections that are susceptible to alteration with deep processing may provide the entire basis for the superior retention of “deeply encoded” items. It also is possible, however, that certain connections, such as those to cortices supporting limbic and predicative representations, are particularly important to long-term retention.

These observations suggest that measures taken to assure multi-component distributed representations of stimuli presented during language therapy may enhance retention. Raymer and colleagues (2006) provided evidence in support of this thesis in a study of noun and verb naming treatment in nine subjects with aphasia. In nearly all the subjects, learning was markedly enhanced when picture presentation was accompanied by a pantomime of the use of the object or the motion of the verb and the subject imitated the gesture as he or she repeated the name.

Feedback during Treatment

In the preceding sections, we have presented evidence that *all* the stimuli to which a subject is exposed during a therapeutic session have the potential for altering neural network connectivity and, hence, for being remembered in some form. The therapeutic goal, however, is to assure that the stimuli targeted by the therapist are particularly well established in neural connectivity in a way that will maximize the potential for retrieval at a later time. Among the many stimuli to which a subject is exposed during therapy are those that we might classify as feedback. We define “feedback” as substantive information regarding performance provided by the therapist to the subject.

Feedback can be divided into two categories: knowledge of results, and knowledge of performance. Feedback about results consists of information provided to subjects regarding the correctness of a response at the operational level (e.g., the phoneme, word, sentence, or intonation actually produced). Such feedback might consist of responses such as “Your answer was correct” or “Your answer was incorrect; here is the correct answer.” Feedback about performance

consists of information provided to subjects regarding attributes of their response that might help them to understand what was wrong with the response and what measures might be taken to improve it (Proctor & Dutta, 1995; Schmidt & Wrisberg, 2004). For example, in a lexical-semantic or semantic treatment program, the therapist might respond to an error with observations such as “The word you produced isn’t exactly correct but it is related in meaning to (or it is in the same category as) the correct word” or “I think you responded too quickly and ended up just repeating your answer to the last question.” In a phonologic treatment program, the therapist might seek to help subjects understand what components of the pharyngeal movement complex led to the error produced through the use of diagrams, mirrors, and palpation by subjects of their own lips and larynx. In a prosody treatment program, the therapist might show subjects the acoustic profile of their response (e.g., using Visipitch [Kay Elemetrics, Inc.]) to help the subject understand what attributes of his or her response were incorrect. Clearly, different therapies have different potential for the provision of feedback about results and performance, and motor therapies most readily lend themselves to feedback about performance (e.g., therapies for apraxia of speech or aprosodia). Any therapy in which there might be useful information in pattern of performance, however, such as semantic or syntactic therapy, might theoretically benefit from feedback about performance.

Knowledge of results generally has little potential for providing subjects with the insight regarding the causes of their errors that might engage them in the development of strategies to systematically correct them. Feedback about results provided to subjects one or more times later in a therapy session, however, or at subsequent sessions can serve to vary the structural and general context associated with that particular response and, thereby, contribute to retention, just as tests and detailed feedback about test performance can enhance retention of knowledge acquired in the classroom (via the spacing effect). Furthermore, if it is possible to provide subjects with graphic knowledge about the pattern of their responses over time, then with certain therapies this might help subjects to see a pattern in their errors and, thereby, develop a strategy for improving performance. This strategy will have the potential for directly enhancing future performance and, if encouraged, might become a useful general context attribute that may carry over to recall situations.

Knowledge of performance can benefit retention via all the mechanisms underlying the benefits of knowledge of results. In addition, it can help to focus subjects on the particular attributes of the performance that are contributing to error and to develop their own strategies, perhaps with the aid of counseling by the therapist (Proctor & Dutta, 1995; Schmidt & Wrisberg, 2004). Feedback about performance can be complicated, and considerable research will be needed to define optimal programs for individual subjects. If

feedback is too complex or is presented inadequately, it may overwhelm the subject. If feedback is too focused, it may inhibit the subject from developing an understanding of the pattern of response that is leading to error (Goodman & Wood, 2004). Feedback that guides the subject to responses within a target range may be more conducive to strategy formation and constructive responses (Schmidt & Wrisberg, 2004). If feedback is too immediate or frequent, it may inhibit self-evaluation, self-judgment, and strategy formation by the subject. Fading the amount of feedback about performance over time, delaying feedback, and presenting patterns in attributes of performance may put needed pressure on the subject to make the necessary changes, develop strategies, and see whether those strategies have been effective (Knock, Ballard, Robin, & Schmidt, 2000; Swinnen, Nicholson, Schmidt, & Shapiro, 1990; Weeks & Kordus, 1998; Winstein, Merians, & Sullivan, 1999; Winstein & Schmidt, 1990).

SPECIFIC REHABILITATIVE STRATEGIES

At this point, we have developed a conceptual PDP model of language processes that subsumes phonology, semantics, lexical-semantics, and grammar. We have carefully considered the types of knowledge implicit in the various components of this model, because these have strong implications for the types of therapy we might pursue in subjects with aphasia and for the success we might expect. We have drawn particular attention to the principle of generalization and the mechanisms that might mediate it, because generalization will be absolutely essential if we are to succeed in the ultimate goal of therapy for aphasia—namely, improving the daily communicative lives of subjects. Finally, we have introduced evidence that the temporal spacing of therapy, structure and context of therapy sessions, stimulus properties, and type of feedback could profoundly influence long-term retention of therapeutic gain. We hope that our arguments have been cogent, but we concede that much of this is new theoretic territory and that vast work remains ahead to test these theories. As we will show below, aphasia treatment studies will be major contributors to this testing. Learning processes are implicit in the model (a by-product of the PDP principle that memory and processing involve the same neural network); therefore, tests of learning will be important to testing the hypotheses implicit in the model.

In this section, we will discuss some specific therapies for aphasia that receive theoretic justification from the model and, in some cases, have already provided support for the model. We hope that this discussion will help to consolidate some of the ideas we have already introduced and aid understanding by providing some concrete clinical examples. It will provide opportunities to introduce some new ideas about therapeutic approaches. Our discussion will be limited

to therapies within the scope of the model. We will not, for example, discuss apraxia of speech, which we view as a disorder stemming from damage to neural networks lying between articulatory motor representations (Fig. 26–1) and projection targets of motor cortex.

Phonologic and Lexical-Semantic Impairment

Our core model (Fig. 26–1) defines three domains of knowledge: (1) sequence (latent in the acoustic-articulatory motor pathway), (2) semantic (latent in concept representations), and (3) lexical-semantic (latent in the pattern associator networks linking concept representations to the acoustic-articulatory motor pathway). Impairment of lexical access (manifested as anomia and word finding difficulty), whether in internally generated language or in naming to confrontation, is by far the most common and debilitating component of aphasia. Treatment of impairment in lexical-semantic access must directly or indirectly retrain lexical-semantic knowledge—that is, the knowledge latent in the pathways between concept representations and articulatory motor representations (Fig. 26–1, pathways 1–2 and 4–3). Traditional approaches have confronted the problem of anomia head-on, through naming therapy (re-teaching of the names of things).¹¹ Our core model (Fig. 26–1), however, suggests that two additional approaches may be of value in selected subjects. If naming is failing because of damage to unimodal, polymodal, and supramodal association cortices supporting distributed concept representations, then it might be improved by redeveloping the knowledge underlying these concept representations (i.e., semantic therapy; see below). If naming is failing because of impaired lexical-semantic function, the presence of two pathways linking distributed concept representations with phonologic representations suggests two potential treatment strategies. The traditional naming therapy approach might logically be directed to subjects in whom the target is the direct concept representations—articulatory motor representations pathway (Fig. 26–1, pathway 1–2). This target would be most logical in subjects with essentially no evidence of phonologic function (poor repetition, reduced auditory verbal short-term memory, no phonemic paraphasias in spontaneous language or repetition, and no improvement in naming with phonemic cues),

¹¹ We use the term “naming therapy” to designate therapeutic approaches in which re-teaching the names of objects features prominently (see Fillingham, Hodgson, Sage, & Lambon Ralph, 2003, for a relatively recent inventory). Lexical-semantic knowledge (Fig. 26–1, pathways 1–2 and 4–3) has not heretofore been commonly recognized as a separate domain of knowledge. In fact, cognitive neuropsychological models of language function, such as that of Patterson and Shewell (1987; see Raymer and Gonzalez Rothi, Chapter 23), specifically encourage one to view naming impairments as stemming exclusively from deficits in semantics or deficits in phonologic word form rather than the “arrow” that connects them. Thus, “naming therapies” also typically involve a component of semantic or phonologic treatment (Howard, Patterson, Rankin, Orchard-Lisle, & Morton, 1985).

such as repetition conduction aphasia and some cases of deep dysphasia. On the other hand, if subjects have some evidence of phonologic function, albeit impaired, the presence of an indirect concept representations—acoustic/articulatory motor pathway suggests that phonologic therapy might improve naming. The presence of phonemic paraphasias in naming or repetition (especially nonword repetition) or evidence of improved naming with phonemic cueing would constitute evidence of some residual phonologic sequence knowledge and partial integrity of the acoustic-articulatory motor pathway.

Naming Therapy

Naming therapy, in our conceptualization, would be the only lexical-semantic therapy available to us in subjects with no phonologic function, and it might provide a useful complement to other techniques for treating lexical-semantic impairment, such as phonologic therapy (see below). The critical limitation is lack of potential for intrinsic generalization, because there is little resemblance between word meaning and word sound (except for onomatopoeic words and derivational forms). Consequently, practical and relatively inexpensive techniques will have to be developed to extend training to encompass useful working vocabularies and to carry out that training with sufficient intensity and over sufficient time to overcome the inefficiencies of naming therapies—in essence, building an extrinsic generalization process. Just how many words comprise a useful working vocabulary would need to be determined. Age-, gender-, and culture-specific vocabularies would need to be developed. An individualized, ongoing dynamic vocabulary list development project involving both subject and caregivers may be the best way to define such personal vocabularies. Once a target vocabulary starts to emerge, a training algorithm that does not require a therapist would then need to be developed, almost certainly involving caregivers and possibly using computers. This algorithm would then need to be executed over many months (and, perhaps, indefinitely) to enable maintenance and expansion of the vocabulary over time. The report of Basso (2003) is paradigmatic (but see also Hillis, 1998).

A word of caution is in order, however. In this discussion, access to articulatory motor representations during internally generated language and during naming to confrontation have been treated as if they were supported by identical neural structures. This assumption provided the basis for the implicit conclusion that if subjects are adequately trained in naming to confrontation, this capacity will generalize to internally generated language. This is not necessarily so, however. In fact, there appear to be two pathways by which we name to confrontation. In the best known (the “semantic route”), the object is seen, a concept representation is formed, and then an articulatory motor representation is elicited in one of the ways described in the foregoing.

The second pathway (the “direct route”) provides the basis for directly associating an object representation in visual association cortex with an articulatory motor representation—that is, without recourse to an intervening concept or any associated meaning. For example, if you are told that the symbol is a framezoid, then if you are later shown this symbol , you will be able to provide the correct name despite the complete absence of any meaning beyond the visual configuration. Two clinical syndromes, reflecting a double dissociation, provide support for this two-pathway confrontation naming hypothesis. Severe damage to the direct route and partial damage to the indirect route presumably provide the basis for optic aphasia; subjects with this disorder exhibit some knowledge of the object they are looking at but cannot name it. Typically, they can name the object given a definition and have relatively preserved lexical access during internally generated language (Bauer & Demery, 2003). Severe damage to the semantic route with relative preservation of the direct route presumably provides the basis for nonoptic aphasia (Shuren & Heilman, 1993). Subjects with this disorder may have difficulty describing attributes or functions of objects they see but can name them with relative facility. They typically exhibit impaired lexical access during internally generated language, presumably because of associated damage to the neural basis for concept representations. Thus, we see the risk latent in naming therapy: It might train the direct route without impacting the semantic route, the route invoking concept representations, which a subject must employ in internally generated language. The extent to which this might occur is unknown; it might depend, in part, on the degree of semantic impairment that is present. To the extent that it does occur, it might be necessary to complement confrontation naming therapy with naming to definition therapy; to train names in the context of sentences, thereby increasing the probability that concept representations will be engaged; or to provide sufficient semantic therapy to assure that the subject adopts a semantic set (see below).

Phonologic Sequence Therapy

The use of phonologic sequence therapy in the treatment of lexical-semantic deficits (specifically, impaired lexical access in internally generated language) is predicated on the existence of the indirect pathway from concepts to articulatory motor representations (Fig. 16–1, pathway 4–3), a pathway that takes advantage of the phonologic sequence knowledge embedded in the acoustic-articulatory motor pattern associator. So long as some remnants of this pathway are left after a stroke (either in the damaged hemisphere or in the normal hemisphere)—that is, so long as there remain some existing phonologic sequence knowledge and some connections between neural networks supporting concept representations and the acoustic-articulatory motor pattern associators

supporting phonologic sequence knowledge—then it may be possible to improve word retrieval by enhancing phonologic sequence knowledge.

Support for this hypothesis comes from studies of language acquisition in young children. They first learn many of the various phonologic sequence regularities of their language (Gathercole, 1995; Gathercole & Martin, 1996). Subsequently, they learn to assemble these various sequences into combinations and to associate these combinations with concepts (meaning), enabling both word comprehension and word production. If this principle of language development also applies to language redevelopment after brain injury, it suggests two possibilities: (1) that effective retraining in phonologic sequence knowledge may generalize to all words containing the trained sequences, and (2) that once given an adequate repertoire of phonologic sequence knowledge during treatment, subjects with aphasia should be able to continue *after* therapy to enhance existing but inadequate connections between the substrate for concept representations and the substrate for phonologic sequence knowledge and to steadily rebuild their working vocabularies. It also is possible that training some phonologic sequences will generalize to other phonologic sequences (e.g., through shared distinctive feature and motor programming sequences).

We have recently completed a phase I study of phonologic sequence therapy for impaired lexical access (Kendall et al., in press). The operational goal of the treatment was to develop phoneme sequence knowledge, but one cannot hope to develop knowledge of sequences without neural instantiation of individual phonemes. The first phase of treatment therefore consisted of developing linked distributed representations of individual phonemes. If treatment were completely successful, insertion of any form of a phoneme into any given domain of the network would instantly generate distributed representations of all corresponding forms in all domains (conceptual, articulatory, acoustic, and orthographic).¹² For example, at the end of

completely successful training, insertion of the acoustic form of /b/ into the acoustic domain (by saying /b/ to the subject) would instantly lead to the generation of distributed representations of the articulatory form of /b/, a concept of /b/, and an orthographic representation corresponding to the letter “b” (Fig. 26–8 illustrates a mechanism by which orthographic representations might contribute to the process). Eventually, all the individual domain-specific distributed phoneme representations would be linked through the network into a multi-domain distributed representation of individual phonemes. The second phase of treatment consisted of training in the regularities of English phonologic sequences, first by inserting single syllables into the network and later by inserting two- or three-syllable nonwords into the network. Distributed representations were presumably generated in all domains and pathways of the network by this phonologic sequence input. One network, the acoustic-articulatory pattern associator network (Fig. 26–1, pathway 7–3), however, is uniquely equipped for accumulating knowledge of the regularities of phonologic sequences, because it is the only pattern associator in the phonologic network that is exposed to sequential input paired with sequential output. Thus, the second phase of treatment primarily involved building up phonologic sequence knowledge in the acoustic-articulatory pattern associator networks on the two sides of the brain.

The ultimate goal of the treatment was to enable naming via the indirect concepts–articulatory pathway (Fig. 26–1, pathway 4–3). Only the knowledge in pathway 7–3 of Figure 26–1 (not pathway 4), however, is enhanced by therapy. We assume two mechanisms by which training of only pathway 7–3, without explicit training of pathway 4, might enhance naming by the indirect pathway: (1) Training of pathway 7–3 enables better use of residual knowledge in pathway 4, and (2) training of pathway 7–3 provides adults with aphasia with a repertoire of phonologic sequences that they can then learn, *outside of therapy*, to combine and link to concept representations through further development of pathway 4. Further development of pathway 4 can occur because, when a subject hears a word, this simultaneously generates a concept representation corresponding to the meaning of the word and a phonologic sequence representation in pathway 7–3. The simultaneous engagement of these two representations enables Hebbian learning involving the connections in pathway 4 to occur. This Hebbian learning would provide the basis for continued growth in the ability to engage phonologic sequence knowledge by distributed concept representations to produce spoken words, just as appears to occur during normal language development in children.

Ten right-handed subjects (mean age, 52 years; mean time poststroke, 60 months) with anomic aphasia (Kertesz, 1982) received a total of 96 hours of therapy (2 hours/day,

¹² The validity of this statement requires considerable broadening of the traditional notion of concept representations (semantic knowledge). Two considerations support this broadening. First, meaning can be instantiated by very abbreviated knowledge of an object. For example, if told that a novel abstract symbol N is a framezoid, we will readily be able to name this symbol if we see it again. Our knowledge of this symbol will consist entirely of the memory of the visual image of the symbol that is stored in hippocampal and visual association cortex connectivity. This type of abbreviated semantic representation could be viewed as an extreme manifestation of the heterogeneity of semantic knowledge distribution that underlies the phenomenon of category-specific recognition impairments (Forde & Humphreys, 1999). Second, if we have phonological awareness, we clearly have knowledge of any given phoneme and can respond to queries about what letters it corresponds to, whether a heard sound corresponds to that phoneme, and so on. If our knowledge of phonemes were confined to their acoustic and articulatory representations, we would not be able to speak about them or make decisions involving them.

Figure 26–8. Connectionist model of phonologic processing. The core model (from Figure 26–1) is depicted in black. An elaboration of the model that includes networks supporting reading, depicted in gray, suggests a means by which letter and orthographic sequence knowledge introduced during the phonologic rehabilitation process might contribute to the development of phonologic awareness (conceptualization of discrete phonemes) and to phonologic sequence knowledge, and vice versa. (From Kendall, D. L., Rosenbek, J. C., Heilman, K. M., Conway, T. W., Klenberg, K., Gonzalez Rothi, L. J., et al. (in press). Phoneme-based rehabilitation of anomia in aphasia; Brain and Language with permission.)

4 days/week, for 12 weeks) using a modified version of the Lindamood Phoneme Sequencing Program (Lindamood & Lindamood, 1998). The group results are summarized in Tables 26–3 and 26–4. One week after completion of therapy, they demonstrated significant gains on the outcome measures most directly related to the treatment (CTOPP-PA, CTOPP-APA, and LAC); the gain on the LAC remained significant 3 months later. Subjects also demonstrated significant gains on the primary outcome measure, the Object-Action Naming Test, 1 week after completion of therapy and significant gains on the Boston Naming Test and the Controlled Oral Word Association Test 3 months after completion of therapy. Because the treatment involved no training of words, these results suggest generalization. Furthermore, the increase in Boston Naming Test and Controlled Oral Word Association Test scores between completion of therapy and 3 months later suggests that continued acquisition of lexical-semantic knowledge (Fig. 26–1, pathway 4-3) occurred after conclusion of therapy (i.e., evidence of extrinsic generalization).

This was a phase I investigation. The results suggest that a phonologic sequence therapy can be used to treat lexical-semantic deficits and provide support for the model that motivated the study, but they are not remotely definitive. If this therapy is to be viable, it must be refined and made considerably more efficient, predictors of response and predictors of extrinsic generalization need to be better

understood, and better measures of daily communication need to be employed.

Semantic Impairment

In a PDP conceptualization, anomia, to the extent that it results from semantic impairment, reflects insufficient engagement of representations of the critical features that distinguish concepts from each other (see Raymer & Rothi, 2000, for detection and quantitation of semantic impairment). The goal of therapy is to alter network connectivity such that these distinguishing features are more reliably engaged at the same time that features shared with other items are relatively disengaged. The left hemisphere perisylvian lesions that commonly are responsible for aphasia and its associated anomia frequently do not involve much of the association cortices that provide the basis for semantic representations. They may, however, damage Brodmann's area 37 and surrounding regions in the posterior temporal cortex (Fig. 26–5), which appear to provide the interface between cortices supporting semantic representations and the dominant perisylvian language cortex (producing anomia as a disconnection syndrome). One might naturally conclude that a lexical-semantic therapy is the best strategy to retrain the knowledge lost in the disconnection. To the extent that the subject has the potential for engaging right hemisphere mechanisms, semantic therapy might aid anomia in all

TABLE 26-3

Acquisition and Retention Data from Before and After Phonologic Sequence Therapy

Immediately Post-Treatment Termination – Pre-Treatment (Acquisition)

(From Kendall, D. L., Rosenbek, J. C., Heilman, K. M., Conway, T. W., Klenberg, K., Gonzalez Rothi, L. J., et al. (in press). Phoneme-based rehabilitation of anomia in aphasia; Brain and Language with permission.)

affected subjects by training up inadequately trained right brain cortices supporting semantic representations. In this way, semantic therapy might have very broad applicability to the treatment of aphasia associated with significant anomia.

A variety of approaches to semantic therapy have been employed with some success (Raymer & Rothi, 2000). These have included:

1. Word-picture matching tasks using semantically related foils.
2. Answering yes/no questions about semantic features of pictured objects.
3. Semantic sorting of objects.
4. Variously cued matching of semantic associates as the number and relatedness of semantic foils is increased.
5. Correction of naming errors by provision of additional semantic information that distinguishes the erroneous response from the correct response.
6. Systematic training in the semantic features of objects.

Unlike naming therapy directed at lexical-semantic deficits, therapy directed to more purely semantic deficits might be expected to intrinsically generalize substantially, because refining featural relationships of trained items (the regularities in the knowledge implicit in the network) will benefit naming of untrained items to the extent that they share some of these featural relationships (Plaut, 1996). Counter-intuitively, training on a spectrum of unusual exemplars of a category can be more effective than training on typical exemplars in inducing generalization (Plaut, 1996). This is because unusual exemplars convey information about both the core regularities defining the category, which help to distinguish it from other categories, and the greater range of regularities that are crucial in distinguishing all the different within-category exemplars from each other. Recent clinical work has confirmed this concept (Kiran & Thompson, 2003).

Even a damaged network still contains a great deal of information, so the task of therapy is to refine network knowledge rather than to reestablish it (Plaut, 1996). The distributed nature of semantics may provide some rationale for the targeting of semantic therapy at particular representational domains (e.g., representations with a substantial visual component in subjects with selective deficits in naming living things). Individualization of vocabulary development, as in therapy for lexical-semantic impairment (see above), also would be needed.

The potential for generalization using current semantic therapeutic techniques appears to be very modest unless the scope of intrinsic generalization can be expanded (and, thereby, impact a significant portion of the semantic domain used in daily life) or mechanisms for promoting extrinsic generalization can be developed. Broad intrinsic generalization is difficult to achieve for most semantic therapies, because their principle aim is to enlarge knowledge of the semantic attributes of single items, one item at a time. The

extent to which this leads to incorporation of semantic features shared with other entities is largely a matter of chance. Knowledge of particular semantic domains (e.g., animals) might usefully be fleshed out in this way, especially through presentation of atypical exemplars (see above) (Kiran & Thompson, 2003; Plaut, 1996), but semantic knowledge that spans the breadth of daily life is difficult to achieve with this approach. Recently, Edmonds, Nadeau and Kiran (in preparation) have developed an innovative and fundamentally broader approach, in which therapy focuses on verb arguments. It takes advantage of the fact that many verbs admit a very broad range of possibilities for both agent and patient, thereby providing an opportunity for highly diverse modifications of the distributed concept representations of agent and patient as well as engagement of atypical exemplars of agent and patient. In this way, the therapy vastly expands the spectrum of semantic features that are incorporated in the training. The therapy also provides subjects with the opportunity to draw exemplars from daily life so long as they are acceptable agents or patients for the verb being presented. Some details about the therapy will help to illustrate.

In the first phase of therapy, subjects were presented with 10 individual verbs (e.g., “write”), one at a time, and tasked with producing three agents for each verb (e.g., author, journalist, and mother) or three patients for each verb (e.g., story, articles, and to-do list) while being cued with who or what questions. They then had to create suitable agent/patient pairs (e.g., author/story). If necessary, subjects were semantically cued through provision of appropriate targets mixed in with foils. Subjects also were asked to produce one personal response (e.g., husband/songs). In the second phase of therapy, subjects were tasked with answering when, where, and why questions about particular agent/patient pairs (an approach that might particularly invite responses related to the subject’s own life, thereby facilitating generalization to daily life). In the third phase of treatment, subjects were read 12 sentences containing the target verb (three semantically correct, three containing an inappropriate agent, three containing an inappropriate patient, and three semantically correct but with agent and patient reversed). A fourth phase replicated phase 1 but without cueing. Four subjects received 2 hours of therapy per week for 4 to 6 weeks in a single-subject, multiple-baseline design. Results of therapy on measures reflecting intrinsic generalization are presented in Table 26–5. Although clearly this therapy needs to be tested in larger populations, predictors of response identified, and impact on measures of language function in daily life established, these results are very promising. They suggest that a therapy engineered to develop semantic representations in a particularly broad way, and in a way that allows subjects to explicitly connect the content of therapy to their daily lives, may achieve impressive results. The design of the therapy suggests that these results were achieved through intrinsic generalization, but of course, one cannot rule out contributions

TABLE 26-5

Results of a Broad Semantic Therapy

Subject	Aphasia Type	WAB		BNT (%)		Connected Speech*	
		Pre-Treatment	Post-Treatment	Pre-Treatment	Post-Treatment	Pre-Treatment	Post-Treatment
1	TM	76.4	82.5	71.7	81.7	52.0	82.1
2	TM	78.5	86.4	86.7	91.7	50.9	67.8
3	Conduction	73.8	81.2	40.7	58.3	62.5	90.8
4	Conduction	70.6	82.3	44.0	68.0	50.4	52.8

WAB = Western Aphasia Battery (Kertesz, 1982); BNT = Boston Naming Test (Kaplan, Goodglass, Weintraub, & Segal, 1983); TM = Transcortical motor.

* Percentage of sentences that contained subject and verb, with or without object, and were relevant to the topic. Connected speech from picture description test of the Western Aphasia Battery, the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 2000), and the Cinderella story.

(From Edmonds, L. A., Nadeau, S. E., & Kiran, S. (in preparation). Effect of verb network strengthening treatment (vnest) on sentence production in persons with aphasia; with permission.)

from extrinsic, contextual, and mechanistic generalization mechanisms.

In our previous discussion of extrinsic generalization, we alluded to results of a trial of semantic therapy we performed that suggested that subjects with evidence of intact frontal systems function, despite the relatively modest potential for intrinsic generalization in the therapy we used, were the only ones who exhibited extensive generalization as well as gain in daily communication, as reflected in the American Speech-Language-Hearing Association Functional Aphasia Quotient (Nadeau & Kendall, 2006). These results, though very preliminary, suggest that more attention should perhaps be devoted to explicitly developing extrinsic generalization techniques on which subjects can be trained and monitored after completion of therapy.

Grammatical Impairment

For subjects who have good lexical-semantic function, impairment in grammatical function may represent only a modest handicap and, therefore, provides relatively less motivation for language therapy compared with lexical-semantic deficits. Assuming that therapy for grammatical impairment is desired, we have identified a number of facilities underlying grammatical function that may be logical targets of therapy:

- Capacity for arbitrary modification of single-noun concept representations.
- Capacity for simultaneous endogenous generation of multiple-noun concept representations.
- Capacity for maintenance of memory of the immediately preceding discourse.
- Capacity for manipulation of multiple related, modified noun concept representations to fit the particular situation.
- Multi-word sequence knowledge (underlying grammatical morphology and phrase structure rules).

The essential neural processes underlying these capacities have not yet been well defined. We suggest at least three:

1. Working memory (engagement of one or more concept representations and recall of immediately preceding linguistic history).
2. Concept manipulation (modification of individual concepts and adaptation of temporal order and content relationships of multiple concept representations to meet the situation at hand).
3. Sequence knowledge.

These essential neural processes are discussed in some detail in the following sections.

Working Memory

Working memory is an intrinsic brain function that appears to be particularly dependent on frontal lobe systems, and it likely is no accident that grammatical impairment is seen predominantly in subjects with major dominant frontal lesions. It is possible that treatment of working memory impairment relevant to language will have to be specific to particular language constructs. It may be, however, that generic improvement in working memory capacity will enable improvement in grammatical function. We suggest two possible strategies, one pharmacologic and one behavioral. The pharmacologic therapy, involving either methylphenidate or D-amphetamine, is motivated by experience with subjects with attention-deficit hyperactivity disorder (ADHD) (Heilman, Voeller, & Nadeau, 1991). These subjects appear to have a disorder involving the selection of plans for action. Plans for action may be formulated (often on the basis of memory or reflex) in more or less automatic response to environmental stimuli, a process that might be termed "reactive intention," which is driven primarily by temporoparietal and brain-stem systems. Alternatively, plans for action may be formulated deliberately as part of an

ongoing problem-solving strategy, a process that might be termed “intentional intention,” which is driven primarily by frontal systems. In this view, subjects with ADHD have a relative imbalance between reactive and intentional plan formulation such that their behavior is dominated by reactive planning. Treating these subjects with methylphenidate appears to redress this imbalance, enabling these subjects to achieve more balanced plan formulation and, most particularly, to sustain the intentional intention that is necessary to successfully complete tasks. We propose methylphenidate treatment of subjects with grammatical dysfunction, most particularly those with simplification of syntax and difficulty articulating complex concepts that might be related in part to working memory deficits. Because these subjects likely have multi-component deficits, methylphenidate treatment might have to be accompanied by behavioral treatment of associated deficits (see below) to demonstrate efficacy.

Our proposal for behavioral treatment of working memory deficits contributing to syntactic dysfunction also is predicated on the concept of something approaching a generic working memory capacity for language and that training of this capacity in one domain will generalize to other domains. Two tests commonly used to probe working memory, the Brown-Peterson paradigm (Peterson & Peterson, 1959) and the Paced Auditory Serial Addition Test (Gronwall, 1977), or PASAT, lend themselves to adaptation as training devices to enhance working memory capacity (the main problem being to reduce task difficulty such that subjects with aphasia can make some correct responses). Both tasks require the maintenance of two working memory compartments, one to support recall of a previous stimulus and one to support a computation (in direct analogy to the working memory demands of language). As we cautioned in the testing of methylphenidate effects, it may be necessary to couple working memory training with other behavioral training in subjects who have syntactic dysfunction before the benefit of working memory training becomes evident. The study of Stablum, Umiltà, Mogentale, Carlan, and Guerrini (2000) suggests that facility with operating two working memory compartments can be trained but provides no insight regarding how this might impact language. Those authors trained subjects with closed-head injury and subjects who have had anterior communicating artery aneurysm rupture on a dual-task paradigm in which the stimuli consisted of two letters, one above the other, placed to the right or left of the center of a display screen. Subjects had to indicate, first, the side of the stimulus (manual reaction time paradigm) and, second, whether the letters were the same or different (verbal report). The chief dependent measure was the reaction time cost of introducing the second task. With the training on this task, subjects showed significant improvement that was sustained over time (to the extent that they became indistinguishable from controls) together with comparable improvement in PASAT performance, which was

highly correlated with dual-task cost. The effect on PASAT performance suggests generalization of the trained dual-task skill to other content domains.

Concept Manipulation

Concept manipulation may have declarative components that render it domain specific, but we suspect that it predominantly represents a set of skills (i.e., nondeclarative memories akin to procedural memory) (see also Ullman, 2004). This means that effective training will require extensive practice and that there should be good generalization of skills across exemplars of particular manipulations. One would not necessarily expect generalization from one type of concept manipulation to another, however, any more than one would expect much generalization from training on serves in tennis to backhand skills. Thus, the extensive practice may need to involve a variety of constructions, no less than phonologic therapy must involve a substantial portion of the repertoire of native phonemic sequences to be successful. Thompson (2001) has shown explicitly that subjects can be trained on specific distributed concept manipulation skills and show generalization to different applications of these skills but not a generic improvement in concept manipulation capacity. Subjects with syntactic impairment trained to produce who questions showed generalization to production of what questions (both involve a verb that requires an agent and a theme) but not to production of when or where questions (in which the verb does not take a theme but may take an adjunctive phrase, e.g., “He is sleeping in the bedroom” and “Where is he sleeping?”). Subjects trained to produce when questions showed generalization to where questions, which also involve verbs that take adjunctive phrases, but not to who or what questions. None of these subjects showed generalization to passive-voice sentence production. Notably, subjects trained on more complex variants of a particular distributed concept manipulation (e.g., cleft object constructions) showed generalization to simpler variants of the same manipulation (e.g., who questions) but not vice versa (Thompson et al., 2003). This suggests that training on more complex variants may constitute a more efficient therapeutic approach. What constitutes a useful repertoire of syntactic skills has not been defined, much less the extended line of therapies that would be needed to train enough of these skills to make a clinically significant difference.

Word Sequence Knowledge

To the extent that multi-word sequence knowledge is like phonologic sequence knowledge, it is procedural in nature and will require extensive practice. At first glance, it might seem that this training process would require repeated exposure to an almost infinite number of word sequences. As discussed above, however, this may not be so, because the

essential memories that are being acquired are between word classes (e.g., noun, verb, and adjective) rather than between word exemplars. To the extent that word class knowledge is incorporated in distributed concept representations and their modifications, which are relatively less susceptible to the effects of discrete lesions, the size of the training task will be reduced.

Constraint-Induced Language Therapy

Up to this point, we have discussed language rehabilitation strategies that are precisely targeted at specific deficits. They are predicated on careful evaluation of the various components of the subject's aphasia, identification of the salient neural system deficits, and design of a specific treatment that takes into account the underlying mechanisms. The achievement of success with such therapies not only is clinically important but also yields scientific information about the neural basis of language processes (see, e.g., Thompson, 2001). Much work remains to refine these therapies, improve efficacy, identify predictors of response, develop variations applicable to different profiles of impairment, and fully explore their potential for elucidating the neural basis of language processes. Much further work also is in order to translate them into approaches that substantially improve the communicative lives of subjects. This will require further study of mechanisms underlying generalization (Table 26–2). Up to this point in our discussion of specific types of therapy, we have focused primarily on intrinsic and extrinsic generalization mechanisms. Any of the therapies discussed also could benefit from socially mediated generalization. In addition, any of the therapies discussed could, to one degree or another, engage a particular type of mechanistic generalization—namely, the development of an intentional bias to use language in lieu of other communicative techniques developed to compensate for aphasia. Constraint-induced language therapy (Maher et al., 2003; Meinzer et al., 2005; Pulvermüller et al., 2001) represents an approach in which the primary aim is to develop intentional bias to use language.

Constraint-induced language therapy seeks to engage subjects in intensive language production by absolutely limiting their opportunities for communication to spoken language (the constraint) and placing them in situations (e.g., partially scripted scenarios, games, or problem-solving tasks) that absolutely require verbally mediated collaboration with others, thus placing considerable pressure on subjects to speak at length. It is inspired by constraint-induced movement therapy, in which the goal is to overcome intentional bias in subjects with stroke to use the normal hand by engaging them in intensive functional task practice with the impaired hand, typically while the normal hand is constrained in a mitt. Constraint-induced language therapy does not seek to develop a corpus of language knowledge that might subserve intrinsic generalization. Its goal is nar-

rowly construed as developing an intentional bias to use language. The efficacy reported in published trials has been sufficient to encourage further research. The most immediate challenge is how to design the process and content of therapeutic sessions to maximize efficacy and efficiency. The recruitment of caregivers into the process might provide a means of engaging extrinsic generalization, contextual generalization, and socially mediated generalization. There is nothing about constraint-induced language therapy per se that precludes incorporation of a program that would engage mechanisms of intrinsic generalization. Thus, for example, a semantic therapy could be pursued in a constraint-induced language therapy format.

Errorless Learning

Therapy employing an errorless learning feature has recently achieved some popularity as an approach to speech-language therapy (for review, see Fillingham et al., 2003). Essentially the same therapy goes under the guise of repetition priming (Best, Herbert, Hickin, Osborne, & Howard, 2002; Patterson, Purell, & Morton, 1983; Raymer, Thompson, Jacobs, & Le Grand, 1993) and its variant, contextual repetition priming (Martin, Fink, & Laine, 2004), although the principles that motivate repetition priming treatment are quite different. Here, we consider the neural rationale for treatments seeking errorless learning.

The efficacy of errorless learning was first demonstrated in studies of pigeons; later studies of human subjects with severe learning disabilities provided some further support for the concept (Jones & Eayrs, 1992). In 1994, Boddey and Wilson applied it for the first time to subjects with acquired brain damage (i.e., subjects with severe anterograde amnesia). The experimental paradigm was somewhat contrived: Subjects were presented with the first two letters of a five-letter word. In the errorful condition, they had to make three guesses regarding the word before being told the correct answer, which they were instructed to write down. In the errorless condition, they were immediately told the correct answer. Subjects trained in the errorless condition showed better retention of word knowledge given the two-letter cues. Baddeley and Wilson interpreted this as supporting their hypothesis that these patients, with their severe impairment in explicit memory function, were relying substantially on implicit memory function for performance of the task. Their results have since been replicated many times, but the implicit memory hypothesis has been successfully challenged (Hunkin, Squires, Parkin, & Tidy, 1998). Errorless learning techniques have since been tried in amnesic populations for a variety of tasks, including associating names with photos of unfamiliar people (with or without cueing with the first letter of the names), learning routes around a room defined in relationship to objects in the room, learning a route through an array of patterned stepping stones, and

programming an electronic organizer (Evans et al., 2000). Errorless learning techniques facilitated cued learning of names of unfamiliar people, but it provided either no clinically important advantage or worse performance on these other tasks. A review of naming therapies for aphasia found no advantage for treatments employing error reduction techniques; too few studies have employed errorless techniques to draw any conclusions (Fillingham et al., 2003).

The errorless learning literature does not provide an adequate basis for drawing conclusions about the mechanisms by which errorless learning might or might not provide benefit, nor about the deficit domains in which it might be effective. Most important, it does not provide information regarding the potential benefit of errorless learning for patients with intact memory function who already have partial knowledge of the correct answer (simply not enough knowledge to produce the correct response reliably). This is the situation in patients with aphasia. Nevertheless, errorless learning techniques have recently gained some popularity in treatment of aphasia, at least in part on the presumption that errorless learning obeys Hebbian principles (i.e., that to the extent two connected neurons are coactive, the strength of the synaptic connection between them will increase). For example, in naming therapy, it is posited that if subjects are asked to name an object and are left to their own devices and arrive at the wrong answer, an opportunity exists for strengthening of connections between that particular concept representation and the articulatory motor representation of that wrong answer. Two immediate problems can be seen with this conceptualization. First, Hebbian learning (and the related synaptic process, long-term potentiation) is a complex and incompletely understood process that requires, among other things, a burst of acetylcholine delivered to the cortex by the nucleus basalis or to the hippocampus by the medial septal nuclei that signals the neurons in question that the activity in which they are engaged is important (Kilgard & Merzenich, 1998). This will occur only if the behavior is rewarded, which a wrong answer would not be.¹³ Second, in naming therapy, the Hebbian learning rationale will apply only to the extent that auditory input delivered by the therapist elicits the correct articulatory motor representation. If the subject has no phonologic function (e.g., has repetition conduction aphasia), then simultaneous auditory presentation of the object name will not be of value, because auditory input will not elicit an articulatory motor representation except via the concept representation. If repetition commonly is associated with

production of phonemic paraphasias, then simultaneous auditory presentation might actually be dysfunctional, because it might lead to production of incorrect patterns of activity in the cortex supporting articulatory motor representations.

Under what circumstances might an errorless learning paradigm be beneficial or harmful? Because of the limitations of the literature, we can only offer some tentative hypotheses. Errorless learning might be beneficial in naming therapy (with the caveats noted in the foregoing) not so much because of its impact on Hebbian learning but, rather, because it can markedly speed therapy and cut through long, frustrating word searches and perseverative responses, thereby vastly increasing the number of stimuli presented and reducing patient frustration. In naming therapy directed at lexical-semantic deficits, only one answer is correct, and no evident reason exists why permitting the patient to struggle might be beneficial. The same may be true for phonologic therapy directed at disorders of phonemic sequencing. For other therapies, however, such as those for speech apraxia and semantic deficits, the therapeutic goal is for the patient to re-differentiate functions that have become de-differentiated because of injury. In apraxia of speech, a reduced number of crude motor responses must be differentiated into a larger number of more refined and specific responses. With semantic deficits, the various exemplars of semantic categories must be re-differentiated from the central tendency of those categories (e.g., from the general concept of “dogness” must be differentiated specific breeds of dogs and particular individual dogs, as well as wolves, coyotes, foxes, hyenas and dingoes). In the realm of syntax, there typically exist many different syntactic approaches (multiple concept manipulations) to any particular communicative problem. In patients with syntactic impairment, as in patents with semantic impairment or apraxia of speech, there may be value in allowing the patient to produce responses with successive corrections by the therapist. Feedback of some type is essential. Thus, we may tentatively posit that errorless learning may be of value when only one response is correct, as in treatment of lexical-semantic deficits, but also that it may be less effective or deleterious when re-differentiation of procedural or semantic representations is needed. These (yet unproven) hypotheses are broadly congruent with the conclusions drawn by Jones and Eays (1992) in their critique of errorless learning.

In considering errorful learning techniques as an approach to treatment of apraxia of speech or semantic or syntactic deficits, an important distinction needs to be made. Truly errorless learning is defined as learning in an environment in which the goal is to completely prevent erroneous responses. Errorful learning, however, need not be completely unconstrained. Guidelines, cues, vanishing cues, and prompts (error reduction techniques) can be used to constrain the domain of error, improving subject focus in a way

¹³ The implicit memory hypothesis is important here, because it is possible—even likely—that implicit memories can be established in the absence of reward. Thus, the evidence against the implicit memory hypothesis provided by Hunkin and colleagues (1998) is directly relevant to the key hypothesis that motivates errorless learning therapies.

that will permit the subject to learn from the pattern of errors and prevent the subject from becoming overwhelmed or frustrated. In short, a profitable middle ground likely exists between errorless learning and wild guessing. Defining this middle ground and adapting it to individual subjects may be a useful topic for speech-language therapy research.

Finally, studies of neural network reorganization in the somatosensory cortex (Buonomano & Merzenich, 1998) suggest that for change to occur in response to somatosensory stimuli, those stimuli must be attended. If this is true throughout the brain, including the association cortices supporting language function, it suggests that in errorless learning paradigms, the target of the subject's attention must be adequately constrained. This should pose no major difficulty at the single-word level (barring subject fatigue and given a task paradigm that sustains subject interest, attention, and effort), but it may be a problem at the sentence level. If whole sentences are provided by the therapist in pursuit of errorless syntactic therapy, it is quite possible that the subject will attend to the phonologic sequence (i.e., performing repetition) rather than to the syntactic structure.

CONCLUSION

In this review, we have introduced a general neural network conceptualization of spoken language processes, attempting to be as specific as possible about the nature of the knowledge represented in the various domains and the neural principles underlying modification of that knowledge. A substantial body of evidence supports certain aspects of this conceptualization (particularly phonology); other aspects are somewhat more speculative (e.g., grammar). Nevertheless, all aspects of our model represent hypotheses only. The particular value of these hypotheses is that experiments testing them will challenge not just a conceptualization of language function but also a conceptualization of the neural network organization of the brain, because we have avidly sought to make these hypotheses neurally plausible (O'Reilly, 1998). As tentative as these hypotheses are, they make many specific predictions regarding approaches to be taken in language therapy, as we have discussed throughout this chapter. The success or failure of implementation of these therapeutic strategies will serve to further test these underlying hypotheses and will add specificity to their predictions (see, e.g., Thompson, 2001). In all of this, we have strived to show how conceptualizing aphasic language and language therapy in relation to neural processes, as opposed to strictly empirically defined processes, contributes to the scientific richness of linguistic inquiry.

We have given major emphasis to mechanisms of generalization, both because of their intrinsic scientific interest and because extensive generalization must occur if language therapy is to impact the daily communicative lives of subjects.

We also have devoted substantial space to the educational psychology literature, because language therapy engages normal learning mechanisms and it behooves us to determine ways of conducting language therapy that will maximize retention of knowledge in forms that are most readily retrievable by subjects in daily life.

FUTURE TRENDS

Much of what we have discussed finds support in research extending over decades (120 years in the case of the psychology of learning). Many of the ideas are new, however, and will require much study for validation. Several specific paths of research inquiry can be defined:

- Further study of neural network models of language function.
- Further study of specific language therapies with high potential for intrinsic generalization (e.g., phonologic, semantic, and syntactic).
- Further study of therapies predicated on mechanistic generalization (e.g., redevelopment of working memory capacity and constraint-induced language therapy).
- Further study of mechanisms of generalization per se.
- Further study of the impact of temporal distribution of training; structure and context of treatment sessions; properties of stimuli; and nature of feedback on long-term retention.
- Further study of error reduction and errorless learning techniques.

KEY POINTS

1. Neural networks are the essential unit of brain function.
2. Neural networks simultaneously support knowledge (long-term memory; as connection strengths), working memory (as patterns of neural activity), and processing (as transformation of input patterns into output patterns).
3. Deficits resulting from brain lesions stem predominantly from loss of knowledge represented in the synapses (neural connections) that were destroyed, although disconnection from sources of knowledge (loss of access) may play an important role in certain syndromes, often referred to as "disconnection syndromes" (e.g., alexia without agraphia because of lesions of the left occipital cortex and the splenium of the corpus callosum).
4. PDP models are particularly appealing, because their structure emulates that of the brain. They can

learn naturally from experience, as does the brain, and implicit rules emerge that represent regularities in the knowledge acquired. PDP models enable us to logically account for complex behavior in terms of brain microstructure, have a natural ability to capture bottom-up/top-down processing effects, and have been remarkably successful at emulating the behaviors of normal subjects and those with brain damage.

5. Processes underlying phonologic and lexical-semantic function can be defined in a PDP model supporting phonologic sequence, lexical-semantic, and semantic knowledge in a way that accounts for nearly all the findings of psycholinguistic studies on slips of the tongue in normal subjects and phonologic, lexical-semantic and semantic errors in subjects with aphasia.
6. Grammar can be conceptualized in PDP terms. The picture that emerges is one of multiple distributed concept representations in association cortices throughout the brain that are modified in various ways, often reciprocally, by verbs, adjectives, and prepositions. Grammatical function is based on the brain capacity for simultaneously supporting multiple distributed concept representations (as working memory), the ready capacity of PDP systems to accommodate an almost arbitrarily large number of modifications of distributed concept representations, acquired knowledge of word sequence regularities, and acquired skill in manipulating concept representations.
7. Semantic knowledge and, possibly, lexical-semantic knowledge represent fact memories that depend on hippocampal function for their acquisition. Phonetics, phonologic sequence and (to a substantial extent) word sequence knowledge, and grammatical skill likely represent procedural knowledge acquired incrementally via hippocampally independent mechanisms.
8. Generalization is the process by which the effects of speech-language therapy extend to material or circumstances not explicitly trained during therapy sessions. A number of generalization mechanisms can be defined, including intrinsic, cross-function, extrinsic, mechanistic, substrate mediated, contextual, and socially mediated.
9. Extensive studies conducted over the past 100 years indicate that a given amount of knowledge taught over a greater period of time is more likely to be retained (i.e., the “spacing effect”). This effect can be accounted for either by an interaction between conditions at the time of acquisition and conditions at the time of retrieval or by the effects of sleep

processes on the consolidation of declarative and procedural memory.

10. Retention of knowledge acquired during speech-language therapy can potentially be increased not only by greater spacing of sessions but also by increasing the commonalities between the conditions of therapy and the normal living conditions of the subjects being treated.
11. Measures taken during therapy to achieve maximal extent of representation of stimuli in cerebral cortical networks (e.g., by engaging visual, auditory, tactile, predicative, and gestural representations of the object) may benefit learning by maximizing the number of neural connections that are engaged and, therefore, susceptible to modification (the depth of processing effect of Craik and Lockhart, 1972).
12. The manner and form in which feedback is provided during therapy may have a major impact on learning and retention.
13. Phonologic sequence therapy may provide a logical approach to many subjects with aphasia who have impaired lexical access, and it has the potential advantage of achieving effects that generalize widely, unlike “naming therapies.”
14. Verbs might be usefully employed in semantic therapy as an effective device to achieve maximally diverse modifications of distributed concept representations and highly atypical exemplars of agent and patient, thereby maximizing the potential for generalization.
15. Training of working memory capacity per se might benefit a number of components of grammatical function.
16. Research on retraining of such grammatical capacities as the ability to generate who, what, when, and where questions from declarative sentences provides support for the PDP conceptualization of syntax as a set of skills in manipulating distributed concept representations. Individual syntactic skills are not word specific but, rather, are specific to type of sentence structure.
17. Constraint-induced language therapy might usefully be employed to induce subjects with aphasia to redevelop a natural intention to use language in the various circumstances of daily life.
18. Although the idea that completely errorless learning techniques are beneficial in aphasia therapy has neither a theoretic nor an empirical basis, varying degrees of constraint on allowable errors may be of value, and the optimal degree of constraint likely will depend on the particular aphasic deficit being rehabilitated.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Discuss the evidence for and against the concept that aphasia reflects loss of access to knowledge rather than loss of the knowledge itself. How can this concept be reconciled with the extensive loss of neural connections that occurs with stroke? How do PDP models provide an alternative account for the evidence of partial preservation of language knowledge after stroke that has motivated the loss of access concept?
2. Discuss the various mechanisms of generalization of treatment effects and what could be done to promote these mechanisms.
3. Explain how a PDP model eliminates the need to posit the buffers and error correction devices frequently incorporated into information processing models of language.
4. Do language errors produced by subjects with aphasia support the concept of graceful degradation?
5. Discuss the ways in which a representation can be distributed. What unique properties does a network capable of supporting distributed representations confer? What are the implications of distributed semantic representations for the spectrum of category-specific naming errors?
6. Discuss the potential roles of sequence knowledge in language function.
7. Why is the traditional conceptualization of a lexicon not neurally plausible? Describe how PDP models can provide an alternate, neurally plausible account.
8. Why is it likely that we use two pathways, a predominantly whole-word pathway and a predominantly phonologic pathway, to name concepts?
9. By what mechanisms might phonemic paraphasic errors be produced?
10. Describe serial and parallel processing theories of language production, and consider how each accounts for the spectrum of observed language behavior.
11. Consider the pros and cons of Chomskian approaches to verbs and the PDP conceptualization of multi-argument verbs as “super-adjectives” that simultaneously achieve a lexical representation and act to produce reciprocal modification and binding of multiple distributed concept representations.
12. Discuss the various features of Broca’s aphasia in terms of the PDP conceptualization introduced in this chapter. Are there alternate, neurally plausible accounts for any of these features?
13. Why are phrase structure rules so infrequently violated in aphasia?
14. Discuss the various factors that constrain article use in different languages and how these might influence the relative frequency of omission errors (agrammatism) and paraphasic substitutions (paragrammatism).
15. Discuss the problems with the theory that lexical semantic knowledge represents declarative knowledge whose acquisition requires the hippocampus.
16. Discuss the relative advantages and disadvantages of procedural and declarative knowledge acquisition mechanisms for aphasia treatment.
17. Discuss potential advantages and disadvantages of more versus less temporally distributed treatment of aphasia. Are there alternative approaches that could be pursued that would achieve some of the potential benefits of more temporally distributed treatment sessions while retaining a relatively condensed schedule? What is likely to be an unavoidable consequence of more condensed scheduling?
18. Discuss the depth of learning concept of Craik and Lockart and how it might be relevant to aphasia therapy?
19. Discuss ways in which feedback might be given during aphasia therapy and their potential advantages and disadvantages.
20. The ability to translate concepts into spoken word form is essential to effective verbal communication. Discuss the various reasons that training a subject to name objects may have little impact on that subject’s ability to name concepts (both those corresponding to objects trained and those corresponding to objects that have not been trained).
21. Why might phonological sequence therapy, semantic therapy, and syntactic therapy generalize in ways that naming therapy cannot?
22. In what ways might improvement in working memory benefit grammatic function?
23. Consider ways that generalization of benefits from constraint induced language therapy might be increased.
24. Discuss the circumstances in which minimal and maximal constraint of error might be desirable in treatment of aphasia.

Chapter 27

Treatment of Syntactic and Morphologic Deficits in Agrammatic Aphasia: Treatment of Underlying Forms

Cynthia K. Thompson

OBJECTIVES

The objectives of this chapter are to present the background, methods, and efficacy data for two treatments for agrammatism. The generalization effects of these treatments to untrained structures and narrative discourse are emphasized. Neuroimaging data also are presented that show the effects of treatment on brain activity.

This chapter discusses two recently developed and researched treatments for sentence production (and comprehension) deficits in non-fluent, agrammatic aphasia. One treatment is designed for improving syntactic deficits and the other for improving grammatical morphology. Derived from mutually supportive linguistic and language processing theories, both treatments promote generalization using a “metalinguistic” training procedure, controlling the linguistic nature and complexity of structures trained based on the underlying representation of target structures. Two principles of generalization underlie these treatments: (1) generalization occurs to structures that are linguistically related to those trained but not to linguistically unrelated material, and (2) generalization is enhanced by beginning treatment with more complex rather than simple structures.

WHAT IS AGRAMMATISM?

Agrammatism is a symptom complex seen in the context of nonfluent (Broca’s) aphasia. Classically, the site of lesion is associated with the frontal opercular region, occupying Brodmann’s areas 44 and 45 adjacent cortical and subcortical regions (Damasio, 1991). Today, however, it is well known that agrammatic speech patterns can result from lesions

(both large and small) occupying these and other areas.¹ The disorder refers to a pattern of erroneous sentence production in which grammatical structure is diminished (or absent). Individuals with agrammatism often use strings of (primarily) content words and have greater difficulty producing verbs as compared to nouns (Kohn, Lorch, & Pearson, 1989; Kim & Thompson, 2000, 2004; Thompson et al., 1997; Zingeser & Berndt, 1990).

Even when individuals with agrammatic aphasia produce verbs, the structures in which they appear generally are simple, subject-verb-object (SVO) constructions (Caplan & Hanna, 1998; Goodglass, Christiansen, & Gallagher, 1993; Saffran, Berndt, & Schwartz, 1989). The *arguments* of the verb—that is, the participant roles required by the verb—also may be missing or mis-ordered around the verb. For example, verb-object (e.g., *fit her*) and subject-verb (e.g., *Shoe uh fit*) sequences are common. In the former, the *agent* is missing from subject position, and in the latter, the *theme* is missing from the object position. Notably, individuals with agrammatic aphasia have marked difficulty producing complex sentences in which noun phrases (NPs) have been moved out of their canonical order (i.e., SVO in English), such as “wh-” questions (e.g., *Cinderella where?* should be *Where is Cinderella?*) (Saffran et al., 1989; Thompson et al., 1995).

Another key problem in agrammatism is production of grammatical/functional morphology, including finite verb inflections (tense, agreement), complementizers (if, whether, that), and other free-standing morphemes (Benedet, Christiansen, & Goodglass, 1998; Bird, Franklin, & Howard,

¹ The lesion site associated with agrammatism can vary greatly. Vanier and Caplan (1990) reported lesions quantified by computed tomographic scans from 20 cross-linguistic cases of agrammatism, ranging from small lesions located in the frontal lobe or outside the frontal lobe, sparing the entirety of the perisylvian lateral cortex, to middle-sized lesions affecting both cortical and subcortical structures to large lesions affecting the entire perisylvian area and other structures in the distribution of the middle cerebral artery.

2002; Caramazza & Hillis, 1989; Druks & Carroll, 2005; Faroqi-Shah & Thompson, 2004; Goodglass, 1976; Menn & Obler, 1990). Either omission or substitution of these elements renders sentences ungrammatical (e.g., *Slipper fell* should be *The slipper is falling* or *The slipper fell*). Consider the following selected utterances produced by a 41-year-old gentleman with nonfluent Broca's aphasia illustrating many of the characteristics of agrammatic speech. He is telling the story of Cinderella:

Cinderella uh . . . scrubbing and uh . . . hard worker.
 Step fa . . . mother uh go . . . but no.
 Scrubbing uh uh whatchacallit uh uh working.
 Stepmother really ugly.
 Dress break . . . stepmother and now what dress?
 Mother Teresa . . . not exactly . . . uh uh magic godmother!
 Dress . . . beautiful and carriage where?
 I can uh . . . pumpkin and uh . . . servants and horse and beautiful carriage and so magic. But, better midnight . . . pumpkin carriage gone.
 Cinderella dance.
 Midnight uh clock uh Cinderella clock!
 Slipper fall.
 Prince can't uh uh stepmother fitting slipper?
 Cinderella where?
 Well locked.
 Sure enough fits because Cinderella uh . . . magic uh . . . girl.
 And probably uh prince and Cinderella marrying and happy.
 That's it.

Agrammatic aphasia also is associated with deficits in comprehension, although general descriptions of the disorder suggest that comprehension remains relatively spared (Goodglass, 1976; for historical review, see also de Blesser, 1987). These patients show particular difficulty comprehending noncanonical sentences, such as passive sentences and object relative clauses (e.g., *The artist was chased by the thief* or *The man saw the artist who the thief chased*), but less difficulty is noted in comprehending active sentences or those with subject relative clauses (e.g., *The thief chased the artist* or *The man saw the thief who chased the thief*) (Berndt, Mitchum, & Haendiges, 1996; Caplan & Hildebrandt, 1988; Grodzinsky, 1986). This pattern of comprehension impairment is referred to as "asyntactic comprehension." It is important to note that agrammatic patients often show particular difficulty with semantically reversible sentences (i.e., those in which two nouns are equally probable candidates for the thematic role of agent of the action).

THEORETIC UNDERPINNINGS

Several theories of agrammatism exist, both representational and processing. No one theory, however, accommodates deficits in both production and comprehension, and no one theory completely accommodates all available data regarding agrammatic speech. In this section, linguistic constructs

and theories that are most relevant to the treatment approaches described below are discussed.

Treatment of underlying forms (TUF), whether focused on syntactic or morphologic deficits, is based on representational (linguistic) theory (within the framework of generative syntax; see Chomsky 1986, 1993, 1995)² and processing accounts of language, which suggest that agrammatic impairments are caused by faulty processing or access to relevant linguistic representations. We begin with a representational description of the syntactic tree, which provides a hierarchy of nodes describing the relation among elements, both lexical and functional, that form clauses and sentences in the English language. Tree structures are abstract descriptions, but they provide a template for well-formed sentences against which observed patterns of sentence disruption in agrammatism can be compared.

The tree diagram shown in Figure 27-1, going from the top-down, includes the complementizer phrase (CP), which is comprised of two positions from which linguistic elements project: the specifier position (Spec, CP), which accommodates "wh-" words in sentences such as *Who did the hiker follow?*, and the head position (COMP), the site for complementizers such as *if*, *that*, and *whether* in sentences with embedded clauses such as *I wonder whether the team will play next week*.³ Thus, CP is crucial for complex sentences that often are impaired in agrammatism, like "wh-" questions and sentences with embeddings (e.g., complement clauses).

The next level is the inflection phrase (IP), which also has two major branches: the SPEC position (Spec, IP), and the INFL (the local head of IP). Spec, IP is the subject position as in *The lady chased the bartender at the party*.⁴ The subject in passive sentences such as *The bartender was chased by the lady at the party* also occupies Spec, IP. The INFL position contains finite verb inflections—that is, tense and agreement information. Some linguists suggest that all inflectional morphology is projected from IP (Bobaljik & Thráinsson, 1988), while others contend that IP is subdivided into pro-

² The theoretical constructs that we exploit are integral to Government-Binding Theory, the Principles and Parameters (P & P) frameworks, and the Minimalist Program (Chomsky, 1986, 1993, 1995; Marantz, 1995), but they also have their counterparts in other linguistic theories. For example, X-bar theory, subcategorization, and argument structure are part of Generalized Phrase Structure Grammar (GPSG) (Gazdar, Klein, Pullum, & Sag, 1985) and Lexical Functional Grammar (LFG) (Bresnan, 1992). Noncontinuous dependencies of the sort that are targeted in syntactic treatment also are considered in GPSG (e.g., the category SLASH, which effectively connects one part of the tree to another) and LFG (i.e., functional control).

³ COMP also is the landing site for auxiliary verb movement—for example, in yes/no questions such as *Are you going to the opera tonight?*

⁴ According to current theory, the subject is generated within the verb phrase (Koopman & Sportiche, 1991), and moves to Spec, CP.

Figure 27–1. General linguistic tree structure, illustrating positions for various structures in the English language. Shown are local trees headed by CP (complementizer phrase), IP (inflection phrase), and VP (verb phrase). Going from the top down, the *specifier* position of CP (Spec, CP) is the landing site for “wh-” words. The head of CP (C', COMP) is the position for complementizers, such as *if*, *that*, *whether*. The auxiliary verb in subject-auxiliary inversion (i.e., verb movement) also takes this position. The next level down is IP. Its *specifier* position (Spec, IP) is the subject position. The local head INFL contains verb tense and agreement information. Finally, verbs and other lexical material are generated in VP.

jections for a tense phrase (TP), negative phrase, and agreement phrase (AgrP) (Pollock, 1989).⁵ Because many agrammatic speakers have selective deficits producing verb inflections, the configuration of IP is relevant to treatment.

The next level in the tree is the verb phrase (VP). The VP is associated with basic lexical categories (e.g., nouns, verbs, adjectives, or adverbs). The main verb projects from the head of VP, and in its sister position are verb complements—that is, internal arguments of the verb—which can be either NPs (theme arguments) or CPs (sentential complements). Thus, the VP accommodates sentence elements that are impaired in agrammatism as discussed below.

Canonical Sentence Computation: The Role of the Verb

The *canonical* (usual) form of sentences in the English language is SVO, with the verb serving as the core of the sentence. Agrammatic speakers have difficulty producing verbs as well as the arguments that go with them, rendering their sentences ungrammatical. That is, the verb provides the scaffolding of grammatical sentences; without a verb, a word string does not qualify as a sentence. In addition, the verb selects and assigns associated syntactic and semantic features, including argument structure and thematic roles. These features also must be present in grammatical sentences. For example **the fairy Godmother fixes*. and **The step-sisters put Cinderella*. are ungrammatical, because all of the arguments of the verb are not represented.

Importantly, several types of verbs are defined by their syntactic and semantic features. Consider the following sentences:

1. Everyday, the parrot AGENT *laughs*
2. Everyday, the dancer AGENT *fixes* her shoes THEME
3. Everyday, the artist AGENT *puts* fresh flowers THEME in the studio GOAL

The verb *laugh* (sentence 1) is a one-argument (pure intransitive) verb. This means that only one participant role is required: agent. *Fix* is a two-argument verb as in sentence 2; it assigns two thematic roles: agent and theme. The verb *put* assigns three-arguments (agent, theme, and goal). Other verbs, such as *wonder*, *care*, *see*, or *believe*, are complement verbs that assign sentential complements as in sentence 4 below:

4. Everyday, the editor AGENT *wonders* whether the writer finished the article SENTENTIAL COMPLEMENT/INTERROGATIVE

Research in agrammatism shows that the number and type of arguments required by the verb influence production. As argument structure becomes more complex, production ability decreases: Three-argument verbs are more difficult to produce than two- or one-argument verbs, and when these verbs are produced in sentence contexts, obligatory arguments often are omitted. This pattern has been noted in English as well as in Dutch, German, Italian, and Hungarian agrammatic speakers (de Bleser & Kauschke, 2000; Jonkers & Bastiaanse, 1998; Kemmerer & Tranel, 2000; Kim & Thompson, 2000, 2004; Kiss 2000; Luzzatti et al., 2002; Thompson et al., 1997). Further, complement verbs such as *wonder* are difficult for patients with Broca's

⁵ The status of IP (i.e., split or unsplit) likely is language specific.

aphasia (Thompson et al., 1997), and intransitive unaccusative verbs such as *melt* and *amuse*-type psychological verbs, which involve complex syntactic and/or semantic computations, are more difficult to produce than agentive intransitive such as *sleep* and *admire*-type psychological verbs, which do not (Bastiaanse & van Zonneveld, 2005; Lee & Thompson, 2004; Thompson, 2003).

Some theories of agrammatic production attribute sentence deficits to verbs and verb argument structure. Bastiaanse and van Zonneveld (2005) found that speakers with Broca's aphasic are better at producing unaccusative verbs like *melt* in transitive sentence frames (e.g., *The sun melted the snowman*) than in intransitive frames (e.g., *The snowman melted*), because the latter word order involves movement of the theme argument (*snowman*) to the subject position of the sentence. Similarly, the Argument Structure Complexity Hypothesis suggests that verbs with more complex argument structure (considering both the number and type of arguments in the lexical entry of the verb) are more difficult than those with less complex argument structure, because the former entail greater phrase structure building demands (Thompson, 2003). Other theories point to representational deficits, such as the Tree Pruning Hypothesis (TPH; discussed in detail below) (Friedmann 2002; Friedmann & Grodzinsky 1997), whereas resource-based accounts suggest that agrammatism results from reduced short-term working memory or limited processing capacity (Goodglass 1976; Kolk 1987; Kolk & Heeschen, 1990).

Phrase Structure Building

Theoretic accounts of phrase structure building suggest that the verb guides this process. In the Minimalist Program, a syntactic operation, Merge, serves to amalgamate two categories to yield a higher-order category, and a series of Merge operations builds the syntactic structure of sentences (Chomsky, 1995, 1993; Marantz, 1995; see also Adger, 2003). Simply put, a lexical item (e.g., a verb) is selected from the lexicon and combines with other selected items to form a higher-order category. So, for example, considering the two-argument verb *chase* and its thematic grid (agent, theme), agent is assigned to the subject position, and theme is assigned to the direct object position. Figure 27-2 demonstrates how this occurs in a sentence such as *The dog chased the cat*. The verb (*chase*) merges with a determiner phrase (DP; *the cat*) to yield V' and assigns the thematic role theme. The V' then merges with another DP (*the dog*), assigning the role of agent and forming a VP. The VP then merges with higher nodes in the syntactic tree. The number of arguments selected by the verb affects phrase structure operations: The greater the number of arguments, the more steps required to build phrase structural frames. (For further discussion of phrase structure building operations, see Lee & Thompson, 2004.)

Figure 27-2. Schematic representation of merge within the verb phrase (VP). DP = determiner phrase; V = verb.

Psycholinguistic and neurolinguistic research findings indicate that verb argument structure also influences sentence processing. Both normal and agrammatic speakers appear to access not only the verb but also its thematic representations when listening to sentences (see, e.g., Shapiro, Gordon, Hack, & Killackey, 1993; Shapiro & Levine, 1990; Shapiro, McNamara, Zurif, Lanzoni, & Cermak, 1991). Using a cross-modal lexical decision task, Shapiro and colleagues found that reaction times for complex verbs (i.e., those with more dense argument structure entries) are longer than for simple verbs. These findings suggest that when the verb is accessed during the temporal unfolding of a sentence, so, too, are its thematic properties. The fact that individuals with Broca's aphasia retain this ability after brain damage is important in the treatment of agrammatism.

Noncanonical Sentence Computation

As noted above, the *canonical* form of sentences in the English language is SVO, such as *Zack climbed Mt. Katadin*. Of course, many sentences do not follow this simple pattern (see sentences 5–8 below). Theoretically, however, all sentences are derived from their underlying SVO representation, a pure representation of lexical information, and despite appearing in different positions, *Zack* is the agent (the person doing the climbing) and *Mt. Katadin* (or what) is the theme (the thing that was climbed) in all sentences:

5. What mountain did Zack climb? (object “wh-” question)
6. It was Mt. Katadin that Zack climbed. (object cleft)
7. Mt. Katadin was climbed by Zack. (passive)
8. Zack seems to have climbed Mt. Katadin. (subject raising structure)

By displacement—*movement*—of sentence constituents from their underlying position to a different location in the sentence, a new surface form is derived. Two types of movement are relevant to agrammatism: *Wh-movement*, and *NP-movement*. Wh-movement is involved in wh-questions (sentence 5) and object clefts (sentence 6); NP-movement is involved in passives (sentence 7) and subject raising sentences (sentence 8).

Figure 27-3. Tree diagram illustrating Wh-movement in “wh-” questions, such as *Who did the thief chase?* Movement is from the direct object position to the Spec, CP. Subject-auxiliary verb inversion also is depicted.

Wh-Movement

Consider the Wh-movement structures in sentences 5 and 6 above. Indeed, on the face of it, these two sentences appear to be quite different. They are fundamentally similar, however, in that both involve Wh-movement. Consider sentences 9a and 9b below; sentence 9a is an approximation of the underlying representation of sentence 9b:

- 9a. Zack_{AGENT} climbed what_{THEME}
 9b. What_i_{THEME} did Zack_{AGENT} climb [_i]

In sentence 9a, *what* is in the direct object position and is assigned the thematic role of theme by the verb *climb*. To derive the noncanonical surface form, *what* is moved to the sentence initial position, leaving behind a *copy or trace* (*t*) in the direct object argument position, as illustrated in sentence 9b. Because the object or theme argument moves from the object position to the subject position, the derived structure is called an object “wh-” question.⁶ Figure 27-3 illustrates this movement from the direct object position to Spec, CP, a non-argument position.⁷

Object cleft structures as in sentence 6 above also are formed by movement of the direct object (theme) to Spec, CP. Consider the underlying form (sentence 10a) and surface form (sentence 10b) of an object cleft construction:

Figure 27-4. Tree diagram illustrating Wh-movement in object cleft structures, such as *It was the artist who the thief chased*. Movement is from the direct object position to Spec, CP, as in “wh-” questions. Importantly, movement occurs in an embedded clause. Note that there is a co-referential relation between the moved element (e.g., *who*) and the head noun of the main clause (*the artist*), marked by subscripted *j*.

- 10a. Zack_{AGENT} climbed Mt. Katadin_{THEME}
 10b. It was Mt. Katadin_i_{THEME} that Zack_{AGENT} climbed [_i]

The crucial difference between object “wh-” questions and object clefts is that in the latter, movement occurs within an embedded clause, as shown in Figure 27-4. This property of object clefts renders them more complex than object “wh-” questions. The issue of structural complexity is addressed further below.

NP-Movement

NP-movement forms, as in sentences 7 and 8 above, are quite different from Wh-movement forms. Unlike Wh-movement, which involves movement from an argument (i.e., theme) position to a non-argument position (Spec, CP), NP-movement involves displacement of an argument (i.e., theme) to another argument position (Spec, IP; the subject position of the sentence). To illustrate the NP-movement involved in passive sentences, consider again the underlying form of sentence 7 approximated in sentence 11a below:

- 11a. ϕ was climbed Mt. Katadin_{THEME} by the Zack_{AGENT}
 11b. Mt. Katadin_i_{THEME} was climbed [_i] by Zack_{AGENT}

⁶ Subject “wh-” questions do not involve Wh-movement (e.g., *Who climbed Mt. Katadin?*).

⁷ The example above (sentence 9b) illustrates movement of an argument, the direct object NP. Wh-movement also can apply to adjuncts, as in *Matt fixed the car [in the garage] -> Where did Matt fix the car?* In this example, the moved element, *where*, corresponds to a locative adjunct prepositional phrase, *in the garage*.

Figure 27-5. Tree diagram illustrating NP-movement in passives, as in *The artist was chased by the thief*. Note that the landing site for movement is the subject position.

To derive the passive, the direct object NP, theme, (i.e., *Mt. Katadin*) in sentence 11a is moved, and a trace of this movement is left behind. The landing site of the moved NP is the empty subject position (ϕ , Spec, TP)*, as in sentence 11b. This movement is illustrated in Figure 27-5.

NP-movement also is involved in subject-raising constructions (see sentence 8 above). In this type of sentence, movement is from the subject position of a sentential complement (subordinate clause) to the empty subject position of the matrix sentence, as in sentences 12a and 12b (Fig. 27-6):

- 12a. ϕ seems Zack to have climbed Mt. Katadin
 12b. Zack_i seems [_{t_j}] to have climbed Mt. Katadin

The linear order of constituents in a sentence affects both sentence production and comprehension. When producing

Figure 27-6. Tree diagram illustrating NP-movement in subject raising structures, as in *The thief seems to have chased the artist*. Note that the moved element lands in the subject position (Spec, TP), as in passive constructions.

* IP is replaced by TP when the inflection phrase is split.

or listening to sentences in which constituents are not in their canonical form, greater processing resources are required as compared to when the ordering of constituents is canonical. When individuals without brain damage process noncanonical sentences with movement, it appears that they “reaccess” the moved element in the vicinity of the trace—well after it has occurred in the sentence. That is, they “hold on to” the moved constituent such that it can be assigned its proper thematic role once the verb in the sentence is heard. Some debate exists regarding whether agrammatic speakers retain the ability to do this. Some researchers have shown that they do not (Swinney & Zurif, 1995; Zurif, Swinney, Prather, Solomon, & Bushell, 1993), but others have found that these speakers show normal online processing of complex, noncanonical sentences despite their inability to comprehend or produce them (Blumstein et al., 1998; Dickey, Choy, & Thompson, 2007).

Some theories of agrammatism suggest that the source of asyntactic comprehension relates to an inability to form traces (or copies) of movement and/or failure to establish co-referential relations between moved constituents and the trace/copy—for example, the Trace Deletion Hypothesis and its variants (e.g., The Trace Based Account) (Grodzinsky, 1986, 1995, 1990) and the Double Dependency Hypothesis (Maunder, Fromkin, & Cornell, 1993). Others suggest that, rather than a representational deficit, the problem is related to processing deficiencies. The Slow-Syntax Hypothesis claims, for example, that comprehension of complex sentences results from delayed processing (Burkhardt, Piñango, & Wong, 2003; Piñango, 2000; Prather, Zurif, Love, & Brownell, 1997; Swinney, Prather, & Love, 2000). On this account, traces are present in the syntactic representation, and their antecedents are “reactivated” at the trace site. The problem is that this reactivation is delayed. Another theory, the Mapping Deficit Hypothesis, suggests that the problem lies in mapping semantic representations onto the syntax, based on the observation that some agrammatic speakers have little difficulty determining the grammaticality of sentences but still show comprehension problems (Linebarger, Schwartz, & Saffran, 1983). This latter theory is similar to the Argument Linking Hypothesis (Piñango, 2000), which suggests that the deficit relates to difficulty coordinating semantic and syntactic linking.

Grammatical Morphology

One representational theory of agrammatism, The Tree Pruning Hypothesis (TPH), suggests that functional categories projecting from higher nodes in the syntactic tree are more at risk than those projecting from lower nodes (Friedmann & Grodzinsky, 1997; Hagiwara 1995). Impairment may occur at any level of the tree, but it will necessarily result in deficits at all higher levels. Accordingly, an IP impairment would also impair CP structures.

Figure 27-7. Illustration of ways that the syntactic tree can be “pruned” according to the Tree Pruning Hypothesis, which assumes a “split-IP.” Functional category members—C (complementizers), T (tense), or Agr (agreement)—may be impaired or underspecified. When a node is impaired, all nodes above the pruned one will be impaired as well.

As discussed previously, Pollock (1989) suggested that IP is “split” into separate tense and agreement nodes. Thus, the TPH also predicts that morphology associated with tense should be more impaired than agreement, because the TP is higher in the tree than the agreement phrase (AgrP). Supporting data have come from Hebrew and Palestinian Arabic (Friedmann, 2002; Friedmann and Grodzinsky, 1997) and Spanish agrammatic speakers (Benedet et al., 1988). For example, Friedmann & Grodzinsky (1997) describe a Hebrew patient with agrammatic aphasia who showed intact representation of lower nodes within IP (AgrP) but selective impairment in higher ones (TP). In addition, their subject showed difficulty with complementizers and embeddings, indicating impaired CP as well (Fig. 27-7).

The validity of the THP, however, has been challenged by research showing patterns of impairment in agrammatism that do not follow the proposed hierarchies in Korean (Lee 2003), German (Burchert, Swobody-Moll, & de Bleser, 2005), and English (Lee & Thompson, 2005). Lee and Thompson (2005), for example, studied four English-speaking patients with agrammatism with spared CP but impaired IP. None of these patients showed more difficulty with tense as compared to agreement inflection. Finally, the participants showed variability in their production ability, indicating retention of partial knowledge rather than a complete loss of ability, which would be expected if a syntactic node or nodes were simply absent of “pruned.” These data suggest that the impairment is more likely the result of faulty processing or access to relevant representation (for a discussion of processing accounts, see Arabatzis & Edwards, 2002).

Considering recovery of grammatical morphology, the TPH suggests that training higher nodes will improve structures projected from lower ones. That is, training CP structures should improve IP structures, and within IP, training tense should improve agreement. Training IP structures should have no effect on CP structures, however, and training agreement should not influence tense. In our functional category (grammatical morphology) treatment, we use the syntactic tree to select treatment targets and to generate hypotheses about generalization within and across functional category members. We also, however, consider the processing mechanisms engaged in accessing and producing them.

TREATMENT OF AGRAMMATISM

Treating agrammatic aphasia is a challenge. Few treatments have been developed for improving grammatical deficits in aphasia, and of these, most are focused on improving syntactic deficits, with fewer being concerned with improving grammatical morphology. In addition, the extent to which these treatments improve language or result in generalization to untrained language structures and/or language use in untrained contexts is not always clear. Indeed, generalization has become the gold standard for efficacious treatment; without it, treatment may be deemed ineffective. In addition, few published tests are available for detailing syntactic and morphological impairments seen in agrammatism. In this section, a short overview of assessment tools is presented, followed by discussion of the treatment for syntactic and morphological impairments in agrammatism, respectively.

Assessment of Agrammatic Deficits

Agrammatism exists within the context of nonfluent (Broca’s) aphasia, which can be diagnosed by administration of a standardized aphasia test battery, such as the Western Aphasia Battery (Kertesz, 2006) or the Boston Diagnostic Aphasia Examination, 3rd Edition (BDAE-3; Goodglass, Kaplan, & Barresi, 2000). Additional measures are required, however, to detail verb and verb argument structure deficits, comprehension and production of canonical and noncanonical sentences, and deficits in grammatical morphology.

In recent years, several measures have been published for testing verb comprehension and production, including one subtest of the BDAE-3 (Goodglass et al., 2000), the Action Naming Test (Druks & Masterson, 2002), and the Verbs and Sentences Test (Bastiaanse, Edwards, & Rispen, 2002). The latter, developed for Dutch speakers and translated into English, also evaluates comprehension and production of sentence types that are compromised in agrammatism. One drawback of these tests is that they are not completely controlled for argument structure.

Figure 27-8. Sample picture stimuli for testing production of one-, two-, and three-argument verbs using the Northwestern Assessment of Verbs and Sentences (NAVS). *Bark* is a one-argument verb, *lick* a two-argument verb, and *give* a three-argument verb.

The Northwestern Assessment of Verbs and Sentences (Thompson), in preparation is a battery of tests developed particularly for evaluating agrammatic aphasia. The measure consists of five tests: (1) the Test of Verb Comprehension, (2) the Test of Verb Production, (3) the Verb Argument Structure Production Test, (4) the Sentence Comprehension Test, and (5) the Sentence Production Priming Test. The verb tests examine one-argument (i.e., intransitive), obligatory two-argument verbs (i.e., transitive), and three-argument verbs (ditransitive both obligatory and optional)⁸ using action pictures (Table 27-1). To test comprehension, subjects are asked to point to the verb named (out of four pictures), and to assess verb naming, they are asked to name the action depicted. Verb argument structure production is tested by adding arrows to denote objects or people in the picture that represent arguments of the verb. Sample stimuli used to elicit production of verbs and verb arguments are shown in Figures 27-8 and 27-9.

The Sentence Comprehension and Sentence Production Priming Tests examine actives, passives, yes/no questions, object “wh-” questions, subject “wh-” questions, object relatives, and subject relative constructions (see Table 27-2 for

sample sentences of each type). In both tests, action picture pairs depicting semantically reversible scenes with transitive (two-argument) verbs are used. Comprehension is tested using a sentence-picture matching task: A picture pair is presented, and the one corresponding to a spoken sentence is selected. The Sentence Production Priming Test elicits sentences by the examiner modeling the target sentence type using one of the pictures in the pair and asking the patient to

Figure 27-9. Stimulus used in the Argument Structure Production Test for production of sentences with two-argument verbs on the Northwestern Assessment of Verbs and Sentences (NAVS). Arrows refer to arguments of the verb.

⁸ Obligatory three-argument verbs are those that require all arguments be overtly represented in sentences (e.g., *put*). Optional three-arguments verbs allow omission of an argument, even though it is part of the verb's lexical entry (e.g., *send*).

TABLE 27-1

Verbs Tested for Comprehension, Production, and Argument Structure Production (in Simple Sentences) in Tests 1, 2, and 3, Respectively, on the Northwestern Assessment of Verbs and Sentences

One-Argument Verbs	Two-Argument Verbs, Obligatory (Ob)	Three-Argument Verbs, Obligatory (Ob) and Optional (Op)
bark	cut	build (Op)
crawl	kiss	deliver (Op)
dive	lick	give (Ob)
howl	pinch	put (Ob)
laugh	pull	read (Op)
sit	shove	send (Op)
sleep	stir	throw (Op)
swim	tickle	write (Op)

produce a sentence of the same type with the other, target picture. A sample picture pair and instructions used to test comprehension and production are shown in Figure 27-10. On these tests, agrammatic speakers show relatively intact comprehension of canonical sentences (i.e., actives, subject “wh-” questions, and subject relatives) and poorer comprehension of noncanonical sentences (i.e., passives, object “wh-” questions, and object relatives). A similar pattern often is seen in production, in which canonical forms are less impaired than noncanonical structures, although as noted above, some canonical forms also present difficulty for some patients.

Virtually no published tests are available for evaluating functional category deficits in aphasia. We, therefore, are in

the processing of developing the Northwestern Assessment of Verb Inflection (Thompson, in preparation), which examines production of finite (inflected) and nonfinite verb forms (Table 27-3). Finite forms include present singular, present plural, and past tense. Nonfinite forms include: present progressive (aspectual ing) and the infinitive. To elicit these forms, a sentence completion task and action pictures are used. The task requires production of the missing verb with the correct verb form.

Analysis of spontaneous discourse also is crucial for uncovering grammatical deficits in agrammatism. Saffran and colleagues (1989) recommend using a story-retelling task to collect language sample. The samples are then coded for utterance type, word class, verb inflections, and so on (Rochon, Saffran, Berndt, & Schwartz, 2000). Sentence constituents (e.g., NPs or VPs) also are coded, and from these data, both lexical and sentence structural analyses are undertaken to derive information such as noun-to-verb ratio, open class-to-closed class ratio, number of words produced in sentences, and proportion of utterances with complete sentences.

Thompson and colleagues (1995) developed a similar method. Patients are asked to tell the story of Cinderella or Red Riding Hood. We also have asked individuals to watch a silent Charlie Chaplin film and then tell about it and describe pictures depicting a sequence of events. Notably, regardless of elicitation condition, individuals with agrammatic aphasia show very similar patterns of language production. Once the sample is collected, it is transcribed and segmented into utterances based on syntactic, prosodic, and semantic criteria. Each utterance then is coded at five levels:

1. The Utterance Level, where codes for a sentence or non-sentence are entered (utterances without verbs are not sentences).
2. The Sentences Level, where sentences are coded by type and as simple or complex.

TABLE 27-2

Sentences Tested for Comprehension (Test 4) and Production (Test 5) in the Northwestern Assessment of Verbs and Sentences

Sentence Type	Sample Stimulus	Semantically Reversed
Active	The girl tickled the boy.	The boy tickled the girl.
Passive	The boy was tickled by the girl.	The girl was tickled by the boy.
Object “wh-” question	Who did the girl tickle?	Who did the boy tickle?
Subject “wh-” question	Who tickled the boy?	Who tickled the girl?
Yes/no question	Did the girl tickle the boy?	Did the boy tickle the girl?
Object relative	I see the boy who the girl tickled.	I see the girl who the boy tickled.
Subject relative	I see the girl who tickled the boy.	I see the boy who tickled the girl.

Figure 27-10. Picture pair used to test sentence comprehension and production on the Northwestern Assessment of Verbs and Sentences (NAVS). For comprehension, the examiner says, "Point to, the dog was watched by the cat." For production elicitation, the examiner says, "For this picture [pointing to the picture on the left], you could say, *The cat was watched by the dog*; for this picture [pointing to the picture on the right], you could say . . ." (Expected response: *The dog was watched by the cat.*)

3. The Lexical Level, where all lexical items are coded by word class.
4. The Bound Morpheme Level, where codes for inflectional morphemes are entered.
5. The Verb Level, which details verbs by type and argument structure.

TABLE 27-3

Northwestern Assessment of Verb Inflection Sores for an Agrammatic Speaker

Verb Inflection Condition	Percent Correct
Present singular: The cat watches the dog.	0
Present plural: The cats watch the dog.	20
Regular past tense: The cat watched the dog.	0
Present progressive: The cat is watching the dog.	80
Infinitive: The cat will watch the dog.	80

The analysis yields data such as mean length of utterance, the proportion of grammatical sentences, open class-to-closed class ratio, noun-to-verb ratio, the proportion of verbs produced with correct arguments, and the proportion of verbs and nouns produced with correct inflection. Although this coding system is quite complex, it is worthwhile for clinicians to become familiar with analyses of this type not only to diagnose the patient but also because changes in these language variables often are seen with treatment. Table 27-4 presents a typical spontaneous language profile for an agrammatic aphasic speaker (compared to unimpaired speakers).

Treatment of Syntactic Deficits

Few treatments for improving sentence structural (syntactic) deficits in aphasia are available, and of those, several focus on instruction and practice in producing the surface form of certain types of sentences. The Helm-Estabrooks Language Program for Syntax Stimulation (Helm-Estabrooks, 1981;

TABLE 27-4

Sample Spontaneous Language Profile for an Agrammatic Speaker (AS)

	AS	Normal*
Mean length of utterance	4.75	14.5 (2.2)
Open to closed class ratio	1.73	0.91 (0.08)
Noun to verb ratio	2.12	1.21 (0.25)
Proportion of grammatical sentences	0.19	0.89 (0.08)
Proportion of verbs with correct arguments	0.50	>0.95
Proportion of correctly inflected verbs	0.57	NA

Key: NA = data unavailable.

*Values are for normal speakers and are presented as the mean (standard deviation). Data from Kim and Thompson (2000).

Helm-Estabrooks & Ramsberger, 1986), for example, is focused on training a set of sentences shown by Goodglass, Gleason, Bernholtz, & Hyde (1972) to be difficult for individuals with agrammatic aphasia to produce (Table 27-5). One sentence type is trained at a time, beginning with that considered to be the easiest (e.g., imperative intransitives [e.g., *Sit down*]). Research concerned with establishing the efficacy of this approach has indicated that patients improve in their ability to produce trained sentences; however, less impressive findings have been reported with regard to generalization across sentence types (Doyle, Goldstein, & Bourgeois, 1987; Fink et al., 1995).

Rather than focusing on the surface form of sentences, other approaches exploit processes thought to be operating in normal sentence processing and production. For example,

TABLE 27-5

Helm-Elicited Language Program for Syntax Stimulation Sentence Types

Sentence Type	Sample Sentence
Imperative intransitive	Sit down.
Imperative transitive	Drink your milk.
“Wh-” interrogative	Where are my shoes?
Declarative transitive	He teaches school.
Declarative intransitive	He swims.
Comparative	He’s taller.
Passive	The car was towed.
Yes/no questions	Did you watch the news?
Direct and indirect object	He brings his mother flowers.
Embedded sentences	She wanted him to be rich.
Future	He will sleep.

Loverso, Prescott, & Selinger (1986) developed a method known as “Verb as Core” treatment, based on the premises that, first, access to verbs often is disrupted in agrammatic aphasia and, second, verbs are required for grammatical sentences. Patients are trained to produce verbs together with specific sentence constituents (usually NPs) that are assigned various thematic roles by the verb (e.g., agent and theme) in simple, active sentences. Little research examining this approach is available.

Another treatment designed to improve both comprehension and production of sentences is Mapping Therapy (Byng, 1988; Rochon, Laird, Bose, & Scofield, 2005; Schwartz, Saffran, Fink, Myers, & Martin, 1994). Like Verb as Core training, this approach is theoretically motivated, based on the Mapping Deficit Hypothesis discussed above. Treatment focuses on verbs and the thematic role of sentence NPs in both canonical and noncanonical structures. Presented with sentences in written form, patients are asked to underline the agent and theme in response to questions concerning the logical subject and the logical object (e.g., “Which one is doing the chasing?” and “What/who is she/he chasing?”). Results of research using this method have shown improved comprehension of both canonical and noncanonical sentence forms. Like Syntax Stimulation, however, improvement is constrained largely to the types of sentences entered into treatment. In a recent study directly comparing Mapping Therapy to TUF, we (Thompson, Shapiro, Kiran, & Mass, in preparation) found that both approaches improve comprehension and production of sentence types trained. But the generalization patterns differed for the two treatments; a greater number of participants showed generalization across sentences resulting from TUF as compared to MT.

Treatment of Underlying Forms for Syntax (TUF_{SYNTAX}) exploits the fact that individuals with agrammatic aphasia have normal access to verbs and thematic information; however, they do not always assign thematic roles normally, nor do they use them fully in sentence production. Further, these patients have difficulty comprehending sentences with movement, TUF_{SYNTAX} uses the active form of target sentences as a starting point for treatment, and tasks are directed toward establishing and improving knowledge of and access to the thematic role information entailed in target verbs. Then, instructions as to how various sentence constituents move to derive the surface form of target sentences, while retaining their thematic roles, are provided (see Appendix 27-1 for detailed treatment protocols).

In a series of studies, it has been shown that this approach improves sentence production and comprehension. Crucially, treatment results in successful generalization to structures that are related linguistically to the structures trained. Ballard & Thompson, 1999; Jacobs & Thompson, 2000; Thompson et al., 1993, 1996; Thompson, Shapiro et al, 1997.

As noted above, a distinction exists among certain sentence types, depending on whether they involve the syntactic operations of Wh- or NP-movement. Object “wh-” questions and object clefts are Wh-movement structures, whereas passive sentences and subject raising forms are NP-movement structures. What do these linguistic descriptions have to do with treatment and recovery of language in aphasia? In sentence production and comprehension work, we have found that sentences that are linguistically related recover together (see Thompson, Shapiro et al., 1997). For example, training object cleft sentences improves both object who and what questions. Similarly, training subject raising structures improves not only untrained subject raising structures but also passive sentences.⁹

For example, in a study examining the relation between Wh- and NP-movement (Thompson, Shapiro et al., 1997), the Wh-movement structures selected for treatment included “wh-” questions, as in sentence 13 below, and object cleft sentences, as in sentence 14 below. In addition, NP-movement structures were selected for treatment and generalization testing. These included passives and subject-raising sentences as in sentences 15 and 16, respectively, below. Individuals with agrammatic Broca’s aphasia were trained to produce one of these sentence types at a time using active sentences, as in sentence 17 below, and TUF_{SYNTAX} protocols:

13. Who did the boy pinch? (object “wh-” question)
14. It was the teacher who the boy pinched. (object cleft)
15. The teacher was pinched by the boy. (passive)
16. The boy seems to have pinched the teacher. (subject raising)
17. The boy pinched the teacher. (active)

Results showed that training Wh-movement structures improved both trained and untrained Wh-movement structures—that is, generalization from object clefts to “wh-” questions was found. The Wh-movement treatment, however, had little influence on production of NP-movement structures. Similarly, when NP-movement structures were trained, generalization occurred to other NP-movement structures (e.g., generalization occurred from subject raising to passives), but no change in production of object clefts or object “wh-” questions was seen.

Ballard and Thompson (1999) as well as Jacobs and Thompson (2000) found a similar dissociation between Wh- and NP-movement sentences. Ballard and Thompson (1999) trained five patients to produce object clefts and/or “wh-” questions and tested passives. All subjects improved in production of Wh-movement structures, but no change in passive forms was seen. Jacobs and Thompson (2000)

trained both object clefts and passive sentences in four patients. Again, all improved on the structures trained, but none showed generalization from object clefts to passives or from passives to object clefts.

Another finding is that generalization is enhanced if the direction of treatment is from more complex to less complex structures. Close examination of data reported in earlier studies (Thompson & Shapiro, 1994; Thompson, Shapiro et al., 1997) showed that for subjects who received Wh-movement training, better generalization was noted from object clefts to object “wh-” questions than from object “wh-” questions to object clefts. In consideration of the complexity of these structures, object clefts are the most complex. The two structures are similar in that they both require Wh-movement; however, as pointed out above, the movement in object clefts is within an embedded clause. The movement in object “wh-” questions occurs in the matrix clause; no embedding is required.

Results of studies directly examining the effects of complexity showed that, indeed, generalization occurs more readily from object clefts to “wh-” questions than vice versa (Thompson, Ballard, & Shapiro, 1998). Further, training even more complex sentences with Wh-movement, object relative clause structures, as in sentence 18 below, results in generalization to both object clefts, as in sentence 19 below, and “wh-” questions, as in sentence 20 below. Generalization from simpler “wh-” question structures (sentence 20), however, does not improve object clefts (sentence 19) or object relative clause constructions (sentence 18) (Thompson, Shapiro, Kiran, & Sobecks, 2003). Figure 27–11 illustrates the collective results of training more than 30 subjects with agrammatic aphasia. Most participants trained to produce and comprehend complex structures show generalization to simpler structures (86%), whereas fewer show generalization in the opposite direction (from simple to complex structures; 17%):

18. The chef saw the busboy who the waitress kissed.
19. It was the busboy who the waitress kissed.
20. Who did the waitress kiss?

Training complex structures before training simpler ones may seem counterintuitive, but these studies, as well as those in other language domains, indicate that optimal generalization results from this approach (Thompson 2007). For discussion of complexity in treatment of phonological, semantic, and syntactic deficits, see Gierut (2007), Kiran (2007), and Thompson and Shapiro (2007), respectively.

Summary of Syntax Training Effects

Work concerned with examining Wh- and NP-movement shows that they are functionally independent. That is, generalization is not seen from sentences relying on one type of movement to sentences relying on the other. Importantly, however, sentences that rely on the same type of movement form a functional class; generalization across from one form

⁹Also see Thompson, Shapiro, and Roberts (1993); Thompson & Shapiro (1994); and Thompson, Shapiro, Tait, Jacobs, and Schneider (1996) for studies training object (argument) “wh-” questions (e.g., *who* and *what*) and adjunct “wh-” questions (e.g., *where* and *when*).

Figure 27–11. Proportion of participants showing successful generalization from less complex to more complex structures, and vice versa.

to others within the same movement class, even when sentences are very different in their surface form. Further, generalization is enhanced when complex, rather than simple, structures are used as the starting point for treatment as long as the simpler structures are related to the more complex ones. These data show that the linguistic underpinnings of sentences are important to consider in treatment of syntactic deficits in aphasia.

Treatment of Grammatical Morphology (Functional Categories)

Treatment research concerned with establishing methods for improving access to grammatical morphemes—either bound or free-standing—is limited to a handful of studies (see, e.g., Cannito & Vogel, 1987; Kearns & Salmon, 1984). These treatments can be considered surface form approaches, because the underlying representation and processing demands of the grammatical morphemes trained were not completely considered.

Treatment of Underlying Forms for grammatical morphology or functional categories (TUF_{FUNCT}) considers both functional category projections from the syntactic tree as well as computational processes involved in producing grammatical morphemes in sentences. Consider the following sentences:

21. The people wonder *if/whether* the boy is ticking the girl.
22. The boy *tickled* the girl.
23. The boy *tickles* the girl.

The complementizer *if/whether* in sentence 21 as well as morphemes marking verb tense and agreement in sentences 22 and 23, respectively, are functional category members. From a linguistic representational point of view, sentence 21 is more difficult than either sentence 22 or sentence 23. As

noted above, the TPH suggests this because complementizers occupy a higher node (i.e., CP) in the syntactic tree compared with tense or agreement (i.e., IP). Further, the TPH holds that tense (sentence 22) is more vulnerable than agreement (sentence 23), again because tense is higher in the tree than agreement (Fig. 27–11). The position of tense and agreement in the syntactic tree is debatable: Some suggest that:

1. Both are subsumed under IP (Bobaljik & Thráinsson, 1998).
2. Tense is above agreement (Pollock, 1989).
3. Agreement is above tense (Chomsky, 1993).

In addition, the computational routines and processing demands required for sentences with complementizers differ from those involved in marking tense/agreement features. Complementizers (*whether*, *if*, *that*) are free-standing morphemes that introduce a complement or subordinate clause. They are strongly syntactically constrained, because they are directly selected for by complement verbs, such as *know*, *wonder*, *see*, and *care*. Conversely, tense and agreement are bound grammatical morphemes that rely on processes such as grammatical encoding and well-formedness constraints (Arabatzi & Edwards, 2002; Faroqi-Shah & Thompson, 2007; Halle & Marantz, 1993). Past tense, for example, requires encoding a past-tense meaning (provided by the temporal adverb *yesterday* or by other contextual information). Verb tense, however, is only indirectly constrained by the adverb: The adverb introduces information about the temporal context, but it does not *select* the verb's tense in the same way that complement verbs select complement clauses.

Why are these distinctions important for treatment of agrammatism? Simply put, both representation and processing accounts suggest that complementizers are more difficult (or complex) than tense or agreement. Because the

underlying representation as well as the processing routines involved in the two structures are different, however, they are linguistically distinct, even though both are functional category members. Given this, training complementizers should have no effect on production of verb tense or agreement, and training verb tense and agreement should have no effect on complementizers.

Predicting generalization from tense to agreement or from agreement to tense is more difficult, however. Both forms involve attachment of inflections to base-form verbs, which likely entail similar computations. They may or may not occupy different nodes in the syntactic tree, however, and one may occupy a higher node than the other. Thus, a functional relationship between tense and agreement is predicted, but no specific prediction regarding the direction of generalization can clearly be made.

We recently trained 12 participants to produce complementizers, tense, and agreement and examined generalization across structures (Thompson et al., 2006). The three structures were trained, one at a time, using TUF_{FUNCT}, with the order of structure trained counterbalanced across participants. As in TUF_{SYNTAX}, TUF_{FUNCT} considers the underlying form of target structures. For complementizers, this is approximated in sentence 24a below, with two separate clauses; sentence 24b below shows the surface form, which results from combining the two clauses with the complementizer + *that*. For tense and agreement, the underlying and surface forms are approximated in sentences 25 and 26, respectively:

- 24a. [_{IP} the people [_{VP} see [_{DP/CP} something]]] [_{IP} the bride [_{VP} is carrying [_{DP} the groom]]]
 24b. [_{IP} the people [_{VP} see [_{CP} *that* [_{IP} the bride [_{VP} is carrying [_{DP} the groom]]]]]]]
 25a. [_{IP} the bride [_{VP} is carrying [_{DP} the groom]]]
 25b. Yesterday [_{IP} the bride [_{VP} carry +*ed* [_{DP} the groom]]]
 26a. [_{IP} the bride [_{VP} is carrying [_{DP} the groom]]]
 26b. Nowadays [_{IP} the bride [_{VP} carry +*s* [_{DP} the groom]]]

Treatment involved the use of written-sentence constituent cards corresponding with the active sentence(s) for each target as well as cards for [if], [that], [whether], [ed], or [s], depending on the grammatical morpheme in training. Each training trial consisted of:

1. Thematic role training of constituents in the matrix clause and for complementizers in the embedded clause as well.
2. Introduction of the grammatical morpheme, its function, and its placement in the sentence.
3. Reassembly of scrambled written sentence constituent cards.

Participants read or repeated the target sentence at each step.

Results showed that all participants improved on trained forms following low and stable baseline performance. Three of four participants trained on complementizers showed no generalization to tense or agreement, and zero of eight par-

ticipants trained on tense or agreement showed improvement on complementizers. These data suggest that even though complementizers and verb inflections are functional category members, they are not functionally related to one another, thus, training one did not influence the other. This finding is similar to that derived from our Wh- and NP-movement studies; even though sentences with both types of movement are noncanonical and difficult for patients with agrammatic aphasia, they involve different types of movement. Thus, a functional relationship does not exist between them. Generalization from tense to agreement or from agreement to tense was seen, however, for 7 of 11 participants. These findings suggest that the two inflected forms are functionally related to one another; however, one is not necessarily more complex than the other.

Effects of Treatment on Discourse Patterns

Changes in discourse characteristics have resulted from both syntactic and morphologic treatment in many participants, with increases in mean length of utterance, the proportion of grammatical sentences produced, and the proportion of verbs (as compared to nouns). Syntactic treatment also improves the proportion of verbs produced with correct argument structure, and treatment focused on grammatical morphology increases the proportion of correctly inflected verbs. Notably, Ballard and Thompson (1999) found improvements in informativeness and efficiency of production following syntactic treatment using the analysis system of Nicholas and Brookhire (1993). This latter finding indicates that treatment focused on structural deficits impacts functional language use.

Neural Mechanisms of Recovery

The language improvement resulting from both TUF_{SYNTAX} and TUF_{FUNCT} affects the neural mechanisms of language. Using functional magnetic resonance imaging, we find two patterns of recovery: Some participants show increases in areas of the brain that are active during language processing, and others show decreases following treatment. In one study of TUF_{SYNTAX}, participants received treatment focused on Wh-movement structures, including object-relative clause constructions, object clefts, and object-extracted “wh-” questions, with all showing improved production and comprehension of all forms. Before and following treatment, the patients were scanned while performing a sentence-picture matching task in which object cleft sentences, such as “It was the judge who the lawyer tripped,” and simpler subject cleft sentences, such as “It was the judge who tripped the lawyer,” were tested. Two (of three) participants showed decreased neural activity following treatment; whereas the third participant showed more widespread activation following treatment. Regardless of the amount of active tissue, however, the final

Figure 27-12. Areas of significant activation found in post-treatment scans that were not active in pre-treatment scans. Note that treatment resulted in increased activation in the left and right perisylvian regions.

scans for all participants showed recruitment of perisylvian tissue, which was not active during pre-scanning. Figure 27-12 shows post-treatment activation for one participant which was not seen on his pre-treatment scan. Before treatment, activation was limited to small clusters of active tissue in the right superior parietal and the middle temporal gyri. No activation was seen in the left hemisphere.

A similar pattern was found for participants receiving TUF_{FUNCT}. Of 12 patients studied, five underwent pre- and

post-treatment scanning. Four of these five participants showed improved production of grammatical morphology with treatment, whereas one did not. The scan task involved production of verbs in their base form (e.g., *save*) or inflected for tense (e.g., *saved*) or agreement (e.g., *saves*). Results showed that the four patients who improved with treatment showed a decrease in activation following treatment. Figure 27-13 shows this pattern for one patient. Interestingly, the gentleman who did not improve with treatment showed an increase in

Figure 27-13. Areas of significant activation before (grey) and after (black) treatment of grammatical morphology for one agrammatic participant. The activation shown reflects the following contrast: production of ((tense + agreement) – bare stem). This participant showed a decrease in activation following treatment. Before treatment, widespread, primarily right hemisphere activation was noted, whereas following treatment, a shift to more focal right perisylvian and left perilesional activation was found. Note that this participant had a large left hemisphere lesion that encompassed the inferior frontal area and extended to superior and anterior temporal regions.

cortical tissue engaged while performing the task, with all activity in the right hemisphere both before and following treatment.

CONCLUSION

Findings from our work in developing and testing the effects of treatment for agrammatism indicate that treatment for sentence production deficits in patients with agrammatic aphasia is efficacious when the linguistic underpinnings of the language deficit exhibited by the individual with aphasia, the sentences selected for treatment, and the treatment strategy used are considered. When lexical and syntactic properties of sentences are not considered, generalization effects are considerably diminished—or even absent. That is, little or no discernible improvement in sentence production beyond constructions trained is found. We also find that the complexity of structures trained is a factor that needs to be considered in facilitating generalization.

The results of our work have important clinical implications. Because of restrictions in health care presently imposed for individuals with aphasia, it is essential that clinicians provide treatment that will result in optimal generalization. Our data suggest that optimal generalization results from treatment when structures that are linguistically similar are selected as treatment targets and when treatment is applied to the most complex of these structures first. While additional data are needed to further substantiate the latter, we conclude that linguistically based treatment can be used successfully for training sentence production in individuals with aphasia who present with deficits like those seen in our subjects.

In conclusion, treatment of both syntactic and morphological aspects of sentence production requires careful analysis of *how* and in *what ways* the sentence processing/production system has been affected with brain damage. Application of treatment explicitly designed to address these deficits is recommended. Indeed, the more we learn about the linguistic and psycholinguistic underpinnings of sentence production and comprehension and in what ways these are disrupted in aphasia, the more detailed we can be about the design of treatment.

► **Acknowledgment**—The work reported here was funded by the National Institutes on Deafness and other Communication Disorders (NIDCD) grant RO1-DC01948, for which the author is very grateful. Special thanks are extended to the aphasic participants and their family members, postdoctoral fellows (Drs. Steve Fix, Miseon Lee, and Lisa Milman), and research assistants involved in this work, and colleagues and collaborators, particularly Drs. Michael Walsh-Dickey and Lew Shapiro, for their invaluable contributions.

KEY POINTS

1. The literature indicates that individuals with agrammatic aphasia show particular deficit patterns that must be carefully tested before application of treatment.
2. Consideration of the lexical and morphosyntactic properties of sentences selected for treatment and for generalization analysis is important for obtaining optimal generalization.
3. Generalization from one structure to another occurs when sentences are linguistically related to one another. When sentences are not linguistically related, generalization is limited.
4. Generalization may be enhanced by training more complex structures first. Generalization from more complex to simple structures occurs when simple structures involve common linguistic representations and psycholinguistic processes.
5. Treatment improves the grammar, content, and efficiency of spontaneous discourse.
6. Neural correlates of treatment-induced behavioral changes can be mapped onto the brain.

ACTIVITIES FOR DISCUSSION AND REFLECTION

1. Two types of generalization occur: generalization to untrained language structures (response generalization), and generalization to untrained contexts (stimulus generalization). Provide examples of both. Discuss why generalization is important for successful treatment and what can be done if generalization does not occur.
2. Beginning treatment with complex structures is counterintuitive, but it has been shown to be successful for treatment of both naming and sentence comprehension/production in aphasia. Consider one of your current or previous clients with aphasia, and create a treatment plan for this client using this concept.
3. Code the language sample presented in section 2 of this chapter. Use the methods described under *Assessment of Agrammatic Deficits* (see p. 741) for coding the Utterance Level and Lexical Level. Calculate the following: mean length of utterance, the proportion of grammatical sentences, open class-to-closed class ratio, and noun-to-verb ratio. Do your results match those of other students in the class? For advanced students, try coding the Sentence Level, Bound Morpheme Level, and Verb Levels.
4. Based on the results of coding (in activity 3 above), develop a treatment plan for this client. Discuss how you will evaluate the effects of treatment.

5. Converging data suggest that the neural networks for language are influenced by aphasia treatment. Discuss the following questions: Do you think that different treatments might result in different patterns of neural recruitment? If so, why? Do you think that some treatments might impede recovery of the neural networks for language? If so, what treatments might have this effect? Is the neurobiology of recovery important? Why, or why not?
6. Administration of treatments that are theoretically based (as are TUF_{SYNTAX} and TUF_{FUNCT}) is difficult for some clinicians because of limits in their knowledge about theories and data pertaining to normal language representation and processing? Do you think it is important for clinicians to have this knowledge? Is so, how can it be obtained? If not, why not?

APPENDIX 27.1

Treatment Protocols¹

Protocol for Training Object Clefts

Pre-Trial Probe Task

A randomly selected, semantically reversible picture pair is presented, such as, (a) girl kissing a boy and (b) boy kissing a girl. Object cleft production and comprehension are tested using sentence-picture matching and sentence production priming (see *Assessment of Agrammatic Deficits* on p. 741).

TREATMENT STEP 1: THEMATIC ROLE TRAINING

The clinician says, “Let’s work on that sentence.” Sentence constituents comprising the active form of the target sentence are presented on individual cards under the target picture. For example, [THE BOY] [IS] [KISSING] [THE GIRL] is placed below the boy-kissing-girl picture. The client reads aloud or repeats the active sentence. Additional cards for [WHO] and [IT WAS] are placed next to the picture. The verb and verb arguments (thematic roles) are identified by the examiner in the following manner: Pointing to the verb, the examiner explains, “This is *kissing*; it is the action of the sentence”; pointing to the Agent (subject NP), the examiner explains, “This is *the boy*; he is the person kissing”; pointing to the Theme (object NP), the examiner explains, “This is *the girl*; she is the person being kissed.” The client is then asked to point to and name the Agent/Action/Theme. The client reads aloud or repeats the active sentence again.

TREATMENT STEP 2: SENTENCE BUILDING

The examiner first explains, “We are going to make a new sentence to go with this picture using these cards.” The [WHO] card is placed next to the Theme card [THE GIRL]. The clinician explains that to make a new sentence, [WHO] is added next to [THE GIRL], because the girl is the person who is kissed. The client is instructed to read aloud/repeat the sentence in the order of the cards: [THE BOY] [KISSED] [THE GIRL] [WHO].

The Theme [THE GIRL] and the [WHO] cards are moved to the sentence initial position, creating the following word string: [THE GIRL] [WHO] [THE BOY] [KISSED]. The examiner explains, “To make the new sentence, these words are moved to the beginning of the sentence. They move together because the girl is the person who is kissed.”

The examiner explains that to make a correct sentence, the [IT WAS] card needs to be added “because it was the man who the

woman kissed.” The [IT WAS] card is placed at the beginning of the sentence. The client reads aloud/repeats the target sentence: [IT WAS] [THE MAN] [WHO] [THE WOMAN] [KISSED].

TREATMENT STEP 3: THEMATIC ROLE TRAINING

The examiner explains that the agent/action/theme are the same in the new sentence as in the old one. The client is asked to point to and name the Agent/Action/Theme. The client reads aloud or repeats the target sentence again.

TREATMENT STEP 4: PRACTICE

Sentence constituents are rearranged in active sentence form, together with [WHO] and [IT WAS] cards (as in Treatment Step 1). The client moves the cards to form the target object cleft sentence. Assistance is provided as needed.

Post-Trial Probe Task

The same procedures as in the *Pre-Trial Probe Task* are used.

Object “Wh-” Questions

Pre-Trial Probe Task

A randomly selected, semantically reversible picture pair is presented, such as (a) girl kissing a boy and (b) boy kissing a girl. “Wh-” question production and comprehension are tested using sentence-picture matching and sentence production priming (see *Assessment of Agrammatic Deficits* on p. 741).

TREATMENT STEP 1: THEMATIC ROLE TRAINING

The clinician says, “Let’s work on that sentence.” Sentence constituents comprising the active training sentence are presented on individual cards under the target picture. For example, [THE BOY] [IS] [KISSING] [THE GIRL] is placed under the boy-kissing-girl picture. The client reads aloud or repeats the active sentence. Additional cards, [WHO] and [?], are put next to the picture. The verb and verb arguments (thematic roles) are identified by the examiner in the following manner: Pointing to the verb, the examiner explains, “This is *kissing*; it is the action of the sentence”; pointing to the Agent (subject NP), the examiner explains, “This is *the boy*; he is the person doing the kissing”; pointing to the Theme (object NP), the examiner explains, “This is *the girl*; she is the person being kissed.” The client is then asked to point to and name the Agent/Action/Theme. The client reads aloud or repeats the active sentence again.

¹ Computerized protocols (**Sentactic**®) for training three Wh-movement sentences, object relative clause structures, object clefts, and object “wh-” questions have been developed and are currently being studied. For description of the program and updates, go to <http://csrlr.colorado.edu/beginweb/sentactics/sentactics.html>.

TREATMENT STEP 2: SENTENCE BUILDING

The examiner first explains, “We are going to make a new sentence, a question, to go with this picture using these cards.” The Theme [THE GIRL] card is replaced by [WHO], and the examiner explains that this is done because *the girl* is WHO is kissed. The question mark card then is placed at the end of the card string, forming an echo question: [THE BOY] [IS] [KISSING] [WHO]² [?]. The clinician explains that the [?] card is needed to make a question sentence. The client reads aloud or repeats the echo questions.

Subject/auxiliary verb inversion is demonstrated, resulting in the following string: [IS] [THE BOY] [KISSING] [WHO] [?]. The clinician says, “To make the question sentence, we need to switch [THE BOY] and [IS].”

² We recognize that proper English requires *whom* rather than *who* in the object position. We use *who* for simplification; we also note that *who* in the object position is now accepted.

Movement of [WHO] to the sentence initial position is demonstrated, as the examiner explains that the question starts with [WHO]: [WHO] [IS] [THE BOY] [KISSING] [?]. The client reads/repeats the question.

TREATMENT STEP 3: THEMATIC ROLE TRAINING

The examiner explains that the Agent/Action/Theme are the same in the new sentence as in the old one. The client is asked to point to and name the Agent/Action/Theme. The client reads aloud or repeats the target sentence again.

TREATMENT STEP 4: PRACTICE

Sentence constituents are rearranged in active sentence form, together with the [WHO] and [?] cards (as in Treatment Step 1). The client moves the cards to form the target “wh-” question, then reads or repeats it. Assistance is provided as needed.

Post-Trial Probe Task

The same procedures as in the *Pre-Trial Probe Task* are used.

Chapter 28

Language-Oriented Treatment: A Psycholinguistic Approach to Aphasia

Donna L. Bandur and
Cynthia M. Shewan

OBJECTIVES

The objectives of this chapter are:

- To define Language-Oriented Treatment (LOT)
 - To outline the implementation of LOT
 - To describe the benefits of an LOT approach
 - To highlight the functional aspects of LOT
 - To demonstrate the efficacy of LOT
-

Language-Oriented Treatment (LOT) is a psycholinguistic approach to the treatment of aphasia. As such, it strives to enable a person with aphasia to use a language processing system at its maximum functional level. This language-oriented approach is based on the application of psycholinguistic research evidence to treatment, reflecting how language normally is processed and how it is altered in the presence of aphasia. Because of the neurolinguistic underpinnings of LOT with respect to theory, application, and evolution, Helm-Estabrooks (1988) categorized LOT as a neurolinguistic approach to treatment. Shewan (1977) developed LOT during the 1970s, over a 2-year period, with the aim of creating an approach consisting of a structured methodology coupled with content based on research data from normal and disordered language. To acquaint the reader with the climate in which LOT was conceived, a brief history of aphasia treatment will be reviewed.

HISTORY OF APHASIA TREATMENT

Little in the way of what we now know as orthodox treatment for aphasia appeared before the beginning of the 20th century. In the early 1900s, the literature reported a few studies describing treatment (Franz, 1906, 1924; Frazier &

Ingham, 1920; Mills, 1904; Weisenburg & McBride, 1935), and even as far back as this, questions were raised, although not answered, relative to the efficacy of treatment.

After World War II, interest regarding aphasia treatment surged because of the number of war veterans with aphasia as a result of trauma. The focus of these rehabilitation efforts was on reeducation, the approach developed for treatment. Because of the effects of trauma on the personality of these individuals, many psychotherapy groups became a part of rehabilitation efforts (Backus, 1952; Blackman, 1950). Reportedly, these groups provided support and positively influenced both communication and personality adjustment (Aronson, Shatin, & Cook, 1956; Blackman & Tureen, 1948). With the exceptions of Eisenson (1949) and Wepman (1951), however, data were primarily anecdotal and not statistically supported. In addition, the data focused on trauma rather than on stroke.

In the 1950s, aphasia treatment shifted, focusing on individuals who developed aphasia as a result of stroke. Schuell's work, both in this era and in the 1960s, predominated (Schuell, Jenkins, & Jimenez-Pabon, 1964). The data published about treatment were controversial, and whether aphasia treatment was efficacious remained an issue. On the one hand, Vignolo's study (1964) reported the significantly positive effects of treatment, but the study by Sarno, Silverman, and Sands (1970) failed to show the positive effects of language treatment.

The 1970s and early 1980s witnessed the publication of several studies, some with and some without control groups, that supported the efficacy of language treatment in patients with aphasia (Basso, Capitani, & Vignolo, 1979; Basso, Faglioni, & Vignolo, 1975; Broida, 1977; Dabul & Hanson, 1975; Deal & Deal, 1978; Hagen, 1973; Prins, Snow, & Wegenaar, 1978; Sefer, 1973; Shewan & Kertesz, 1984; Smith, Champoux, Leri, London, & Muraski, 1972; Wertz et al., 1978, 1981). The ideal study, using a randomized no-treatment control group, had not been completed, and some believed that only this study would put to rest their doubts about the efficacy of aphasia treatment. Despite some studies that disputed the efficaciousness of language treatment (David, Enderby, & Bainton, 1982; Meikle et al., 1979),

enough evidence had been gathered by 1982 for Darley (1982) to conclude that the foregoing collage of studies “collectively provides a series of answers and together lays our doubt about efficacy to rest” (p. 175).

Darley’s proclamation did not, however, convince everyone, and efficacy studies continued throughout the 1980s and into the next decade, with the majority favoring the significant and positive effects of treatment (Brindley, Copeland, Demain, & Martyn, 1989; Holland & Wertz, 1988; Poeck, Huber, & Willmes, 1989; Schonle, 1988; Springer, Glindemann, Huber, & Willmes, 1991; Wertz et al., 1986; Whitney & Goldstein, 1989). In summarizing the results of most large group studies, Holland, Fromm, De Ruyter, and Stein (1996) described them as demonstrating the value of aphasia treatment, particularly when therapy is frequent and conducted over a lengthy interval. The authors also highlighted the contributions made in recent years by small-group, single-subject experimental studies and individual case studies. These investigations have provided more detailed descriptions about the efficacy of specific approaches when applied to particular language problems. Because the individuals studied in these reports generally have been in the chronic stages of their recovery, the language gains realized are not likely to be attributed to spontaneous recovery.

More recently, Bhogal, Teasell, and Speechley (2003) reviewed the aphasia literature for language treatment studies reported from January 1975 through May 2002 to determine the possible relationship between intensity of therapy and language outcomes as assessed using the Porch Index of Communicative Abilities, or PICA, and the Functional Communication Profile, or FCP. The authors found that studies with positive treatment results were associated with greater than 2 hours of therapy per week. Our work would support the idea that further studies employing carefully tailored, intensive treatment approaches directed at addressing the underlying nature and complexity of the behavioral symptoms will best delineate what specific approaches work best for whom.

EVOLUTION OF LANGUAGE-ORIENTED TREATMENT

From the foregoing summary, one can see how both the study and our understanding of aphasia have evolved. With pressures not only to demonstrate that therapy results not only in improved linguistic performance but also in meaningful functional outcomes, we are compelled to examine and describe what processes we are addressing that result in these positive changes. When LOT was first conceptualized, the aphasia literature contained few descriptions of treatment that were sufficiently detailed to assure clinicians they were, indeed, actually replicating that treatment. The predominant type of treatment was stimulation therapy, but there remained many patients for whom this approach did

not bring about significant change. The need for alternative methods, which incorporated the accumulating research data regarding how individuals with and without aphasia process language and which could be clearly defined for replication, became apparent. Because clinicians were being pressured to reexamine their treatment approaches and accompanying rationales, it became imperative that theoretical information be incorporated into designing therapy and be described in such a way as to be systemically applied across patients. Subsequently, LOT was designed, outlining a structured methodology in which an individual progressed through steps of increasing difficulty, with the content of therapy based on psycholinguistic research data. Next, LOT was pilot tested (Shewan, 1977) with a small group of patients. The resulting data were promising and led to a full-scale clinical trial (described later in this chapter). A decade passed from ideational conception to the publication of a book fully describing LOT, complete with treatment guidelines, treatment materials, and efficacy data (Shewan & Bandur, 1986). Ongoing research has necessitated modifications, particularly to the content of LOT.

The 21st century has witnessed a surge in the use of technology, with advances in neuroimaging techniques. Positron-emission tomography and functional magnetic resonance imaging have enabled the growth in our understanding of how those with and without aphasia process and produce language (Gernsbacher & Kaschak, 2003; Martin, 2003). Information derived from these avenues of research can complement the work of those addressing psycholinguistic measures of language to assist clinicians in better understanding the neural basis of language and cognition and how those functions may be altered in the presence of lesions in various areas of the human brain. With this understanding, greater customization of assessment tools, treatment goals, and strategies is possible, which in turn can positively impact our clinical efficiency and outcomes. Studies demonstrating the brain’s plasticity and ability to adjust to injury have been emerging and lend further support for the importance of our language interventions (Belin et al., 1996; Calvert et al., 2000; Cao, Vikinstad, George, Johnson, & Welch, 1999; Cappa, 2000; Leger et al., 2002; Thiel et al., 2001; Thomas, Altenmuller, Marckmann, Kahrs, & Dichgans, 1997; Warburton, Price, Swinburn, & Wise, 1999).

As our understanding of normal language processing has advanced, along with greater specification of language impairments and their functional impact on those with aphasia, LOT has been refined. As additional research findings emerge, LOT will continue to evolve.

Philosophy and Rationale

Aphasia treatments typically are based on a theoretic construct of aphasia, and LOT is no exception. As defined here, aphasia represents impairment in the language system and in

access to the language system. Processes for understanding and producing language thereby are affected. This theoretic view of aphasia is derived from the work of Zurif and his colleagues (Zurif and Caramazza, 1976; Zurif, Caramazza, & Myerson, 1972; Zurif, Green, Caramazza, & Goodenough, 1976). It is proposed that the linguistic or conceptual knowledge base is not lost in aphasia but, rather, no longer can be accessed automatically, at an unconscious level. Language, or at least certain aspects of language, must be mediated by more conscious and explicit mechanisms (Byng & Black, 1995).

In the LOT method, the content of language treatment is extremely important, with the ultimate goal being to provide the patient with a language-processing system that operates at its maximum functional level by applying neurolinguistic findings to treatment. This approach is in contrast to that of providing indiscriminant stimulation of the language system, with expectations that exposure to a variety of tasks will facilitate change in performance. For example, workbook activities selected to match symptoms can lead to frustration and discouragement when responding appears to be inconsistent, when difficulty levels may be inappropriate, and when changes in communicative performance ultimately are not realized.

Language-Oriented Treatment is designed to provide a highly individualized and tailored approach to treatment

based on the language profile, the interests, and the goals of the patient. Guidelines are detailed to assist with organizing and implementing therapy but are not intended to be prescriptive in nature. An effort has been made to maintain a high degree of flexibility with the approach while providing enough structure to allow effective replication.

Content

Implementation of LOT requires careful analysis and understanding of the pattern of deficits presented by a particular individual. A hypothesis regarding the underlying nature of the problems is based on available information from normal language processing and that found in those with aphasia. A psycholinguistic approach emphasizes the need for clinicians to ensure that their interpretation of symptoms is guided by theoretic hypotheses rather than relying on intuition and that treatment is individualized with respect to the symptoms displayed by the specific person being treated (Albert, 1998; Byng, 1992). To provide a system whereby the content of language can be described comprehensively and to facilitate data collection, LOT divides the communication system into five modalities, which are non-overlapping and mutually exclusive (Fig. 28-1). The five modalities are (1) auditory processing, (2) visual processing,

Figure 28-1. Schematic model of the language modalities and areas within these modalities that make up the communication system.

(3) gestural and combined gestural-verbal communication, (4) oral expression, and (5) graphic expression.

Each modality is further subdivided into mutually exclusive areas that, collectively, encompass the entire modality. With each modality segmented into component parts, a clinician can clearly specify the content of treatment being provided. Rather than advocating a particular breakdown of the communication system, the division is intended to facilitate specification of the content of treatment and to permit its replication.

Within each area of a modality (e.g., comprehension of sentences within the Auditory Processing modality) treatment materials are organized according to the level of difficulty based on available data from research literature. The goal of language treatment is to improve a patient's language deficits by presenting material that increases in difficulty level at a pace that the individual can accommodate.

Although the modalities have been delineated to assist in outlining LOT content and areas for potential treatment, treatment within one modality or area may be targeted to facilitate performance in another. For example, within the Oral Expression modality, oral reading rarely would be chosen as a goal in and of itself. Instead, an oral reading task may be selected to achieve a variety of objectives, such as self-monitoring, auditory processing, reading comprehension, and so forth. When selecting an activity within an area, it is essential that it correspond to the established goal, and how responses within an activity, area, or modality might reflect or challenge other language processes must be considered.

The content areas within each modality are considered to be the base in treatment or guidelines for consideration, but they are not necessarily arranged in a hierarchical order or intended for use with every patient. As our understanding of aphasia evolves, along with our knowledge about the effectiveness of specific treatment techniques, these advancements can be incorporated into the content of LOT.

Because LOT was designed to be flexible and promote the use of procedures that facilitate optimal responding by the patient, more than one modality typically are treated simultaneously, either within the same session or even within the same activity. To this end, the clinician must be cognizant of the many variables that impact performance, design tasks that can meet the goals selected, and organize them in ways that allow changes to be measured and documented.

Methodology

The methodology of LOT has adopted a paradigm in which the major components are stimulus, response, and reinforcement. In contrast to operant conditioning, however, the goal is not to learn specific stimulus-response connections, such as certain words in a word retrieval task or specific sentences in a sentence formulation task. Rather, the

paradigm of presenting stimuli followed by responses with accompanying descriptive feedback enables patients to process or use language at levels appropriate, yet challenging, given their current capabilities. To enhance correct responding, modifications may be made to the stimuli or task requirements because difficulties are encountered. Facilitated Problem Solving has been used to describe treatment that is characterized by the relationship between a narrow focus in the materials used, what the patient is required to do with them, and the interaction with the clinician (Byng & Black, 1995). This process of adjusting the task in response to the patient at a given point in time has been proposed to be one of the critical elements of therapy.

Approaching treatment from a stimulus-response-reinforcement construct enables the clinician to collect data about performance and provides objective feedback to both the clinician and the patient about progress over time on particular tasks and/or areas. Because improvements in treatment may not be immediately reflected in changes on standardized test measures, demonstration of steady gains across a hierarchy of activities can be an invaluable source of reinforcement for the patient, significant others, and those who may be challenging the value of financial support for ongoing treatment. Alternatively, this method provides objective information, in a timely manner, regarding when a task or procedure should be modified or, perhaps, even abandoned.

Difficulty Levels

In LOT, activities are presented in order of increasing difficulty to optimize opportunities for success and minimize feelings of frustration and failure on the part of the patient. Several variables can affect the difficulty level of a task, such as type of materials incorporated, mode of presentation, complexity of response required, and amount of clinician support provided. Difficulty levels may be based on an analysis of results from standardized testing and systematic probing in concert with information from research literature regarding normal and/or disordered language functioning.

The stimuli and their responses in treatment are presented in blocks of 10 items each. To advance the level of a task, a patient must achieve 70% or more correct responses on two consecutive blocks of items at the same level of difficulty. When this criterion is met, the difficulty of the task is increased to the next level in the hierarchy. If the 70% correct criterion is not achieved, the block of 10 stimulus items is repeated. The difficulty level of the task is decreased if the patient is unable to meet the 70% criterion, followed by discontinuation of the task should the alteration in task difficulty not produce the desired outcome. A criterion of 70% correct was chosen to allow flexibility in response performance and to accommodate some error without unduly delaying progress in treatment. If a particular patient

demonstrates the need for a higher criterion, it can be altered, although the efficacy data reported later in this chapter reflects the use of the 70% criterion.

Cueing

If a patient cannot generate an independent response, the clinician may incorporate the presentation of cues within an activity, with a hierarchy of difficulty levels established, based on the amount of support provided by the clinician. The goal in implementing a cueing system is to determine which cues are facilitative, to develop the individual's awareness of those that are effective, to transfer the responsibility for initiating and providing cues from the clinician to the patient, and to increase the production of independent responses, with self-cueing as needed.

Criterion Response and Branching

Defining the elements of a correct response is required to advance the level of difficulty. As described earlier, the clinician decides what constitutes a correct response. Because flexibility in establishing this decision is available, the definition of a correct response may differ for each task. In most tasks, many different levels of response are possible, and what is accepted as correct may change with time and as improvement occurs. For example, early during treatment, a clinician may decide that, in a naming task, a recognizable production meets criterion. Later, however, a phonetically correct response may be required to score it as meeting criterion.

When the difference between two adjacent levels of difficulty proves to be too great for a patient to master, the clinician can create levels of intermediate difficulty (branching). Branching constructs a link between the initial task and assists the patient in advancing to the next level. Another situation requiring branching may arise when a clinician determines that dividing a large group of equally difficult material into two subgroups might be advantageous in providing additional language processing opportunities with each subgroup rather than omitting some of the material.

Feedback

Feedback is a key aspect to the implementation of LOT. Information regarding the correctness and quality of a response promotes a better understanding of the language impairment and the factors influencing performance. By engaging in mutual problem-solving exchanges and encouraging self-evaluation, the patient becomes a more active participant in treatment. The patient can serve as an invaluable source of information and insight for the clinician, with a personal and, many times, richer perspective, through indicating or describing how a particular response has occurred and/or was facilitated.

Recording Data

Because the patient's performance dictates when tasks should be increased or decreased in difficulty, recording data is an important component in LOT. Two forms can be helpful in this respect. A LOT Goals Form (Appendix 28-1) may be used for each area in each modality. The difficulty level, stimuli, presentation method, type of cueing, criterion for a correct response, and response method are recorded, with space for additional observations. A LOT Data Record Form (Appendix 28-2) specifies the amount of time spent in each session for each area and modality, difficulty level of the task, number of items presented, data collected, and any other pertinent observations that a clinician may wish to record. Both forms are useful in charting the course of treatment and highlighting for the clinician when difficulty levels or tasks might be altered.

Patient–Clinician Relationship

Although LOT is structured in content and methodology, it is carried out within a caring and positive interpersonal environment. Albert (1998) describes the loss of ability to communicate as being tantamount to the loss of personhood, and evidence suggests that the self-esteem of individuals who have suffered strokes can contribute to their functional abilities, at least during the early phases of recovery (Chang & MacKenzie, 1998). Le Dorze and Brassard (1995) have reported on the impact of aphasia on both patients and their significant others. Negative communication consequences include increased effort, irritation, frustration, and fatigue in communication, with language disabilities having a marked impact on interpersonal relationships.

Sarno (1997) has described how intensive, long term rehabilitation that addresses language, communication strategies, functional communication, and psychosocial issues for the first year positively impacts the quality of life of persons with aphasia. In this context, the importance of the patient–clinician relationship cannot be overstated. Understanding and respecting premorbid personality and lifestyle characteristics of patients are the first steps in developing collaborative, supportive relationships both with them and with their significant others. Creating a climate for an open and honest exchange of ideas and feelings is needed to facilitate mutual goal setting and a sense of partnership. Skilful clinicians are mindful of how central the therapeutic relationship is to the treatment of aphasia. Helping patients and their support systems understand the loss accompanying aphasia is a necessary component of treatment. In turn, this creates the foundation for working through the many challenges and, sometimes, disappointments that are encountered throughout the rehabilitation process.

Language-Oriented Treatment employs a structured methodology of stimulus–response–reinforcement, in concert

with clearly defined hierarchies and scoring systems, but this approach does not preclude the establishment of a patient-centered milieu in treatment. The patient and significant others play integral roles in determining goals and activities based on their needs, interests, and abilities. To facilitate the transfer of skills to more functional aspects of the patient's life, the clinician must develop an understanding about the impact of aphasia on the whole person and the world in which he or she participates. Chapey and colleagues (2000) described the importance of a life participation approach to aphasia, or LPAA. Those authors suggested that, at every step of the rehabilitation process, the clinician needs to understand and address the impact of aphasia on the attainment of the patient's personal goals and direct treatment to identify the supports needed to enable participation in his or her environment as a competent individual.

IMPLEMENTATION OF LANGUAGE-ORIENTED TREATMENT

Guiding Principles

In the following sections, a description of each modality will be provided. It is not possible to address all the areas within the confines of this chapter, so only some of them will be highlighted, particularly as they reflect current practice or changes since the inception of LOT. The reader is referred to *Treatment of Aphasia: A Language-Oriented Approach* (Shewan & Bandur, 1986). A complete listing of the areas incorporated in each of the modalities also is found in Figure 28-1. It is worth noting that this chart reflects the content of LOT at the time of its original development. Since then, approaches to treatment have been refined in some areas, and these new or expanded treatment applications will be discussed in the descriptions of the modalities that follow.

Consideration of lesion site and an understanding of that area's role in cognitive and linguistic processes are essential in guiding a comprehensive assessment. The decision regarding which modalities and areas to introduce initially during treatment can be made once a hypothesis as to the nature of the underlying deficits is established. Only with integration of knowledge about neural substrates and psycholinguistic principles can we inform our treatment decisions and educate our patients regarding prognostic implications.

At the conclusion of the treatment section, some case illustrations will be provided to demonstrate the practical applications of LOT with patients exhibiting a range of aphasic deficits. These descriptions provide evidence that systematically addressing the underlying problems results in functional improvements.

The Role of Computers

Generally, therapy for aphasia takes place in a face-to-face setting between the clinician and the patient, with the clinician presenting activities and related feedback while modifying tasks according to the response characteristics of the patient. Advances in computer technology and its increased accessibility have led investigators to explore computer applications in aphasia management. The role of the computer in delivering therapeutic tasks and in serving both as an alternative-augmentative communication system and as a tool for work and recreational activities has been examined.

The literature reflects varying degrees of improvement in language functioning related to implementation of computerized programs. When evaluating the results of an unsupervised home-based computer program, Petheram (1996) failed to find a relationship between progression through a hierarchy of tasks and improvements on formalized language measures. Amount of time spent on the computer varied widely and appeared to be associated with less frequent opportunities for hobbies or other forms of social interaction.

Weinrich, McCall, Boser, and Virata (2002) examined the impact of Computerized Visual Communication (Steele, Weinrich, Wertz, Kleczewska, & Carlson, 1989), or C-VIC, training on sentence production and discourse in five patients with nonfluent aphasia. They found an improvement in sentence formulation skills on a picture description task both in oral and C-VIC formulation for trained items and, to a lesser extent, for untrained vocabulary. Procedural and narrative discourse performance proved to be similar. Spoken was described as less accurate than C-VIC productions, which the investigators attributed to the increased cognitive load required in the former task.

Greater success with computerized treatment has been reported in the realm of word retrieval. Doesborgh and colleagues (2004) described positive changes in naming performance by a group of patients with chronic aphasia, following implementation of a computer-based treatment program. With Multicue (Van Mourik & Van de Sandt-Koenderman, 1992), opportunities for the user to independently determine and select cues to facilitate naming of both high- and low-frequency pictured words were provided. Improvements in word retrieval were found on standardized testing at the end of a 2-month period. Positive gains in naming skills in a group of patients with chronic aphasia also were reported by Aftonomos, Steele, and Wertz (1997) through coupling home- and clinic-based computer instruction. Icons associated with natural lexical items, representing various categories, were manipulated in a range of activities. The amount of daily home practice (mean, 2.04 hours) was judged to be a significant contributor to the treatment outcome.

Mortley, Wade, and Enderby (2004) used their computer-based treatment program to target word retrieval skills in a group of patients, again, with chronic aphasia,

implementing a home-practice paradigm that was monitored through the Internet and telephone interviews. Significant improvements in naming scores were found after a 27-week period of home practice, with the participants spending, on average, 2 hours and 45 minutes per week engaged in the computer activities. Other stated benefits were family and patient reports of the improved confidence and independence in everyday communication exchanges exhibited by the patients.

Others have studied the treatment of syntactic comprehension deficits through application of computerized tasks. Beveridge and Crerar (2002) reported on the use of Multimedia Microworld, a program based on a mapping therapy protocol (Schwartz, Saffran, Fink, Myers, & Martin, 1994). Active, passive, and object cleft sentences were produced by the computer in written form, accompanied by auditory presentation, with the subjects required to arrange pictorial elements to represent the sentences. Eight 1-hour treatment sessions were provided, with minimal clinician input. At the conclusion of therapy, all three patients demonstrated significant improvement in written sentence comprehension for trained sentence forms, along with variable improvement in auditory processing.

Positive treatment outcomes in reading comprehension also were reported by Katz and Wertz (1997), employing a hierarchy of activities from simple letter matching to sentence comprehension tasks. Following therapy, consisting of 3 hours of practice per week over the course of 26 weeks, those who had received reading comprehension training demonstrated significantly more improved scores on overall language measures than those who were provided with only computer stimulation tasks.

Wertz and Katz (2004) reviewed the literature for reports on treatment outcomes in patients with aphasia through the use of computers. Studies were evaluated with respect to the model of Robey, Schultz, Crawford, & Sinner (1998), defining outcome, efficacy, effectiveness, and efficiency, along with a five-phase outcome research model. The American Academy of Neurology's 1994 level of evidence scale also was incorporated into evaluating the findings. Only the Katz and Wertz (1997) study met the criterion of Class 1 evidence (i.e., evidence from one or more well-designed, randomized, controlled clinical trials), with the remainder providing Class 3 evidence (i.e., expert opinion, nonrandomized historical controls, or one or more case reports obtained in Phase 1 and 2 investigations).

With many individuals now having computers in their homes, development of carefully structured treatment activities using a hierarchy of difficulty levels may well be incorporated into the LOT approach, providing additional avenues for practice. The previous studies suggest that reading comprehension and naming activities might well be areas of consideration for supplementation with computer assignments. Construction and processing of electronic mail

(e-mail) could be effectively incorporated into a treatment hierarchy and bridge the gap between structured therapeutic tasks to those of a more functional nature.

The use of both low and high-tech Alternative and Augmentative Communication (AAC) strategies to support communication in those with aphasia was reviewed by Van de Sandt-Koendermann (2004). Overall, Van de Sandt-Koendermann suggested the lack of advancement within the field of AAC to be attributed to the few published case reports with respect to design and efficacy, which then places the burden on clinicians to establish time-consuming alternatives, with limited resources for a heterogeneous population. Challenges with implementation of low-tech devices include factors such as the severity of the language disorder and, perhaps, cognitive impairments faced by the individuals most in need of them, in addition to the issues of acceptance by the user and/or communication partner.

The C-VIC was designed both for treatment and as a method of communication for those with agrammatism. Although it has proven to be effective in improving oral sentence formulation skills, success in establishing online communication exchanges or transfer of skills outside the clinical environment has not been demonstrated. More recently, a Personal Communication Assistant for Dysphasic People, or PCAD, has become available. Van de Sandt-Koendermann described it as a small, portable device that is individually configured according to the modules that might be appropriate for the user. A hierarchy of options is available, including words, drawings, photographs, and pictograms, along with a voice output option. In a later study of 28 patients with aphasia, with time post-onset ranging from 3 months to 13 years, Van de Sandt-Koendermann, Wiegers, and Philippa (2005) determined that PCAD could be used as a functional communication system in the environment. In their investigation, which excluded those with cognitive impairment and poor auditory comprehension, 77% of the participants reported use of the device outside of the therapy sessions. Those who were most successful were older. The authors suggested that acceptance of a communication device might occur only when patients are in the more chronic phase of their disability and have accepted their limitations with oral speech. Because of the increasing popularity and familiarity of handheld devices in the general population, this option may hold further promise for at least some individuals with aphasia.

Wade, Petheram, and Cain (2001) considered whether voice recognition software could be a tool to assist those with aphasia in functions such as dictation and use of environmental controls and, potentially, as an input modality for treatment. They studied six individuals with a range in severity of aphasic deficits along with a control group and examined their success, over a period of five sessions, in training the software to recognize 50 words and 24 phrases. A great amount of variability was found in both groups

during single-word training, with the phrase training demonstrating even greater variation in the group with aphasia. Not unexpectedly, the lowest accuracy levels were associated with greater levels of severity in speech production.

The introduction of voice recognition software also was explored for a patient with problems involving word finding and expression of complex information following a left parietal stroke (Bruce, Edmundson, & Coleman, 2003). Although reading skills were relatively well preserved, written spelling was significantly impacted. At the conclusion of 8 months of training and practice with the system, written skills had improved, and the patient reported using the system for constructing e-mail, letters, and lists. The investigators postulated that the system's success depends on an individual's ability to manage the large number of errors during the recognition training of the system. Some partially preserved spelling skills also were judged to be important in error correction. From these studies, one might conclude that as the technology undergoes further refinement, a future role exists for voice recognition software in assisting those with milder forms of aphasia.

A more recent focus in computer use by those with aphasia has been placed on facilitating Internet access, with the goal of broadening opportunities for communication exchanges. Sohleberg, Ehlhardt, Fickas, and Sutcliffe (2003) conducted a study to examine e-mail training with a small group of subjects having varying neurologic etiologies, including right and left hemisphere strokes. They concluded that the major barriers were lack of computer familiarity and difficulty with learning to operate the mouse/cursor functions. Problems with generating ideas for message construction, lack of error detection, and subsequent limitations in editing also were apparent. Overall, however, the participants proved to be highly enthusiastic and motivated to develop their abilities to formulate and send e-mails.

Egan, Worrall, and Oxenham (2004) examined whether patients could be taught to access the Internet through development of a written guide and a series of six training sessions provided by a volunteer. A range of tasks was included, such as turning on and off the computer, searching the World Wide Web, constructing e-mail, and so on. Before training, the subjects were found to have a low level of independence with computer tasks, with 8 of 20 patients ultimately achieving a high level of independence on the specified tasks. E-mail use proved to be the most popular function for all subjects.

Given that many people with aphasia are able to access—or have the potential for learning to access—information from the Internet, aphasia Web sites have more recently drawn attention. The accessibility and quality of Web sites for those with aphasia were examined by Ghidella, Murray, Smart, McKenna, and Worrall (2005) through ratings given by samples of patients with aphasia and speech-language pathologists. The speech-language pathologists judged

www.aphasiahelp.org as being the one containing the highest quality of information and accessibility. Those with aphasia ranked www.speakability.org.uk as being the most accessible site, although www.aphasiahelp.org also proved to be highly rated. Other aphasia Web sites included www.aphasiocenter.org, www.aphasiahope.org, and www.aphasia.org.

Cognition and Language

The relationship between cognition and language has been of long-standing debate in the aphasia literature. The roles of attention and memory in aphasia are intertwined with the impaired language system, making it challenging to separate their potential effects. Burgio and Basso (1997) have described long-term problems with verbal memory associated with even mild aphasia. Although memory problems were found across all of their subjects in the acute phase, some individuals showed improved performance over time with story retelling as compared to word list (paired associate) learning. These findings indicate that tasks dependent on verbal memory may not all be equal and may reflect that differing processes are at work.

Evidence suggests that some individuals with aphasia may experience problems even with tasks that involve orienting, sustaining, focusing, or dividing their attention and that these difficulties may occur with both visual and auditory input (Murray, 1999). Especially with patients who have more severe impairments and are unresponsive to auditory and/or visual input, directly addressing attentional skills may be the first avenue of treatment. A specific cognitive approach to treatment was reported by Helm-Estabrooks (1998) to meet with success. Attention and concentration activities included cancellation tasks, repeating and alternating graphomotor patterns, and trail making. Other cognitive tasks were incorporated that addressed visual memory, visuoperception, judgment, and semantic knowledge. Post-treatment testing revealed significant gains with auditory comprehension.

Advancing her claims that aphasia therapy outcomes are dependent on cognitive processes, Helm-Estabrooks (2002) cited five domains of cognition—attention, memory, executive functions, language, and visuospatial skills—as important areas to consider in developing therapeutic approaches. She designed the Cognitive Linguistic Quick Test, or CQLT, to screen for problems in cognition that potentially impact linguistic performance (Helm-Estabrooks, 2001), with findings indicating that impairments of executive functions were the cognitive skills most often associated with aphasia.

Murray (2004) posited that, because of common lesion sites, attention and working memory may be disturbed in those with aphasia and may, in fact, intensify the actual language symptoms. Successful remediation approaches have

heretofore not been well documented. Although developed for the population with acquired brain injury, Attention Processing Training-11 (Sohlberg, Johnson, Paule, Raskin, & Mateer, 2001), or APT, was used by Murray, Keeton, and Karcher (2006) with a patient demonstrating long-standing conduction aphasia. The APT hierarchy did not correspond to the patient's hierarchy of task difficulty. After 50 hours of treatment, modest improvements in attention and memory scores were reported, with no changes in auditory comprehension other than improved latencies in listening to paragraphs. The patient and caregiver reported no positive changes from a functional perspective.

Baldo and colleagues (2005) explored the relationship between language and problem solving in those with normal language skills and in those with aphasia. Using the Wisconsin Card Sorting Test (Heaton, Chelune, Talley, Kay, & Curtis, 1993), or WCST, they found a consistent correlation between this measure and comprehension and naming scores in the patients with aphasia. These findings were most evident in those with Wernicke's aphasia. When the subjects with normal language skills were required to vocalize during administration of the WCST, their performance became significantly impaired. The authors hypothesized that as tasks become particularly complex, one relies on covert vocalization to aid performance. When access to "inner" speech is disrupted, a reduced working memory capacity may therefore occur. The investigators further suggested that verbal working memory is a "specialized form of covert verbalization that allows one to rehearse/maintain information online, whereas covert verbalization is a more general capacity for subvocalizing ongoing thought processes" (p. 248). Another possible explanation may be the existence of a general working memory or attentional allocation system that underlies both language and problem solving.

Auditory Processing

General Considerations

Various types of auditory processing problems occur in aphasia, including auditory imperception, pure-word deafness, and auditory agnosia. The most prominent difficulties, however, generally are associated with auditory comprehension and, consequently, have received the most attention in designing treatment strategies. In LOT, auditory processing has been divided into two major categories: Auditory Perceptual Processing Deficits, and Auditory Comprehension Deficits. Generally, auditory perceptual activities are introduced only if success cannot be attained with auditory comprehension tasks. By developing auditory perceptual skills, the patient may learn to tune into the auditory modality and prepare this mechanism for comprehension activities.

Auditory Perception

Auditory perceptual deficits are addressed in three areas:

1. Awareness of Nonspeech and Speech Stimuli
2. Recognition of Nonspeech and Speech Stimuli
3. Monitoring Speech

In establishing awareness of nonspeech and speech stimuli, the patient is required only to respond differentially, but not necessarily to demonstrate recognition of the stimuli. Environmental sounds, music, familiar and unfamiliar speakers, and foreign languages may be used. In the second area, Recognition of Nonspeech and Speech Stimuli, however, the patient must attach meaning to the stimuli presented, such as matching a telephone ring to its corresponding referent.

In the final area, Monitoring Speech, activities are incorporated to develop the patient's ability to monitor the accuracy and/or meaningfulness of speech stimuli, whether these stimuli are his or her own productions or those of others. It has been suggested that auditory comprehension may not be tied directly to monitoring skills or, at least, may not totally account for the monitoring problems encountered by patients (Marshall, Robson, Pring, & Chiat, 1998). In this account, ability to detect neologisms was purported to be affected by impaired access to the phonologic output lexicon from semantics. Following a course of treatment designed to improve semantic associations between written words and related pictures, significantly improved judgments regarding the accuracy of verbal responses were noted. This approach might be used with those patients who are able to identify clinician errors as well as errors in their own productions off-line but who persist with erroneous online judgments.

Auditory Comprehension

Treatment for auditory comprehension has been divided into five areas:

1. Comprehension of Single Units
2. Comprehension of Short Series
3. Comprehension of Short Meaningful Linguistic Units
4. Comprehension of Paragraphs
5. Comprehension of Narratives and Discourse

Comprehension of Single Units involves stimuli at the single-word level. In designing activities, some important factors related to vocabulary selection are frequency of occurrence, grammatical class, and semantic category. Depending on the type of aphasia, various hierarchies may be established through systematic alteration of both stimuli and response variables. A hierarchy for semantic word categories for three types of aphasia is illustrated in Figure 28-2 (Goodglass, Klein, Carey, & Jones, 1966; Goodglass & Wingfield, 1993). It has been proposed that auditory comprehension of visually presented stimuli may be negatively

	Broca's	Wernicke's	Anomic
Easy	Body parts	Body parts	Body parts
	Actions	Actions	Objects
	Objects	Objects	Actions
	Numbers	Numbers	Numbers
	Colors	Letters	Colors
	Letters	Colors	Letters
Difficult	Geometric forms	Forms	Forms

Figure 28–2. Hierarchies in difficulty levels, showing differences according to semantic categories.

impacted if the items depicted represent functionally conceived, man-made objects (e.g., furniture) rather than those that are visually conceived or based on physical properties (e.g., animals) (Goodglass, 1993). Finally, evidence from lexical decision tasks indicates that both normal controls and subjects with aphasia experience greater priming for concrete versus abstract word pairs, suggesting that abstract words may be less rich in semantic representations, thereby making them more difficult to access (Tyler, Moss, & Jennings, 1995). In addition to carefully selecting and ordering stimuli, manipulating response variables such as picture relatedness and number of response choices can increase task difficulty (Pierce, Jarecki, & Cannito, 1990).

Comprehension of Short Series might be introduced when memory variables need to be stressed, because the word series themselves do not form a syntactic unit. For example, when presenting a group of numbers, the patient must attend to each item in order to identify the series correctly. Syntactic units are incorporated in the area of Comprehension of Short Meaningful Linguistic Units, where variables such as word frequency and topic familiarity are important to consider.

Individuals with aphasia have demonstrated superior performance on language tasks, including comprehension of yes/no questions (Wallace & Canter, 1985) when personally relevant material is used. Other issues to be considered include situational context, speech rate, emotional content, and topic familiarity.

Particularly with sentences, stress as a suprasegmental cue has been found to influence performance (Goodglass, 1975, 1976; Kellar, 1978; Pashek & Brookshire, 1980). Patients with severe comprehension problems may obtain information from intonational contour to differentiate among questions, statements, and commands (Boller & Green, 1972; Green & Boller, 1974). Word frequency has been shown to affect comprehension in sentences, with common, frequently occurring vocabulary items facilitating processing.

Sentences that are longer and reflect more complex syntax tend to be more difficult (Shewan, 1979). Altering the canonicity of thematic roles (i.e., agent, theme, and goal) or

incorporating a second verb or proposition in a sentence has been shown to negatively impact comprehension in aphasia (Caplan, Waters, & Hildebrandt, 1997). Patients also may benefit from the use of context in sentence comprehension activities (Pierce, 1988). Cannito, Hough, Vogel, and Pierce (1996) found that patients in the post-acute phase (5 weeks to 6 months) of their recovery experienced a facilitative effect in processing reversible passive sentences when they followed a paragraph of a predictive nature. Patients in the chronic stages of recovery (>6 months) benefited equally from both predictive and non-predictive paragraphs preceding sentence presentation. Repetition of key lexical items in the paragraph was believed to reduce the semantic processing load for the target sentences so that more resources could be assigned to understanding the relationships between the nouns. Decreased verbal memory span also was associated with those who were able to make the best use of context. With these findings in mind, sentence comprehension activities might incorporate a hierarchy of sentence types in concert with a presentation of predictive and non-predictive paragraphs, teaching the patient to recognize salient or redundant cues in the narratives and then use them to assist with sentence processing.

Although sentence comprehension is influenced by word frequency and syntactic complexity, these variables have less impact on discourse processing (Nicholas & Brookshire, 1995b). In addition, a weak link between comprehension of individual sentences and comprehension of discourse has been offered. In analyzing discourse, comprehension has been shown to be superior for main ideas as compared to details, and directly stated information is recalled with greater accuracy than implied information, by both normal subjects and those with aphasia.

Pierce and Grogan (1992) describe a number of factors that normally are involved in narrative comprehension. Briefly, they identify the microstructure (words and their relationship to the text) and macrostructure (gist) as the two major text components. Bringing one's own formulation of goals, expectations, and previous experience to the interpretation of the narrative forms a schema. Schemas will vary among individuals, and the macrostructure that is formed is influenced by situational variables (e.g., listening to a news broadcast versus a classroom lecture). Finally, the authors point out that while a text base (meaning of the narrative) is being developed, the listener brings his or her own knowledge and opinions to the topic, which assists with inferencing. In aphasia, it is suggested that with greater coherence or a strong relationship between propositions, comprehension and retention are facilitated. Knowledge about the topic increases inferencing, coherence, and ultimately, comprehension. Less cohesive narratives may be better understood by providing a topic theme. Alternatively, using narratives with several topic changes can facilitate recall of details.

Some patients may experience difficulty in comprehending referents from contextual information (Chapman & Ulatowska, 1989) and may benefit from specific instruction for processing them. More errors in recalling details of high-ratio dialogues (i.e., ones in which the amount of speaking between the participants is significantly disproportionate) also have been noted. Finally, mode of presentation may affect performance such that audiotape, videotape, and live presentations can have varying impacts, depending on the individual.

When addressing Comprehension of Paragraphs and Comprehension of Narratives and Discourse, many of the above variables can be manipulated to form individualized hierarchies depending on the nature and degree of the impairment. Identification of the gist, main ideas, and details in narratives of increasing length and decreasing personal relevance could be considered. Other tasks might include those directed at improving inferencing skills by capitalizing on the patient's knowledge of scripts and developing awareness and use of contextual cues. Altering the amount of cohesion and/or redundancy within narratives and discourse could be additional factors to control while varying the response requirements.

Case Example

SK is a 24-year-old, male university student. Following excision of a left temporo-occipital arteriovenous malformation, he demonstrated fluent aphasia characterized by moderate anomia, auditory and visual processing problems, and mild agraphia. Formalized testing included administration of the Boston Diagnostic Aphasia Evaluation, the Auditory Comprehension Test for Sentences, the Revised Token Test, and the Boston Naming Test.

Auditory comprehension problems were initially found in SK's comprehension of material at the paragraph level and in his processing of linguistically complex, lengthy instructions. The first treatment area selected was comprehension of paragraphs. Further probing revealed that SK experienced increased difficulty when required to make inferences and when the number of facts included within a paragraph was substantially increased.

For the first level of difficulty, the clinician aurally provided short paragraphs consisting of a high degree of redundancy, with SK required to answer inferential questions. When a 70% success rate was achieved at this level, more facts were included in the paragraphs to increase difficulty. As treatment progressed, difficulty levels were further adjusted by altering topic familiarity. More complex responses on the part of the patient were gradually required so that, before questioning by the clinician, SK was asked to recall as many details as possible from the paragraph. Further information was then extracted through use of either factual or inferential questions.

Comprehension of Narratives and Discourse was next developed. Short radio broadcasts were presented, followed by videotaped news segments and lengthier documentaries. Task difficulty was again altered by increasing the complexity of the response and varying the degree of topic familiarity.

SK was an active participant in developing treatment goals and hierarchies. He provided detailed feedback regarding the variables that he found affected his performance and reported on written spelling. SK returned to university to complete his Master's degree.

Sample Activities

Level 1

Stimuli: Paragraphs 60 to 80 syllables in length, high degree of redundancy, and high degree of topic familiarity.

Procedure: The paragraph is read aloud by the clinician, followed by inferential questions requiring a yes/no response.

Level 2

Stimuli: Paragraphs 60 to 80 syllables in length, low degree of redundancy, and high degree of topic familiarity.

Procedure: The paragraph is read aloud by the clinician, followed by inferential questions requiring a yes/no response.

Level 3

Stimuli: Paragraphs 60 to 80 syllables in length, low degree of redundancy, and low degree of topic familiarity.

Procedure: The paragraph is read aloud by the clinician, followed by inferential questions requiring a yes/no response.

Visual Processing

General Considerations

Visual processing refers to the processing of information presented in pictorial, gestural, and/or written forms. As with the auditory modality, this area can be subdivided into visual perception and reading comprehension. Patients with aphasia demonstrate reading impairments of varying degrees. Those with the most severe language impairments can experience limitations with visual recognition such that even matching objects, drawings, forms, colors, letters, and words may be compromised. Visual acuity and field deficits also can affect performance, resulting in problems with visual attention, scanning, and tracking.

Inability to comprehend written material because of brain damage is referred to as alexia. When applied to those with aphasia, this term is used only when particular patterns

are observed. Alexia without agraphia, or pure alexia, consists of reading problems with preserved writing. Patients may have difficulty recognizing words, although identification of high-frequency vocabulary and letters may be superior. Reading usually is accomplished using a letter-by-letter approach, making longer words more difficult to decode because of memory load (Goodglass, 1993). Comprehension of oral spelling typically is intact, and words traced in the palm of the hand or palpated often can be recognized. Although no accompanying agraphia is present, the patient is unable to read his or her own writing. Both color naming and color name recognition can be impaired.

Alexia with agraphia is characterized by a severe reading impairment, often along with problems in reading musical notes and numbers, and a calculation deficit. Those affected are unable to recognize orally spelled words and to spell words aloud. Tracing or palpating letters is not facilitative (Lecours, 1999). Marked writing problems usually are found in conjunction with a right homonymous hemianopsia.

Although the area of Oral Reading was initially included under the Oral Expression modality, it will be addressed here for ease of description and application. Three disorders of oral reading have been described because of their unique pattern of errors (Goodglass, 1993; Webb & Love, 1994). The most salient feature of deep dyslexia is substitution of semantically related words bearing no structural or phonologic similarity to the targets, with functor words typically being substituted or omitted. From easiest to most difficult to read are nouns, verbs, and adjectives. Failure to read pseudo-words also is encountered. Some consider deep dyslexia to be a variant of phonologic alexia (Friedman, 1995), which is characterized by disruption in applying grapheme-to-phoneme correspondence rules to enable the reading of pseudo-words. Errors involving visually similar words may be encountered.

Various patterns of symptoms have been associated with surface dyslexia. Commonalities reflect impairments in effectively accessing semantics and whole-word phonology along with an overuse and faulty application of phoneme-to-grapheme conversion rules.

Another reported syndrome, although rare, is visual agnosia. Patients experience difficulty recognizing material presented visually (Benson & Geschwind, 1969; Eisenson, 1984), but presentation of stimuli through another modality (e.g., touch and hearing) can meet with success. Breakdown occurs for both verbal and nonverbal material.

More current approaches in studying reading impairments in aphasia tend to focus on construction of a model for reading that details the effects of breakdowns at the various levels or stages of processing. Hillis, Kane, Barker, Beauchamp, and Wityk (2001) identified the processes that most researchers agree are involved in reading. Briefly summarized, the orthographic input lexicon (OIL) is accessed when irregularly spelled vocabulary is introduced. The

meaning of a word is derived from the lexical-semantic level, which is activated by the OIL. Once the lexical-semantic level is sufficiently activated, it in turn provides input to the phonological output lexicon if reading aloud of irregularly spelled vocabulary is required. Orthography-to-phonology conversion (OPC) is responsible for one's ability to read aloud pseudo-words or regularly spelled vocabulary, which do not need to rely on meaning or activation of OIL. The final stage, which is activated for all spoken tasks, involves motor planning and articulation.

In attempting to determine the neural correlates of reading, Hillis and colleagues (2001) assessed hypoperfusion of cortical areas in patients during the hyperacute stages of stroke. They determined that some regions were responsible for more than one component of the reading system, whereas some individual components were associated with more than one cortical area. Disruption of OPC and OIL mechanisms were associated with hypoperfusion of the angular gyrus, although access to the OIL also was negatively impacted by hypoperfusion of the posterior middle temporal gyrus. Lexical-semantic impairments were noted in four areas: the left angular and supramarginal gyri and middle temporal gyrus, with the most important role being played by Wernicke's area.

Hillis and colleagues (2005) later studied the contribution of the visual word form area, or the left midfusiform gyrus (BA 37), to reading because of its known consistent activation during reading tasks. Hypoperfusion of BA 37 was associated with impairments in oral and written naming, whereas difficulty with word comprehension was related to hypoperfusion in the left posterior, superotemporal, and angular gyri. The investigators hypothesized that both the right and left midfusiform gyri play roles, although only one is essential, in the prelexical activity of forming a representation of a sequence of graphemes, called the "graphemic description" (p. 554). The left angular gyrus relies on stored knowledge for OPC, with the modality-independent lexical representations required for output being subsumed by BA 37. A cortical network, involving frontal, temporal, parietal, and occipital cortices, was considered to be essential for various aspects of reading, depending on factors such as spelling regularity, word familiarity, rate of presentation, and level of an individual's reading skills.

Berndt, Haendiges, and Mitchum (2005) summarized the reading impairments of left dominant hemisphere individuals to be caused by impairment of a possible lack of availability of grapheme-to-sound conversion, reducing sublexical activation, which in turn impacts formulation of the abstract sequential code for graphemes required for accessing the graphemic lexicon. These investigators found that more than half of the errors in oral reading consisted of word substitutions, and the majority of these items were visually similar to their targets. Although some individual variation was noted, letter errors increased from the beginnings to the ends of

words. Because subjects without neurologic impairment demonstrate faster reaction times in naming words that have several orthographic neighbors, the authors contend that a tendency exists for those with left hemisphere dysfunction to substitute their targets with words that have letter overlap in the early part of the word. This hypothesis was supported by earlier work (Whitney & Berndt, 1999) demonstrating that, in reading, activation levels are highest at the beginning of a word, followed by a gradual decline because of the activation of subsequent letters and then an increase at the final letter position because no additional letters follow.

Under normal conditions, processing of single words, sentences, and narratives reflects changes in neural circuitry (Xu, Kemeny, Park, Fratalli, & Braun, 2005). In narrative processing, the left hemisphere activations have been found to be stronger, with involvement of the temporal, parietal, and opercular areas at the beginning of a story. These regions are deemed to be implicated in the processing of the factual aspects of a narrative, such as setting, characters, and time. The right hemisphere activations are heightened toward the ends of the narratives, when information is being synthesized and conclusions are being drawn. Others have examined “theory of mind,” or the ability to understand the behavior of others based on interpretation of, for example, feelings, intent, and motivation (Fletcher et al., 1995). Activation has been found bilaterally in the temporal poles, in the left superior temporal gyrus and the posterior cingulate cortex, during narrative processing tasks. The theory of mind tasks, however, implicated the left medial frontal gyrus, with further analysis revealing that more complex social interactions were found in those stories.

Many factors, such as the individual’s educational level, occupation, and avocational interests, are considered in determining the extent to which the visual modality is addressed during treatment. In addition, with patients demonstrating severe impairments, this modality may be better preserved than others (Helm & Barresi, 1980; Helm-Estabrooks, 1983) and can serve as an appropriate entry point in treatment.

Visual Perception

Treatment of visual processing is divided into six areas. Three of these areas fall under the category of visual perception, with the first specifically addressing visual perceptual deficits.

Area 1, Matching Nonverbal Material, requires the patient to match objects, pictures, and geometric forms. In developing a hierarchy of difficulty, picture complexity and degree of stylization can be adjusted (in addition to altering the stimulus category). The task may then be made more difficult by requiring category recognition.

Area 2 incorporates Matching of Verbal Material, such as numbers, letters, and words. Individual hierarchies are established considering variables of length, visual similarity, and size of the stimuli. To tax attention and memory, a series of these items may be introduced.

Area 3, Visual Correspondence/Recognition, demands that the patient recognize different visual forms of the same stimulus. For example, the task may require matching a printed word to a corresponding object, or matching trademarks to referents. Other activities in this area might attempt to strengthen semantic activation through having the patient make decisions about subordinate–superordinate relationships. Individuals with aphasia may experience even more difficulty in performing categorization tasks that involve functional relationships (e.g., things that write) as opposed to those consisting of superordinate relations (McCleary & Hirst, 1986).

Visual Comprehension

Two areas for treatment of visual processing fall under the category of visual comprehension. Area 4 focuses on Reception of Gestured Messages. Although gesture recognition may be a less impaired modality (Porch, 1967), patients with aphasia, as a group, tend to perform more poorly in interpreting pantomimes than do those with normal language abilities. A strong relationship has been found between gesture recognition and the ability of the person with aphasia to imitate non-meaningful movements (Wang & Goodglass, 1992). Pantomime recognition and production are correlated with each other and with auditory comprehension, but not with a global measure of aphasia.

One hierarchy that has been suggested for developing comprehension of gestures, in increasing order of difficulty, is associating object, action picture, object picture, and line drawing to corresponding gestures (Daniloff, Noll, Fristoe, & Lloyd, 1982; Netsu & Marguardt, 1984). Typically, this area would be developed in the context of preparing a patient for a gestural production system. Additional detail will therefore follow in discussion of the Gestural and Gestural-Verbal Communication modality.

Recognition of Spelling is addressed in Area 5. Tasks may involve proofreading activities that include presentation of the patient’s written production or those of others for correction. This activity might be considered a form of monitoring for those who rely heavily on written communication. Also, individuals with surface dyslexia may benefit from sentence judgment tasks requiring homophone recognition (e.g., *We took our/hour car*) (Scott & Byng, 1989).

Reading Comprehension

In the final area for treatment of visual processing, or Area 6, Reading Comprehension activities are initiated in which stimuli may consist of single words, phrases, sentences, or

paragraphs. Treatment of single-word reading deficits has received the most attention in the literature and will be addressed in greater detail. Many treatment methods have been designed for those who demonstrate features of pure alexia or letter-by-letter reading. Investigators tend to agree that the deficits found in pure alexia are associated with prelexical problems and, typically, intact lexical-orthographic and phonologic knowledge (Arguin & Bub, 1994; Coslett, Saffran, Greenbaum, & Schwartz, 1993). It has been hypothesized that the encoding of printed words is forced to be accomplished by the right hemisphere, which is unable to encode individual letters and has limited ability to process low-imageability words, morphemes, and functors (Burbaum & Coslett, 1996). This, in turn, forces the patient to analyze individual letters rather than using a more holistic approach in reading words. Additionally, more difficulty in reading lowercase as compared to uppercase letters may be encountered. One therapeutic approach (Arguin & Bub, 1994) addressed what those authors posited as being the underlying problem of pure alexia, the failure of the patient to encode abstract letter types. Uppercase and lowercase letters of varying fonts were used in matching tasks, followed by speeded reading of pronounceable four-letter strings consisting of uppercase letters and a font resembling script. Improvements were reported for matching tasks, in addition to increased speed and accuracy of reading letter strings.

Another method in treating pure alexia has been to capitalize on the tactile-kinesthetic feedback that the patient may be able to use (Lott, Friedman, & Linebaugh, 1994). A treatment hierarchy was established, starting with copying sets of individual letters in a uniform way, first, in the palm of the hand, followed by naming of the target and then presentation of cards with printed words for copying and oral production. Reading of both trained and untrained word lists improved with this therapy.

Beeson and colleagues (2003) examined the natural recovery and treatment response of a letter-by-letter reader through implementation of a program involving multiple oral reading trails (Moyer, 1979) to improve the reading rate of text. Treatment was not initiated until 22 weeks post-stroke, although performance was monitored before this time to assess changes as a result of spontaneous recovery. Spontaneous recovery of letter naming and single-word reading accuracy did occur, with a slow reading rate of text persisting until the initiation of therapy. The improvement in reading rate after treatment was threefold greater than the gains made during the period (1–3 months) associated with the most significant improvements resulting from spontaneous recovery (Robey et al., 1998). By week 54, the length effect in reading single words was no longer present. Although reading rate continued to be slow, the patient reported being able to once again read for pleasure.

An errorless learning approach has been applied to treating letter-by-letter reading (Sage, Hesketh, & Ralph, 2005).

Errors in reading words of increased length and reduced familiarity were described in a patient with some preserved ability to make semantic judgments of concrete words. The first treatment method was designed to facilitate whole-word reading by having the patient listen to production of a word along with simultaneous visual presentation of its printed form. Repetition of the word was then required until the word was read spontaneously with 80% accuracy. Tactile and visual cues were introduced later to assist in meeting the criterion. At the end of 7 weeks, significant improvement in reading of the trained set occurred, with no generalization to the control items. The second treatment method was implemented in an attempt to improve the accuracy and speed of the patient's letter-by-letter reading. The instructor identified the individual letters of printed words while tracing them in the subject's hand. Gradually, support was withdrawn, with independent oral reading then being required. At the end of 7 weeks, improvements in both the trained and untrained word sets were realized. Although an overall decrease occurred in the number of errors after the implementation of both methods, the investigators noted that the patient's reading pattern evolved to resemble that of deep dyslexia, with an increase in semantic and visual errors. Specific treatment techniques also have been applied to the problems associated with surface dyslexia (Nickels, 1995). In surface dyslexia, in which the impairment is believed to occur at the lexical level, pairing words with mnemonic aids such as pictures improved oral reading of irregularly spelled words, using a whole-word approach, with generalization to untrained items. Another patient was provided with sentence completion tasks involving homophone selection to establish the route from the visual input lexicon to the semantic system. Improvements were particularly evident with treated homophones and, to a lesser extent, with those that were untreated.

Individuals with deep dyslexia are impaired in using grapheme-to-phoneme correspondence rules and in using the whole-word reading route (orthographic input to phonologic output lexicons) and must access the semantic route for reading. Closed class words and pseudo-words are read more poorly than open class words, but semantic value does not appear to be the sole contributing factor (Siverberg, Vigliocco, Insalaco, & Garrett, 1998). Greater accuracy in oral reading was found when comparing list to text forms of presentation, particularly for closed class words. Bound class morphemes were read more accurately than free class morphemes, especially in the list format, although again, both benefited from text presentation. Those authors suggested that treatment emphasizing reading in context might be more advantageous than single-word reading or the training of phoneme-to-grapheme correspondence rules. Teaching grapheme-to-phoneme correspondence rules, however, has been used successfully in some patients with deep dyslexia. Patients were taught to

link letters of the alphabet with specific words that they had selected and then to sound out letters of simple words and nonwords using these established associations (Nickels, 1995).

Stadie and Rilling (2006) compared two forms of treatment for deep dyslexia in a single case study. The first treatment applied was lexically based, with the underlying premise being that greater activation of the target word could be achieved by priming, with presentation of semantically and/or phonologically related words. Prime words were presented on a computer screen, followed by their targets. Feedback and additional cues were provided as needed. After 10 sessions, reading accuracy for trained items had significantly improved, although generalization to untrained vocabulary did not occur. The investigators did note that a part of speech effect no longer was apparent following therapy. The second phase of treatment was non-lexical, teaching grapheme-phoneme correspondence rules by initially pairing graphemes with specific words selected by the patient. Following 19 sessions, reading significantly improved from pre-treatment measures for both trained and untrained vocabulary. Particular gains were found in the reading of content words. Because lexical and sublexical reading processes overlapped in time course, the authors speculated that a combined lexical and non-lexical approach might prove to be the most beneficial.

From the foregoing descriptions of treatment approaches for some of the more clearly defined and studied forms of alexia, efforts have been made to associate the symptomatology with a breakdown in one or more aspects of a model for processing written words. Treatment hierarchies can then be established by altering vocabulary and contextual variables that are known to play specific roles in each of these disorders based on site of lesion. When phrases and sentences are introduced, other factors such as syntax and number of content words relevant to length may be considered. Similar to performance in listening, patients benefit from the presentation of predictive and non-predictive preceding paragraphs to facilitate comprehension of at least certain complex sentence forms (Germani & Pierce, 1992). Altering the degree of redundancy and amount of context can be used in developing a hierarchy for treating various sentence types.

At the paragraph level, overall length can be systematically adjusted while varying individual sentence length, complexity, vocabulary difficulty, and thematic content. In developing or selecting paragraphs, one strives for high passage dependency, which reflects the degree to which accurate responses to questions about the paragraph are dependent on having read the paragraph and not on previous knowledge (Thomas & Jackson, 1997). Other issues affecting passage dependency are the relatedness of the test questions to each other and the plausibility of the answers given a multiple-choice sentence format. Questions involving little known facts and those requiring more detailed answers would be

harder to answer without having read the paragraph on which they are based. It is suggested that if the patient is able to answer less than half the questions without having read the paragraph, higher passage dependency is indicated.

Area 7 completes this modality with Reading Textual Material. As empirical data are limited, individual hierarchies must be developed considering variables such as overall length, vocabulary, redundancy, grammatical complexity, amount of cohesion, use of anaphoric reference, and familiarity (Shewan & Bandur, 1986).

As well, many of the factors outlined in auditory comprehension of narratives and discourse could be applied to and incorporated in this section.

Case Example

NH is a 69-year-old homemaker who suffered from multiple strokes resulting in left frontal and right parietal occipital lobe infarcts. Administration of the Western Aphasia Battery, or WAB, and of the Auditory Comprehension Test for Sentences and the Boston Naming Test revealed a mild auditory processing problem, a mild verbal dyspraxia, anomia, and moderate visual processing and graphic expression difficulties. Because the patient reported being an avid reader up until the time of her most recent stroke, visual processing activities were introduced simultaneously with activities from other modalities.

Language testing suggested good single-word reading comprehension and ability to read short, simple paragraphs. Additional probing demonstrated reading comprehension to be compromised above a Grade 3 readability level. Degree of abstractness also significantly affected performance. The first difficulty level involved presentation of short paragraphs with a readability level of Grade 3 to Grade 4. The patient was required to read the paragraphs and to reformulate them orally using printed who, what, when, where, and why/how prompts. Once NH was successful in recounting the significant points from the paragraphs at this level, the same length of paragraph was used, but the grade level was increased to Grade 5. Over time, paragraph length, abstractness, and grade level were systematically increased. Newspaper articles and short stories were gradually introduced, with the patient eventually reporting success in reading romance novels for enjoyment.

Sample Activities

Level 1

Stimuli:

Paragraphs 75 to 100 syllables in length, Grade 3 to Grade 4 readability, and printed who, what, when, where, and why/how cards.

Procedure:

The patient reads the paragraph and orally responds to who, what, when, where, and why/how prompts.

Level 2

Stimuli: Paragraphs 75 to 100 syllables in length, Grade 5 readability, and printed who, what, when, where, and why/how prompts.

Procedure: The patient reads the paragraph and orally responds to who, what, when, where, and why/how prompts.

Level 3

Stimuli: Paragraphs 75 to 100 syllables in length, Grade 5 readability, and no printed cues.

Procedure: The patient reads the paragraph and orally provides the relevant information.

Gestural and Gestural-Verbal Communication**General Considerations**

Gestural production may prove to be an alternative mode of communication for some patients with severe aphasic impairments or may be used to augment verbal expression attempts. For others, this modality may serve as a starting point in treatment, with gradual transition to oral expression activities.

As noted in the previous section, the gestural modality tends to be less affected than others in aphasia (Porch, 1967), although individuals with more severe impairments have been shown to use fewer complex gestural forms spontaneously in their communication attempts, with gestures becoming nonspecific and unclear (Glosser, Wiener, & Kaplan, 1986). As a group, patients with severe aphasia communicate more often and for longer periods of time through nonverbal means than their communication partners (Herrmann, Reichle, Lucius-Hoene, Wallesch, & Johannsen-Horbach, 1988). Pantomime production is reportedly infrequent, but at least in untrained users, a greater use of codified gestures has been observed, suggesting, perhaps, that they require less creativity and praxis skills. Wang and Goodglass (1992) found a strong correlation between auditory comprehension skills and measures of pantomime recognition and expression. Pantomime performance also was strongly linked to the ability to produce meaningless gestures on imitation. Duffy, Watt, and Duffy (1994) have proposed that both language and neurophysiologic motor and visual processing disorders are tied to pantomime deficits.

Individuals with significant language limitations may be able to acquire some single signs, and patients with less involvement may, perhaps, be capable of acquiring and generalizing simple grammars (Coelho, 1990). Ability to generalize signs has been inversely related to severity of aphasia (Coelho & Duffy, 1987). Aphasia severity may, in fact, be the most significant determinant of successful sign use (Coelho

& Duffy, 1986). Some positive effects on the reception and production of gestures through pantomime training have been described (Schlanger & Freemann, 1979). The American-Indian (Amer-Ind) Sign System (Skelly, 1979) has been used with varying reports of success. Rao (1994) has suggested that possible prognostic indicators for success with Amer-Ind code include good pantomime recognition and that limb apraxia is not severe and predominantly ideomotor rather than ideational in nature. Rose and Douglas (2003) studied the relationship between limb apraxia and gestural use in seven patients with nonfluent aphasia, all of whom had demonstrated a limb apraxia on formalized testing. Conversational samples were elicited and analyzed for the presence of gestures. Despite the presence of an identified limb apraxia on test measures, the patients demonstrated several instances of gestural use to supplement or replace their oral speech attempts. These investigators concluded that the highly conscious nature of the testing, requiring abstract thought, in addition to the removal of meaningful context negatively impacted the patients' performance on those measures. They suggested that gestural training and/or enhancement might best be targeted in naturalistic settings, capitalizing on opportunities to provide reinforcement, modeling, and shaping of behaviors.

Finally, use of gestures can facilitate oral speech production for some patients by serving as a cue for word retrieval or by adding greater descriptive value to verbal output. Individuals may not automatically use this strategy, so specific instruction and coaching may be required for it to be successfully incorporated into communication exchanges.

Social Signals

Area 1 of gestural and gestural-verbal communication, Attention, is an elementary step in gestural communication. The patient learns to obtain the attention of a communication partner through eye contact, touch, vocalization, gesture, or a combination of these.

With Area 2, Acknowledgment of the Message Received, some form of gesture, such as a head nod, is developed to indicate that a message has been received, although not necessarily understood.

Gestures

Single gestures and combinations of gestures are used in Area 3, Gestural Communication. Some investigators have found propositional gestures to be more difficult to acquire than nonpropositional ones (Buck & Duffy, 1980). A possible hierarchy might consist of appropriate facial expressions, conventional gestures, and propositional gestures.

Successful outcomes have been described with Visual Action Therapy, or VAT, in improving both apraxia and gestural communication abilities (Helm-Estabrooks, Fitzpatrick, & Barresi, 1982). In this nonvocal, visual/gestural program,

a hierarchy of activities, ranging from tasks such as requiring the patient to match objects and pictures to gesturing the use of items hidden from view, is used. Modifications to VAT were based on the finding that patients experience less difficulty using gestures representing objects involving proximal movements compared with those involving distal movements (Helm-Estabrooks, Ramsberger, Brownell, & Albert, 1989). With patients demonstrating severe language problems, VAT may serve as the initial phase in treatment, advancing to implementation of Amer-Ind code training.

Communicative importance or personal relevance is one factor that may affect the ease of sign acquisition (Coelho & Duffy, 1986). Patients also have a tendency to experience less difficulty in learning signs that have a high degree of iconicity—that is, those for which the meaning is evident based on their physical or structural characteristics (Coelho & Duffy, 1986). Other important variables to consider are the stimuli selected to teach the gestures. Objects and action pictures have been found to evoke superior gestural performance to line drawings (Netsu & Marguardt, 1984).

A treatment hierarchy has been described by Rao (1994) for training patients with aphasia in the use of Amer-Ind code. It consists of a continuum of tasks: demonstration, recognition, imitation, replication, consolidation, retrieval, and initiation. Additional strategies to ensure generalization include involving significant others in the program and encouraging some risk taking on the part of the patient.

Speech Acts

Area 4, Simple Speech Acts, incorporates both message content (proposition) and intent of the speaker (elocutionary force). Elocutionary force is communicated with gestures and/or vocalization to signal a command, statement, or question. Simple pointing gestures may be used to communicate content, such as indicating the action, agent, or object. Area 5, Speech Acts, includes a combination of verbal and nonverbal communication. Gestures continue, however, to carry the burden of communication, although some verbalization may be produced.

Case Example

AG is a 62-year-old, retired political consultant who suffered a stroke, with a large left middle cerebral artery infarct, resulting in global aphasia and a right hemiplegia. Initially, the Boston Assessment of Severe Aphasia was administered. Relative strengths were found in the areas of oral-gestural expression, gesture recognition, and visuospatial tasks. Various treatment strategies were used to develop oral expression skills, including VAT and Melodic Intonation Therapy as well as LOT naming and sentence formulation activities. Functional oral communication skills, however, remained severely limited.

The Amer-Ind Sign System (Skelly, 1979) was next introduced. Because this treatment approach focuses on new learning as opposed to stimulation of previously learned material, a strict LOT paradigm could not apply. Ten common agents and actions were chosen for training. Initially, the clinician provided a gesture along with an array of four action pictures from which the patient was to select the one associated with the gesture. Once recognition was established, AG was required to produce the gesture in response to an action picture. In the next phase of treatment, situations were simulated in which AG provided the gesture in the absence of the action picture.

The subsequent difficulty level involved encouraging the use of trained gestures in conversational attempts. AG consistently progressed through his treatment program, successfully producing gestures that had not even been trained. Continuous encouragement and counseling were needed, however, because AG was reluctant to use gestural communication as a substitute for oral speech, even several months poststroke.

Sample Activities

Level 1

Stimuli: Ten pictured actions, along with 20 foils.

Procedure: The clinician presents an array of four pictures to the patient and produces a gesture corresponding to one of the actions depicted. The patient points to the appropriate picture.

Level 2

Stimuli: The 10 action pictures used in Level 1 for identification.

Procedure: The pictures are presented one at a time, and the patient is required to produce the associated gesture.

Level 3

Stimuli: The 10 action pictures used in Levels 1 and 2.

Procedure: A sentence or brief story is aurally presented, and the patient is required to complete the sentence with the appropriate gesture (e.g., *When you are hungry, you*).

Oral Expression

General Considerations

Oral expression problems vary with respect to both nature and severity in aphasia. Although oral expression patterns differ among types of aphasia, many patients share common impairments. Problems may be encountered with highly overlearned or automatic speech, phonologic articulatory skills, repetition, oral reading, naming, sentence formulation, and discourse planning/production. Because these

areas are not mutually exclusive, limitations involving one area may directly affect another. Treatment therefore may simultaneously incorporate two or more areas. In developing a therapeutic plan, the areas of deficit, along with their nature and severity, are carefully examined.

Automatic Speech

Area 1 of Oral Expression addresses development of Automatic Speech Series. Activities are designed to facilitate oral speech in those patients with very limited verbal output. Stimuli such as greetings, number sequences, poems, days of the week, months of the year, and letters of the alphabet may be incorporated.

Voluntary Control of Involuntary Utterances, or VCIU, is a treatment approach designed for patients with nonfluent aphasia that attempts to use their stereotypic expressions as a step to develop meaningful propositional speech (Helm & Barresi, 1980). It incorporates a progression through oral reading, confrontation naming, and conversation involving production of the stereotypic words and phrases.

Phonological-Articulatory Production

Misarticulations that occur with aphasia may be the result of phonological problems, articulatory problems, or a combination of both. Phonologic-articulatory impairment resulting from an anterior left hemisphere lesion, in and surrounding Broca's area, most often is termed verbal dyspraxia. Posterior left hemisphere lesions also may result in sound production errors, generally in the form of literal or phonemic paraphasias.

Language-Oriented Treatment activities in Area 2, Phonologic-Articulatory Production, are based on Shewan's (1980) Content Network for treating verbal dyspraxia. Separate hierarchies for presentation method, stimulus characteristics, type of response, and facilitation of response variables have been constructed according to difficulty levels. These hierarchies are based on data provided by a variety of researchers. A step-by-step progression toward the goal of achieving spontaneous production of propositional speech is used, as the patient can accommodate. Support provided by the clinician is gradually reduced to ensure that the patient develops more independence in oral speech.

In selecting treatment stimuli, several variables may be critical. At the phoneme level, vowels are easier to produce than consonants, and highly frequent consonants are less difficult than those of low frequency. Distinctive feature characteristics also play a role in ease of production, with nasality and voicing features being less problematic than manner and place. In phoneme selection, the clinician therefore can establish a hierarchy incorporating all of these parameters.

When introducing single words, performance is influenced positively by concrete, functional words. Additional variables that may be important to control are word fre-

quency and length. Howard and Smith (2002) examined a group of 12 individuals with aphasia who demonstrated phonologic errors in repetition. They found that two-syllable words with word final stress were most likely to be impaired in both repetition and naming tasks. When they did occur, errors were significantly more frequent on production of the second syllable. In repetition, the majority of errors of stress assignment were produced on words with weak-strong stress patterns. In both picture naming and repetition, three-syllable words with primary stress on the second syllable were the most affected. In conclusion, those authors found that weak-stress and weak-strong-weak patterns were less likely to be produced correctly. They hypothesized that stress-related errors are related to problems with phonologic assembly when stress does not automatically occur on the first syllable.

Beyond single words, phrase/sentence length, stress pattern, and linguistic complexity may be systematically varied to increase the difficulty levels in treatment. Differing presentation methods also can be incorporated into a hierarchy. Combined auditory-visual presentation may facilitate correct speech production more easily than either auditory or visual presentation in isolation.

The clinician may alter the type of response required, such as production following a model, unison production, or production requiring a number of consecutive responses. Facilitating response variables can be manipulated to elicit more accurate productions. For example, associated movements, such as finger tapping, may accompany speech. Inserting a schwa (/ə/) between consonants in a cluster may enhance performance. Facilitating responses may be used temporarily by some and be required as long-term strategies by others.

As the patient advances within the treatment hierarchy, additional response complexity can be required while maintaining the presentation method, stimuli, and facilitating response variables constant. More spontaneous productions are incorporated, with the clinician gradually withdrawing assistance.

Repetition

Although the ability to repeat is not an end goal in treatment, this skill is described in Area 3, to facilitate performance of other related speech-language behaviors. For example, repetition tasks may be used in treating verbal dyspraxia and play an important component of Melodic Intonation Therapy, which consists of a hierarchy of three levels in which multisyllabic words and short, high-probability phrases are musically intoned, followed by longer, phonologically complex sentences (Sparks, Helm, & Albert, cited in Helm-Estabrooks & Albert, 1991).

When preparing stimuli for repetition activities, many factors can influence performance. Single-word repetition is

affected by phonologic complexity, frequency of occurrence, semantic class, and if the stimulus is a foreign or pseudo-word (Ramsberger, 1996). When abstractness and frequency are controlled, repetition of emotional words is superior to that of nonemotional vocabulary. High probability (Goodglass & Kaplan, 1972, 1983) and personally relevant material (Wallace & Canter, 1985) are easier to repeat, as are shorter items (Gardner & Winner, 1978). When sentence-level material is introduced, a hierarchy that varies sentence forms (Goodglass 1968, 1976) can be used, because patients demonstrate repetition difficulty with increasing syntactic complexity.

Response variables can affect accuracy and/or ease of production. For some individuals, use of a delay before initiation of a response can facilitate performance, although for others, this strategy may have a negative impact (Gardner & Winner, 1978). It therefore is important for the clinician to determine the direction of this effect before its implementation in treatment.

Oral Reading and Spelling

Area 4, Oral Reading, most often is used as a vehicle for treating other aspects of speech-language skills, as Area 3 is. Improvements in language functioning, such as reading comprehension, oral expression, auditory comprehension, and written expression, have been described (Cherney, Merbitz, & Grip, 1986; Tuomainen & Laine, 1991). Oral reading of sentences and paragraphs, whether in unison and independently, has resulted in improved language skills in those with fluent and those with nonfluent aphasia. Presentation of scrambled written sentences for oral reading can be used with patients who may demonstrate impulsive responding and poor self-monitoring skills. They can be required to point to each word in the sentence while reading aloud, with sentences being systematically adjusted for length and syntactic complexity.

Some forms of dyslexia have been characterized by differences in oral reading performance. These were described in detail in the discussion of the Visual Processing modality, within the area of Reading Comprehension. Area 5, Oral Spelling, may be used as an activity to enhance written spelling skills and be practiced as a strategy for word retrieval with some patients.

Word Retrieval

Word-finding problems are associated with all types of aphasia and also may occur in patients with non-aphasic disorders. Anomic aphasia has been associated with lesions outside the perisylvian region in the anterior or inferior temporal regions. For example, Damasio, Tranel, Grabowski, Adolphs, and Damasio (2004) examined the naming of specific categories in individuals with brain damage. In their investigations, errors in naming unique persons were associ-

ated with lesions primarily in the left temporal pole; errors in naming of animals with lesions in the left antero-inferior temporal lobe, anterior insula, and dorsal temporo-occipital junction; and errors in naming of tools in the posterolateral temporo-occipito-parietal junction. These investigators proposed that although the perisylvian structures are involved in the transient reconstruction and explicit phonemic representation of word forms, additional neural sites mediate between those that support conceptual knowledge and the perisylvian structures, triggering and conducting the process of reconstruction. They claimed that no single mediational site exists for words but, rather, that separable regions exist within a large network, which would preferentially assist in the processing of words denoting varied kinds of entities (e.g., unique persons).

Having an appreciation for a model of lexical processing and formulating hypotheses regarding the cause of word retrieval symptoms in a given patient can lead to the design of individualized treatment procedures. Responses can be analyzed more effectively; not only enabling the clinician to successively respond online but also, with explanation, enabling the patient to develop a greater understanding of how and when errors may be generated.

The generally agreed-on cognitive processes involved in single-word production are semantic or meaning-based, involving word selection to convey a concept, and phonologic, which is used to access phonemes (Goldrick & Rapp, 2002). Researchers disagree concerning the degree to which these two processes interact (Dell, Schwartz, Martin, Saffran, & Gagnon, 1997; Levelt, Roelofs, & Myers, 1999). The model of Goldrick and Rapp (2002) is termed a restricted interaction account of spoken word production. In the first stage, a concept activates numerous semantic features, with the activation spreading to the next level (L-Level or lexical representations), with the target word and its neighbors that share semantic and/or syntactic information being activated. Activation also spreads to the phoneme level, again activating the target word and its related neighbors. In turn, the phoneme level provides feedback to the L-Level, activating the target and competitors that are phonologically similar. The most active unit, as compared to its neighbors, at the L-Level is chosen and feeds information down to the phoneme level, along with weaker activation of its competitors. Continued feedback from the phoneme level to the L-Level eventually results in the most appropriate word being selected from those with competing semantic and syntactic information.

Martin and Saffran (2002) examined the outcomes of investigations concerning the relationship between input and output phonologic processing and tested their hypothesis that such a relationship exists. On measures of phoneme discrimination and on rhyming judgment tasks, those with poor performance also made more nonword but phonologically related errors on picture naming. During

comprehension, acoustic information is mapped to phonologic and then to lexical, followed by semantic and then conceptual, representations. The top-down lexical-semantic processing could help to compensate for an impaired phonologic network. The authors proposed that, in production, impairment of a single phonologic network would create a greater challenge, because the benefit from lexical-semantic feedback is less than that provided during the input process.

These models can be used to account for the various error types found in aphasia (Goldrick & Rapp, 2002). Damage to the semantic or L-Levels results in production of semantic errors, with impairment at the phoneme level causing multiple error types. The effect is postulated to be comparable to introducing noise into the processing system. If noise affects the L-Level, various errors can occur because of decreased activation of the target, allowing an opportunity for increased activation of semantically related and unrelated neighbors. Disrupted feedback to the phoneme level can result in nonword errors being produced from the lack of signal strength of the appropriate phonemes.

Nickels (2002) reviewed the aphasia literature addressing word retrieval treatment methods described through single-case studies. Findings indicated the positive effects of treatment but left unanswered specifically what form of treatment might work best for a given individual and how these improvements can be generalized to functional language use. It might be argued that greater specificity regarding selection and control of vocabulary as well as cueing strategies might be better delineated according to the specific word retrieval problem of the individual patient. Methods of strengthening activation patterns at the levels of disruption during the naming process need to be explored so that the underlying nature of the deficit can be treated with greater precision.

In creating activities in Area 6, the goal is to facilitate the actual word retrieval process rather than to teach specific vocabulary items. The clinician first attempts to determine the nature of the word retrieval problem or where in the process the breakdown appears to occur, establishes the vocabulary level and type with which the patient experiences errors, and determines whether patterns of performance vary across picture description, confrontation naming, and conversational activities.

Selecting vocabulary and developing a hierarchy includes consideration of the lesion site and its known impact on naming, including word characteristics. Differences in the ability to recall living (e.g., animals, food, flowers, or body parts) as opposed to non-living object labels have been described (De Renzi & Lucchelli, 1994). One explanation is that members of living categories are discriminated among each other based on visual features, rendering them more difficult to name, whereas identification of tools is based on functional characteristics. Others argue that when con-

founding effects are controlled, animacy and operativity do not play significant roles in word retrieval (Howard, Best, Bruce, & Gatehouse, 1995). A trend does, however, appear to exist for objects experienced through multiple senses to be better named. Many patients also demonstrate greater success in naming objects that are not embedded in a physical context (e.g., doorknob) or are separate from their environment.

In other activation studies involving normal subjects, Damasio and colleagues (2004) found a small area of activation in the temporal lobe for naming unique persons, animals, and tools. Increases also were found in rCBF in the left temporal pole for persons; animals and tools activated the left posteroinferior temporal region, with tool naming activation noted in the posterior middle and inferior temporal gyri. Bandur, Parrent, and Steven (2006) studied intraoperative naming errors in patients undergoing dominant anterior temporal lobectomies for epilepsy. During electrical stimulation, naming errors were incurred at sites located more anterior to those identified during implementation of traditional language mapping tasks. Of those sites, the majority included naming errors involving unique persons, which is consistent with results from lesion studies and activation findings in normal subjects.

It has been purported that word retrieval of common nouns in conduction and Broca's aphasia can occur late in lexical retrieval once semantic activation has occurred and some indication of word form has been established or, in some instances, may reflect unsuccessful lemma retrieval (Beeson, Holland, & Murray, 1997). Reporting on the frequently observed tip-of-the-tongue phenomenon, the authors found that these two groups were more successful than chance in identifying the initial letters of target words (names of famous faces). Alternatively, more limited evidence exists to suggest that word form knowledge is intact for patients with Wernicke's and anomic aphasia.

The influence of grammatical class on naming has been examined in neurologically intact subjects using positron-emission tomography. Tranel, Martin, Damasio, Grabowski, and Hichwa (2005) reported that areas associated with action naming were the left frontal operculum and the left posterior middle temporal region. The middle temporal area was more activated in naming actions than in naming tools. The naming of homonymous verbs (e.g., comb) resulted in less activation of the frontal operculum and middle temporal area. The homonymous nouns activated the frontal operculum and the left inferior temporal area, but the non-homonymous nouns only produced activation in the left inferior temporal lobe. The authors concluded that grammatical class does play a role in word retrieval.

Berndt, Burton, Haendiges, and Mitchum (2002) studied the effect of word class on word retrieval of nouns and verbs in aphasia and a matched normal control group through use of various elicitation contexts. When matched for frequency,

both patients with aphasia and controls demonstrated more difficulty in naming pictured actions using latency measures. The authors judged that imageability was not a contributing factor. The poorer naming performance of verbs by patients correlated with poor sentence production skills. This group also tended to substitute nouns for verbs across all the tasks as compared to those with anomia.

Some investigators have reported that semantic and grammatical categories may be differentially affected depending on the type of aphasia (Berndt, Mitchum, Haendiges, & Sandson, 1997; Goodglass et al., 1966). Noun impairments have been specifically associated with severe anomia, although verb retrieval deficits can occur with both Broca's and Wernicke's aphasia. Lu and colleagues (2002) studied the controversy regarding whether category-specific naming deficits are attributed to grammatical or semantic category specifications. They found that patients who had undergone left anterior temporal lobectomies performed more poorly than those who had undergone right temporal lobectomies and that both groups were less successful at naming actions than at naming objects. It also was noted that patients in the left anterior temporal lobectomy group demonstrated better naming of objects defined by visual attributes compared with those associated more with human action.

Within the grammatical category of verbs, other factors also may affect performance. Light verbs (e.g., have, do, and come), although frequently used, may generate a number of meanings when activated, which, in turn, render them more difficult to retrieve compared with heavy or more complex verbs (e.g., run, hit, and stop) (Breedin, Saffron, & Schwartz, 1998). Lambon-Ralph, Braber, McClelland, and Patterson (2005) studied a group of patients with nonfluent aphasia to compare production of regular and irregular verb forms. They found that those patients demonstrating the most consistent problem in producing regular past tense verbs were those who were most impacted by phonologic complexity (consonant clusters) and atypicality (syllabic stress falling on the second syllable).

Finally, some additional stimulus variables to consider are word length, frequency, and concreteness. An item may be easier to name if its label is of low uncertainty. Uncertainty indicates the consistency with which an item is called a particular name. Some individuals may be sensitive to prototypicality, or the degree to which an item is characteristic of its class.

Once stimuli have been selected, effective cueing strategies are determined for each patient. Best, Herbert, Hickin, Osborne, and Howard (2002) studied a group of 11 individuals with aphasia to examine the effects of training with cues including repetition, rhyme, and phonemic and orthographic cues. All cue conditions were effective, and they remained so for a period of 10 minutes. The authors did not find a relationship between degree of impairment and the

ultimate size of the facilitation effect. The largest cue effects were found in those whose impairments did not lay at either the semantic or phonologic levels but appeared to be associated with mapping between the two levels.

Patients with anomia also seem to demonstrate a preference for semantic cues (Li & Williams, 1990) when verbs are presented. Wambaugh (2003) compared the use of phonologic and semantic cues in the treatment of one patient with chronic anomia. Although both types of cues proved to be beneficial, a greater and sustained effect after 6 weeks was found with the lists trained using semantic cues.

Some findings (Stimley & Noll, 1991) indicate that presentation of semantic cues increases the number of semantic paraphasias, with a decrease in unrelated word errors. Phonemic cue presentation, on the other hand, may increase the number of phonemic paraphasias. Another factor to consider in cue presentation is the use of simultaneous cues (e.g., initial syllable combined with sentence completion format). Particularly with those who demonstrate more severe impairments, combined presentation may be most effective (Huntley, Pindzola, & Werdner, 1986). Marshall, Karow, Freed, and Babcock (2002) examined the facilitation effects of personalized cues on naming in a group of unimpaired speakers and in a group with patients with aphasia. Each group was required to learn a list of names from a subordinate category (dogs) by developing their own cues that would potentially aid recall. Training sessions occurred three times per week over a 4-week period. For the group without brain damage, no effect for cue type on learning was found. The group with aphasia, however, demonstrated a positive effect for semantic as compared to only phonologic information.

Hickin, Best, Herber, Howard, and Osborne (2002) studied the long-term effectiveness of phonologic and orthographic cueing in facilitating word retrieval with 8 patients who demonstrated difficulty mapping semantics to phonology. In this study, patients were given the choice of cues that they wished to be presented. Seven of the eight patients demonstrated a significant improvement on a 200-word naming task at the end of 8 weeks of treatment conducted once weekly. No one cue was found to be more effective, which could reflect the fact that both cues were trained within the same sessions. The authors suggested that the success of their study might be related to the patients choosing the cues, perhaps signaling more active reflection during the tasks. The three individuals who benefited most from therapy were those with good repetition and oral reading skills.

The hierarchy shown in Figure 28-3 is an attempt to integrate the findings of various researchers. A number of activities and contexts may be employed to assist the patient in developing an understanding of the effectiveness and use of cues. Less difficulty may be encountered in naming pictured stimuli than in providing responses to definition or sentence

Most Effective	Cue
	Repetition—The target word presented as a model for the subject.
	Delay—The subject delays before responding with a name.
	Phonemic—The initial phoneme or syllable is provided by the clinician.
	Sentence completion—A sentence is presented by the examiner with a blank for the subject to complete with the target word. The fewer the number of possible words that can complete the sentence the more efficient the cuing.
	Semantic association—A word that is semantically associated with the target word is presented by the clinician.
	Printed word—The printed target word is presented.
	Description—A description of the item is provided by the clinician.
	Rhyming word—A word that rhymes with the target is presented by the clinician.
	Situational context—A situation in which the item would be found is provided.
	Spelled word—The target word is spelled orally for the subject.
	Functional description—The function of the target item is given by the clinician.
Least Effective	Superordinate—A superordinate term is provided by the clinician.
	Generalization—A general statement that provides little specific information is given by the clinician.

Figure 28-3. Hierarchy of cues according to effectiveness level.

completion tasks (Berndt et al., 1997), particularly in the presence of auditory comprehension problems. Patients with anomia, on the other hand, may benefit from the presentation of a sentence frame containing a word semantically related to the target (McCall, Cox, Shelton, & Weinrich, 1997). Both the syntactic context and/or syntactic constraints imposed, supplemented by semantic information, appear to be facilitative.

Differing findings regarding the use of real objects, colored photos, or line drawings have been cited, so the clinician may need to alter this presentation variable on an individual basis (Benton, Smith, & Lang, 1972; Bisiach, 1966).

As patients advance along a hierarchy—that is, using increasingly difficult levels of vocabulary and cue presentation—responsibility for cueing is shifted from the clinician to the patient. Ultimately, tasks should be implemented that allow practice to occur in meaningful, naturalistic situations. For example, application of Promoting Aphasics' Communicative Effectiveness (Davis & Wilcox, 1981), or PACE, which encourages patients to use multiple channels to communicate, has met with some success in developing effective cueing strategies (Li, Kitselman, Dusatko, & Spinelli, 1988).

Sentence Formulation

Area 7, Sentence Formulation, focuses on the generation of meaningful units at the phrase and sentence levels. A hierarchy of sentence types may be established, such as that found in the Helm Elicited Language Program for Syntax Stimulation (Helm-Estabrooks, 1981), or HELPSS. This approach was developed for patients with nonfluent aphasia to improve their use of syntax by training 11 sentence types with a story completion format. Sentence types range from the imperative intransitive to use of the future verb tense.

A hierarchy of sentence types for training also might be created based on order of reappearance in language samples

(Ludlow, 1973) elicited from those with aphasia. Difficulty levels can be developed by varying the uses of morphological markers (Goodglass & Berko, 1960) and by varying phrase/sentence length. The stress pattern of a sentence may influence performance of some individuals. Patients with Broca's aphasia, for example, tend to initiate utterances with stressed words. Use of stress in these cases would be an important variable to include in the treatment hierarchy.

Another highly researched approach in treating agrammatism has been mapping therapy (Byng, Nickels, and Black, 1994; Marshall, 1995; Schwartz et al., 1994; Thompson & Shapiro, 1995). The mapping deficit hypothesis suggests that some patients are unable to relate sentence form to meaning (Marshall, 1995). The problem can arise from a lexical deficit in which the verb fails to provide information about its thematic structure (goal or agent) or a procedural deficit in which the rules assigning thematic roles to moved argument structures are lost. These limitations occur in both comprehension and production, although patients generally are able to carry out grammaticality judgments, perhaps related to residual syntactic skills. No one particular application of mapping therapy has proven to result in qualitatively or quantitatively similar outcomes for all patients, requiring highly individualized implementation. Typically, treatment involves both comprehension and production tasks to encourage explicit analysis of verb-noun relational structures in canonical (e.g., subject-verb-object) and non-canonical sentence types (Schwartz et al., 1994). Colored lines may be drawn on cards to represent syntactic class (noun phrase and verb), with the patient required to select the appropriate color-coded written phrases to match the cards and corresponding pictured representation (Byng et al., 1994). Eventually, the patient is required to produce the sentence, with prompts from the clinician to enable the development and use of self-monitoring and problem-solving skills. Byng and colleagues (1994) described increased verb

retrieval with their patients using this method. Other improvements were noted but varied with individuals, perhaps reflecting differing patterns of deficits and/or a need for more customized approaches. Although no specific training in production was provided to their group with chronic, nonfluent aphasia, Schwartz and colleagues (1994) found that the majority of patients improved on one or more of their production measures following a course of mapping therapy.

Mapping therapy for sentence production has been investigated by Rochon, Laird, Bose, and Scofield (2005). Improvements on all trained sentence structures were found with varied degrees of generalization. The authors commented that performance might have been reflective of the heterogeneous skills with thematic role mapping demonstrated by the participants, even before the beginning of treatment. Thompson and Shapiro (1994) concerned that treatment approaches for sentence formulation were targeting only the surface forms of sentences and not their linguistic and psycholinguistic underpinnings developed a Linguistic-Specific Approach (LST). They proposed that by addressing the underlying representations and processes of sentence formulation, generalization to untrained items could be enabled. The LST was applied to training of sentences in which noun phrases (NPs) had been moved out of their canonical positions. The investigators initiated treatment with more complex forms: NP-Verb-NP-PP (e.g., *The mother is taking flowers from her son*) vs. NP-Verb (copula)-NP (e.g., *Flowers are plants*). They found generalization to the less complex sentences of the same type and, in three of the eight patients, generalization to untrained sentence types. The authors claimed that improvement on untrained sentence types resulted because they involved similar underlying forms and processes. Individual differences were noted across patients, indicating that other variables may need to be considered, such as lesion site and/or psychological factors. In a study conducted to validate the generalization findings from complex to less complex structures (Thompson, Shapiro, Kiran, & Sobecks, 2003), the authors again revealed this phenomenon with significantly less generalization occurring when simpler forms were trained first. They also found an improvement in comprehension skills, although a similar generalization pattern was not apparent. Other noteworthy findings were an increase in utterance length and in the proportion of grammatical sentences documented in narrative analysis.

Generalization of LST treatment gains to discourse was further studied by Thompson and Shapiro (1995). At the completion of treatment, they found that more complex sentences in discourse were evident, along with an increase in the number of verbs produced. Ballard and Thompson (1999) determined this approach to be successful in a group of five patients with Broca's aphasia; those with the least severe impairments benefited most, with narrative produc-

tions becoming more informative and efficient. Jacobs (2001) further detailed discourse changes following LST and found that communicative efficiency improved, with only a positive trend in informativeness for four of the five patients studied. Significant improvements in grammar were not shown, although listener comfort was rated as being higher post-treatment. In summary, the application of a systematic psycholinguistic approach, such as LST, to address the underlying nature of agrammatism has shown promising results. This approach challenges our thinking in the development of sentence hierarchies, and it leads us to reexamine the complexity factor within that context.

The use of C-VIC has been widely investigated, particularly with respect to its use with patients exhibiting nonfluent aphasia. In this system (Weinrich, McCall, Weber, Thomas, & Thornburg, 1995), patients were introduced to a lexicon consisting of animate nouns, common nouns, verbs, prepositions, and modifiers. Icons with printed words were available to be inserted into slots provided for the patient and clinician/interactant to form simple syntactic constructions. Employing comprehension and formulation tasks, while encouraging subsequent verbalization, subject-verb-object constructions improved both when using C-VIC and in spontaneous speech. Improvements also were noted in the use of locative prepositional phrases (e.g., in, on, and by). Some patients have demonstrated a positive response through C-VIC training that targets tense inflection (Weinrich, Shelton, Cox, & McCall, 1997). Gains in retrieving verbs also were a by-product of this approach. To date, successful attempts to facilitate the generalization of single sentence production in C-VIC to narrative production have not been reported (Weinrich, Shelton, McCall, & Cox, 1997).

The C-VIC training might be employed as a branch step in LOT to facilitate oral sentence forms with those who are unable to make gains in these abilities using the methods described previously. For some with severe aphasic limitations, C-VIC might serve as a more permanent avenue of communication. Naeser and colleagues (1998) studied a group of patients with severe aphasia to isolate factors that might play a role in determining successful candidacy for C-VIC. These authors concluded that the best outcome (ability to initiate communication with C-VIC) was associated with a lesion sparing large portions of either the posterior or anterior systems involved in language recovery. Inability to use C-VIC was associated with bilateral lesions. Overall test scores on the Boston Assessment of Severe Aphasia (Helm-Estabrooks, Ramsberger, Morgan, & Nicholas, 1989b) also were good indicators of response to C-VIC when considered along with lesion data.

Finally, in selecting treatment tasks and or materials, the impact of contextual variables, such as use of pictured stimuli or conversation, needs to be considered in terms of how they may impact responses. Some patients produce a

greater number of major utterances (subject-predicate) in response to pictures compared with the number in conversation (Easterbrook, Brown, & Perera, 1982); others may produce more words, depending on the gender bias of the picture (Correia, Brookshire, & Nicholas, 1990).

Conversation and Discourse

Current practice delineates four categories of discourse: conversational, expository, procedural and narrative. Although conversation is formally addressed in Area 8, many of the parameters affecting performance also apply to other forms of discourse (Area 9) and will be outlined in that section. Unique to conversation, however, are the roles of turn taking and repair (Ferguson, 1998). Turn taking was found to be unimpaired in a sample of speakers with fluent aphasia when conversing with both familiar and unfamiliar communication partners. Perkins (1995) suggested that conversational partners respond based on the amount of shared knowledge, degree of linguistic impairment, and individual discourse styles. For example, the presence of significant difficulties in oral expression in the context of shared knowledge regarding a particular topic may result in glossing over of problematic aspects in conversation rather than in working to modify them through collaborative repair. Variability of tolerance for pauses also can be found among communication partners, which can impact turn taking and repair.

Successful use of the involvement of significant others in treating conversation has been reported by authors incorporating different approaches. Conversational coaching (Holland, 1991) uses prepared scripts, requiring the patient, with initial support from the clinician, to communicate the story to a significant other. The clinician assists the communication partner in identifying opportunities for and practicing implementation of effective strategies to facilitate the exchange. Hopper, Holland, and Rewega (2002) studied the efficacy of conversational coaching with two couples. Ten treatment sessions were provided in which communication strategies were described, modeled, and then practiced by the pairs. Following treatment, the patients demonstrated an increase in the number of main ideas conveyed in telling stories to their partners. The investigators suggested that developing an understanding of the couples' communication patterns and styles before treatment were important factors in facilitating conversational success.

Using a modified approach in a case report, Boles (1998) selected three aspects of a spouse's conversational style for intervention. With the spouse reducing her rate of speech, percentage of talking turns, and topic shifts, the patient participated more effectively and to a greater extent in conversation.

Kagan, Black, Duchan, Simmons-Mackie, and Square (2001) reported on the effectiveness of teaching conversa-

tional strategies to communication partners of those with aphasia called Supported Conversation for Adults with Aphasia, or SCA. The program was designed to assist those with aphasia to express, verbally and/or nonverbally, their knowledge, thoughts, and feelings by directly training others to enhance communication opportunities, both as a listener and as an enabler for more successful communication attempts. The volunteer training program consisted of a 1-day workshop focusing on behaviors that assist in both acknowledging and revealing the competence of those with aphasia, followed by conversational opportunities, in which the volunteers' skills were rated and compared to those of an untrained, matched control group. This approach was proven to be effective in improving the skills of the volunteers and the effectiveness of conversations in those with aphasia.

Simmons-Mackie, Kingston, and Schultz (2004) studied the conversational interactions of a patient when the communication partner was successful in using a variety of behaviors, such as eye gaze, posture, and introduction of contextual referents to enable the person to successfully convey his or her message. The authors maintained that, although some individuals might intuitively adopt these behaviors, others benefit from more direct training.

Another form of communication, collaborative referencing, has been examined in the context of aphasia (Hengst, 2003). This process was examined in a group of patients with aphasia and familiar communication partners when they were jointly performing a complex task. The couples demonstrated a number of different verbal and nonverbal means to communicate information, perspectives, and goals. It was observed that the pairs relied on their shared personal histories to frame their communication, and over the course of the trials, communication became less effortful and overt, a pattern similar to that found in those without aphasia. These patients were in the chronic stage of aphasia, so it was difficult to determine the role that treatment may have played in enabling them to use various strategies with their routine communication partners. The study does, however, demonstrate that even those with moderate to severe aphasia can learn and modify behavior through collaborative referencing tasks, and this area may be an important one to address in establishing more functional communication exchanges and/or in attempting to generalize targeted areas in treatment.

Reported speech is a common form of conversation and one that may be enhanced in those with aphasia to promote more functional communication. Hengst, Frame, Neuman-Strizel, and Gannaway (2005) described reported speech to be an act of discourse for quoting or paraphrasing an individual's words from another point in time. The rephrasing and/or restating may consist of the production of one's own words or of someone else's. In examining the conversational patterns of seven individuals with aphasia who had either

completed or were in the course of the therapy, the investigators found that reported speech was used by those with aphasia and actually provided contextual information to their partner for them to successfully communicate despite syntactic and linguistic errors. The authors suggested that measures of reported speech could be used for documenting functional changes in communication over time and could be included as a goal in therapy. Five forms of reported speech were described and coded: direct (direct quotation), indirect (paraphrased), projected (suggesting what someone should have said or to speak for animals/objects), indexed (not stated directly or indirectly but "pointed to," e.g., *That's what I heard*), and undecided (unable to categorize). The first two forms of reported speech are the ones used most often and may be appropriate tasks for treatment. The value of a shared history was an important factor in reported speech, so involving significant others in this aspect of treatment would be especially important.

Drawing on the work of the previously mentioned authors, one might develop a hierarchy of activities in enhancing conversational exchanges between patients and significant others. Communication partners might benefit from specific instruction in dealing appropriately with pauses in conversation, altering their rate of speech, effectively introducing new topics, and modifying their turn taking. Various forms of conversation also could be introduced, in which the amount of shared knowledge or new information is controlled. Although pragmatic deficits in conversation have been documented less frequently in those with aphasia, some may require instruction and practice in turn taking, topic maintenance, seeking clarification, and initiating repairs. Treatment in the area of conversation also may focus on the generalization of specific linguistic skills, such as word retrieval, gestural production, or writing, to everyday communication situations.

A model for evaluating discourse can be useful for both assessment and planning intervention in Area 9. Chapman and Ulatowska (1992) described discourse as involving an interaction between cognition and language and detailed the components of discourse production. Superstructure refers to elements such as setting (e.g., characters, time, and place), complicating action (sequence of events), and resolution. The global meaning or semantic content is termed macrostructure, which is closely tied to cognition and, to a lesser degree, linguistic performance. Tasks that address this aspect of discourse may include summarizing the story, selecting the main idea/gist, identifying the main hero, formulating a title, and deriving a lesson/moral. As the complexity and degree of abstraction are increased with these activities, opportunities for incorporating more linguistically complex sentence forms become available.

The ability of the speaker to maintain coherence or a unified theme depends not only on the macrostructure but also on the microstructure components of discourse (Hough &

Pierce, 1994). Microstructure coherence deals with the conceptual links that are established between sentences or propositions. Appropriate use of pronouns (with corresponding referents), articles, and ellipsis (the sentence construction is incomplete, but the intent is understood) signal that the speaker is aware of when information is novel or has, in some way, already been communicated to the listener. Coherence also is aided by inclusion of cohesive ties between sentences such as coreference and anaphora.

When developing a hierarchy for discourse production, many variables can be altered, depending on the particular profile of the patient. One might initiate treatment with tasks that require identification of the components of the superstructure in relation to a particular topic. Practice in identifying the main concepts can be followed by development of accuracy and completeness of information. Nicholas and Brookshire (1995a) determined that the presence, completeness, and accuracy of main concepts in connected speech were related to the severity of aphasia. Patients with less severe aphasia generally were found to have fewer absent main concepts and more accurate/complete main concepts than those with more severe aphasia when a variety of speech samples were studied. When analyzing speech samples for number of words spoken per minute and percentage of words that are correct information units, Brookshire and Nicholas (1994) concluded that it is important to elicit samples from different forms of discourse and that a total sample of 300 to 400 words leads to more reliable interpretation.

The difficulty level can further be increased by requiring the sequencing of information and the establishment of coherence at the macro- and microstructure levels. Specific instruction in the use of pronouns and other devices for maintaining cohesion may be needed. When constructing tasks to improve grammatical form or word retrieval skills in discourse, the context might be altered to promote greater opportunities for practice. Patients may demonstrate varying degrees of grammatical complexity in relation to the type of discourse involved. Expository discourse (related to a particular topic, as in picture description), procedural discourse (consisting of steps, either conceptually or chronologically associated), and narrative discourse (information about an event, or story retelling) have been compared (Li, Volpe, Ritterman, & Williams, 1996). The most complex grammar was elicited through picture description, followed by the procedural discourse task and then the story retelling condition. In contrast, however, a significantly higher percentage of content words was found with story retelling as compared to expository and procedural discourse, suggesting that the patients were conveying the informational load through lexical rather than grammatical avenues.

In some instances, topic familiarity may play a role with grammatical complexity in discourse production. When provided with less familiar topics, grammatical complexity

can increase for procedural discourse but appears to have no similar effect for story retelling (Williams, Li, Volpe, & Ritterman, 1994). In that study, the number of content words increased with both procedural discourse and story retelling conditions involving familiar topics. Listener familiarity evidenced no impact on discourse production.

Picture description and procedural discourse tasks involving less familiar topics might be chosen when the emphasis on discourse production is to improve grammatical form. Alternatively, story retelling and procedural discourse tasks incorporating familiar topics could be presented when one is attempting to elicit a greater number of content words.

Because the interplay between cognition and language is particularly evident in discourse, some of the mental operations (Chapey, 2001) associated with language processing and production are considered in this section. Convergent thinking or the development of logical conclusions based on information provided is involved in tasks such as explaining similarities and differences between concepts, retelling stories, describing procedures, making inferences, and organizing ideas in a logical order for expression. Divergent thinking demands the production of alternatives from given information, with an emphasis on quantity, elaboration, and originality. In discourse, this skill might be reflected by producing alternate perspectives, presenting a variety of ideas, predicting different outcomes or solutions, and changing the direction of one's responses. A hierarchy of tasks could be constructed addressing all these parameters, in addition to varying the degree of abstractness and the familiarity of the stimuli.

Chapey also highlighted the role of evaluative thinking or judgment. Some aspects included in discourse are selecting the best word to fit the situation; determining an appropriate metaphor, idiom, or proverb; and judging what can and cannot be said in various contexts with different communication partners.

The processing and production of figurative language are integral to discourse. In addressing these aspects of communication, however, several factors must be considered. The ability to provide correct idiom interpretation has been correlated with years of formal education and auditory comprehension skills (Tompkins, Boada, & McGarry, 1992). Accurate explanation of proverbs also tends to be related to educational level and age (Nippold, Uhden, & Schwarz, 1997), with highly educated subjects without brain damage performing better than their peers in all age groups. Performance has been shown to peak at 20 years and declines significantly after 70 years of age. Those with higher verbal ability demonstrate less of a decline with age compared to those with lower verbal ability. In examining proverb interpretation and explanation abilities in patients with fluent aphasia and relatively high auditory comprehension skills, comprehension of proverbs proved to be relatively intact (Chapman et al., 1997). This performance is in

contrast to the significantly impaired performance of subjects in providing explanations for both familiar and unfamiliar proverbs. Interpretation and explanation of idioms and proverbs can be used as higher-level, cognitive-linguistic tasks with patients experiencing problems in conveying information of a more abstract nature. In selecting stimuli, however, the patient's age, educational background, and familiarity with the stimuli must be considered.

Finally, strategies may be introduced to facilitate self-evaluation, such as monitoring for inclusion of and appropriate sequencing of relevant details and checking for redundancy and tangential or off-topic remarks. The use of written stimuli can be particularly beneficial in this area, either by having the patient write his or her narrative when possible or by having the clinician transcribe it for review and editing.

Case Example

LP is a 44-year-old engineer who underwent a craniotomy with resection of a left frontal glioma. The WAB, the Auditory Comprehension Test for Sentences, and the Boston Naming Test were administered. A nonfluent aphasia was exhibited, with oral speech limited to sentence fragments and frequent word retrieval problems. Auditory and reading comprehension were both mildly impaired. Written output paralleled spoken speech.

Along with activities targeting other areas, word retrieval was chosen for treatment. Probing revealed that LP was 80% successful in naming pictured objects characterized by monosyllabic word forms using Grade 1 and Grade 2 vocabulary levels. Polysyllabic nouns were named spontaneously, with 50% accuracy at these grade levels. No successful responses were elicited when pictured actions were presented.

Subsequent testing determined that the most effective cues for LP were presentation of the initial phoneme, description of physical and/or functional properties, and provision of the situational context (i.e., the situation in which the item may be found). Because the clinician believed that phonemic cueing would be a difficult process to transfer from the clinician to the patient, use of description and situational contexts was emphasized.

In the first stage of the treatment hierarchy, specific training in the area of providing physical and functional descriptions and identifying situational contexts for pictured polysyllabic objects at a Grade 1 to a Grade 3 level was provided. Written prompts were used on individual cards to remind the patient of the various physical and functional attributes. For example, the phrases *What color?*, *What size?*, *What shape?*, and *What material?* were printed on one card, and on another, the question *What is it used for?* was printed. Once LP achieved a 70% success rate in providing the required information, another series of stimuli at the same level of difficulty was presented. In this activity, the patient, by providing descriptions

and situational contexts, was required to help the clinician identify pictured objects hidden from her view.

When the provision of the cues became more automatic for LP, confrontation naming tasks were used, in which he provided needed cues only when naming was not spontaneous. To limit the patient's reliance on the clinician, the pictured items were again seen only by LP. Difficulty levels also were systematically increased by introducing advanced vocabulary grade levels and other grammatical form classes (e.g., verbs and adjectives). In addition, practice with implementing self-cueing strategies was provided in various conversational activities. When treatment was discontinued, LP was a highly functional communicator, encountering word-finding problems primarily beyond a Grade 6 vocabulary level. His self-cueing strategies usually proved to be successful in assisting him to retrieve the intended word.

Sample Activities

Level 1

Stimuli: Grade 1 to Grade 3 polysyllabic pictured objects and printed cue cards (*What color?*, *What size?*, *What shape?*, *What material?*, and *What is it used for?*).

Procedure: The patient is required to provide oral responses to information requested on the cue cards.

Level 2

Stimuli: Grade 1 to Grade 3 polysyllabic pictured objects and printed cue cards (*What color?*, *What size?*, *What shape?*, *What material?*, and *What is it used for?*).

Procedure: The pictures are hidden from the clinician's view. The patient provides information prompted by the cue cards to enable the clinician to guess the identity of the pictures.

Level 3

Stimuli: Grade 1 to Grade 3 polysyllabic pictured objects and printed cue cards (*What color?*, *What size?*, *What shape?*, *What material?*, and *What is it used for?*).

Procedure: The pictures are hidden from the clinician's view. The patient first attempts to name the object spontaneously. If unsuccessful, he or she provides the information prompted by the cue cards to facilitate self-retrieval or identification by the clinician.

Graphic Expression

General Considerations

Graphic Expression refers to the written output of communication through the use of graphemes (letters) or drawing.

Writing frequently is the most severely affected modality in aphasia. Historically, varying patterns of writing problems or agraphia have been described in the literature, along with a number of classification systems (Benson, 1979; Ellis, 1982; Goodglass, 1993; Margolin, 1984). They include pure agraphia, in which writing defects occur in relative isolation of other language impairments, and agraphia with alexia, in which patients are unable to retrieve the graphic form of letter strings and, sometimes, even individual letters. Differing symptoms and localization have been noted in pure agraphia. Signs may include the inability to write words, as compared to individual letters, although oral spelling is intact.

More recent research trends have focused on developing computational models to describe the various processes involved in writing, with attempts being made to relate disruption at or between given levels to specific cortical regions. It generally is agreed that the writing of a familiar word first involves activation of the semantic system or the word meaning, and then its spelling, through access of its orthographic representation in the orthographic output lexicon (OOL), Maintenance and sequencing of these graphemes are the responsibility of the graphemic buffer until written production is completed through allographic conversion and a motor response. In the writing of less familiar vocabulary and pseudo-words, phonology-to-orthography conversion rules are implicated (Hillis, Change, Breese, & Heider, 2004; Hillis et al., 2002).

In studying patients during the hyperacute phases of their strokes, Hillis and colleagues (2002) were able to associate patterns of written performance with areas of cortical dysfunction. Impairments with semantic-lexical processes were reflected in the production of semantic errors in writing, resulting from hypoperfusion/infarct in the following areas: Wernicke's (BA 22), posterior middle and inferior temporal gyrus (BA 37), angular gyrus (BA 39), supramarginal gyrus (BA 40), and visual association cortex (BA 19). Patients experiencing difficulty accessing their semantic systems demonstrate imageability effects (Schmalzl & Nickels, 2006). Specific damage to the lexical route of spelling has been termed lexical or surface dysgraphia (Beeson et al., 2003; Schmalzl & Nickels, 2006). Errors, although sparing phoneme-to-grapheme conversion (PGC) rules, involve irregularly spelled vocabulary and demonstrate a word frequency effect. Hillis and colleagues (2002) noted regularization errors and/or omissions in spelling familiar words, with involvement of Broca's area (BA 44 and 45), although accurate spelling of pseudo-words was possible. More recently, a relationship was identified between hypoperfusion/infarcts in BA 44, 45, and 6 and three cases of pure agraphia, with disrupted access to lexical orthographic representations (Hillis et al., 2004). Verbs proved to be particularly error-prone, as were the skills required for conversion of graphemes to letters during writing. Weekes,

Davies, and Parris (2003) found that in their subjects with surface agraphia, words that were learned earlier in life were better spared. Rapcsak and Beeson (2004) discovered an association between lexical agraphia and damage to the left fusiform gyrus and inferior temporal gyrus (BA 37 and 20). Co-occurring impairments consisted of alexia and naming problems, leading the investigators to conclude that BA 37 and 20 may be involved in a variety of language tasks that require integration of semantic, phonologic-lexical, and orthographic information, impacting multiple modalities.

Phonologic dysgraphia, with damage to the angular gyrus, is characterized by disrupted phoneme-to-grapheme conversion. Although real words may be accessed through the lexical output system, spelling of pseudo-words and unfamiliar words is negatively impacted. Impairments to both the OOL and to the phonology-orthography levels, with production of semantic substitutions, has been termed deep agraphia.

Graphemic buffer deficits as a result of injury to BA 39 include word length effects, letter substitutions, omissions, and sequencing errors, and yet accurate copying. Ellis (1988) detailed a number of stages that intervene between selection of graphemes and handwriting. The allographic system is responsible for selecting letter case and style. For example, Del Grosso Destreri and colleagues (2000) described a patient with severe alexia and agraphia subsequent to a left temporoparieto-occipital hemorrhage. Better preserved spelling of lowercase versus uppercase letters and impaired letter substitutions resembling the physical forms of their targets were noted.

With activation of graphomotor patterns, letter stroke sequences can be specified in detail. Partial activation of neighbors with similar strokes also occurs so that disruption at this level can result in substitution of visually similar letters. Production of poorly formed or illegible letters are claimed to be related to impairment of additional components of the graphomotor pattern that affect size, orientation, and order of strokes and has been termed apractic agraphia. Allographic conversion, dependent on the use of skilled hand movements, has been associated with hypoperfusion/infarct in the area anterior and posterior to Broca's area (Exner's area; BA 6) (Hillis et al., 2004).

The premorbid skills and interests of the patient will dictate the degree to which the Graphic Expression modality will be incorporated into or, perhaps, even be the sole focus of treatment. In some instances, writing can be facilitative for oral naming or can be targeted simultaneously when sentence or discourse formulation skills are being developed.

The final portion of this section will briefly address the use of drawing in aphasia. This channel for expression might be considered as a compensatory form of communication, with varying degrees of success being reported in its implementation.

Graphomotor Access

Areas 1 and 2 focus on establishing graphic and graphemic motor patterns, with Area 3 stressing the recall of highly overlearned grapheme motor patterns. In Area 1, Tracing and/or Copying Nonverbal Material, two- and three-dimensional representations of nonverbal material are used. Task difficulty may be increased by altering the complexity of the designs in producing geometric forms and objects. Letters, numbers, and words are introduced in Area 2, Tracing and/or Copying Verbal Material. Activities are designed to address such problems as incorrect letter elements, inappropriate spatial positioning, rotation of letters/elements, and repetition of elements/letters. Some patients have demonstrated better ability to print in uppercase letters than to write in cursive script (Goodglass, 1993; Hanley & Peters, 1996), so this variable also might be included in designing tasks or considering response variables. Single items may be practiced, followed by those in a series (e.g., letters and numbers). In Area 3, Writing Familiar Material, highly overlearned stimuli, such as the patient's name, address, and telephone number, are incorporated.

Word Orthography

Areas 4 and 5, Written Spelling and Naming, may include activities such as writing to dictation, oral spelling, and written naming. A hierarchy can be established by selection of vocabulary across several dimensions. Word frequency, imageability, concreteness, emotionality, and grammatical class may influence the accuracy of the patient's performance. When a part-of-speech effect is observed, spelling of nouns is more readily available than verbs, followed by adjectives and grammatical functors (Goodglass, 1993).

Length is an important variable to alter, because shorter words occasion fewer errors than longer ones do (Friederici, Schonle, & Goodglass, 1981). Stimuli containing the most regular expression of phoneme-to-grapheme correspondence rules are easier than those in which letter combinations are a less frequent realization of sounds (e.g., /f/ in telephone) (Friederici et al., 1981). Although order of difficulty varies among patients and types of aphasia, double vowels, double consonants, and regular versus irregular spelling may be incorporated into a treatment hierarchy. Words containing suffixes may prove to be more difficult for patients (Langmore & Canter, 1983), as may production of homonyms and homophones.

In the last number of years, treatment approaches directed at addressing breakdowns within the various levels of the orthographic output model have been detailed (Hillis, 1992). With a patient demonstrating deficits within the semantic system, therapy was designed to teach semantic distinctions. Generalization of improved written naming to
