untrained items was found within the same semantic category. Another successful approach, with a different patient, involved implementation of a cueing hierarchy for written naming incorporating anagrams and initial letter cues. Schmalzl and Nickels (2006) applied two types of therapy to address a semantic spelling deficit, with impaired access to output orthography and suspected degradation within the OOL in a patient with a left temporal lobe infarction. Two-hundred irregularly spelled words were chosen for remediation, with attempts made to strengthen or improve access to their orthographic representations. The first phase of the treatment program consisted of the patient studying a word presented on a card, copying it, and then rewriting it once the card was removed after a 5-second delay. The second phase incorporated the use of mnemonics. Only the set of words trained with mnemonics improved, with no evidence of generalization to untreated items found. Another noteworthy finding was the reduction of phonologically related errors at the conclusion of treatment. Persisting errors resembled the orthographic representations of their targets, suggesting increased attempts to access the lexical route of spelling.

Problems arising from the OOL, in the context of intact PGC skills, may result in errors that are phonologically plausible (Hillis, 1992). In this instance, treatment targeting production of homophones could be beneficial. If disruption to the PGC mechanism is invoked with an intact OOL, spelling of nonwords is problematic. Hillis reported successful outcomes with tasks designed to develop the PGC system using cueing hierarchies. In one example, self-cueing was established for a patient with verbal apraxia, and in another, written monitoring of semantic errors was facilitated. Although the goals of addressing the impaired PGC system were different in these patients, systematic approaches to treating the disorder produced positive functional changes in other areas.

Raymer, Cudworth, and Haley (2003) examined the effectiveness of a treatment program for a patient who demonstrated impairments in the grapheme buffer characterized by spelling errors, increasing with word length, and omission of letters in the latter halves of words, along with letter substitutions, transpositions, and insertions. The OOL also demonstrated disruption, with regular and irregular words being error-prone, along with a frequency effect. The treatment method consisted of copying and recall of printed word lists. Initially, the patient was required to copy a presented written word, with the clinician then covering the first two letters and requiring the patient to recall and reproduce the letters. The clinician continued to conceal additional letters until the entire word was hidden and reproduction required. The word sets crossed a number of grammatical classes and were controlled for frequency and length. At the conclusion of treatment, which had been supplemented by home practice, a significant improvement in

spelling to dictation was found, along with greater accuracy in writing narratives. The investigators cited evidence that the treatment had impacted both the graphemic buffer and the OOL deficits. Generalization to at least some sets of untreated words suggested increased capacity of the graphemic buffer, whereas transfer of spelling knowledge from the trained words to at least some untrained items with similar spellings indicated improvements in the OOL.

Rapp and Kane (2002) treated two patients who had selective deficits in the OOL and the graphemic buffer using the same approach to better understand the underlying cognitive deficits and how they respond to treatment. The first patient, with lesions involving the left posterior parietal and temporal areas, exhibited an agraphia impacting the OOL. The second patient, whose lesion involved the left anterior parietal region, experienced a consequent graphemic buffer impairment. The overall severity of the agraphia was similar in both patients. Three sets of words were developed that were matched according to frequency and length. Most items were nouns, with the remainder consisting of verbs and adjectives. The therapy paradigm consisted of auditory presentation of the stimulus, followed by repetition and attempted written spelling by the patient. If unsuccessful, the clinician provided the written word, identified each of the letters, removed the card, and asked the patient to write the word. Therapy concluded when the subjects had achieved a 95% success rate in writing the treated words. The patient with OOL deficits demonstrated a significant improvement on treated items at the conclusion of therapy, with no signs of generalization. Generalization to untreated items, however, was noted in the patient with the graphemic buffer deficit.

Treatment of writing also has been investigated to promote more functional communication. Robson, Marshall, Chiat, and Pring (2001) examined the potential for developing written communication in a group of patients with jargon aphasia. A personalized vocabulary consisting of 20 common and 20 proper nouns was used as stimuli. Initially, twice-weekly, 45- to 60-minute treatment sessions were conducted that incorporated a number of tasks, such as word-picture matching, completion of anagrams, delayed copying, and written naming. Four patients made significant improvements, although all patients demonstrated some treatment gains after approximately 12 sessions, with more correct responses and closer approximations to the targets. Generalization to the control sets or to use in conversation was not found. A second stage of therapy was introduced to three of the participants. Each received six 45-minute sessions of "message therapy" incorporating treated vocabulary. The patients and their partners were instructed on the utility of writing words to convey information in conversation and were provided with strategies to facilitate more meaningful exchanges. Follow up assessment of conversations and partner interviews revealed that patients were

using writing in these contexts, with untreated words being incorporated in this functional activity.

Clausen and Beeson (2003) targeted writing to develop conversational exchanges in a small group of subjects with chronic aphasia. In their study, they trained four patients with global aphasia to write a list of personally relevant words pertaining to family, work, personal history, and interests, with the goal of establishing conversation in a group setting. The vocabulary was not controlled for frequency, grammatical class, or spelling regularity. Copy and recall training was provided, with the subjects required to write a word in response to a picture representation accompanied by auditory presentation. If unsuccessful, a model was provided for copying until success was achieved spontaneously in response to the picture stimulus. Thirteen weeks of individual treatment were provided, followed by weekly group sessions with the four patients. A facilitator attempted to provide a natural communication setting for the subjects to practice their trained vocabulary in the absence of any pictured stimuli. Each of the participants was encouraged to provide written responses or questions to the other members of the group. The writing of four out of five words in a set by an individual in the group session was the measure of success required before proceeding to training of the next set of words. Once criterion was reached in the group setting, a conversational interaction was arranged with a novel communication partner. The authors reported that the patients demonstrated improved pragmatic use of the written words in the group setting and demonstrated support for one another. Although written words were used frequently in that more routinized context, production with an unfamiliar communication partner was more limited, with earlier trained words being better maintained than those more recently targeted.

Text

Grammatical structures are first introduced in Area 6, Written Formulation, in which material at the phrase, sentence, and paragraph levels may be used. Sentence complexity and length may be altered, along with topic familiarity. Many of the same variables found to influence oral expression can be incorporated into this area and developed simultaneously. At the paragraph level, a hierarchy can be established focusing on the structure of the text (Labov, cited in Freedman-Stern, Ulatowska, Baker, & Delacoste, 1984) such that task requirements might include mention of time, place, participants, complicating action, and result/resolution. Once the patient is successful in including these obligatory elements, optional ones, such as coda/moral of the story, may be required. Instruction in the use of cohesive devices, such as anaphoric reference, relative clauses, and temporal ordering, can be systematically approached, perhaps initially through identifying their application in read-

ing comprehension activities and then by their incorporation in written output.

In addition to the variables stated above, in Area 7, Writing Complex Material, a response hierarchy that addresses the purpose and complexity of the text can be established. A possible progression from easy to difficult is narrative, letter, and expository (Freedman-Stern et al., 1984). This aspect of treatment requires a highly individualistic application given the diversity of functions that writing may serve in a patient's day-to-day activities.

Case Example

BC is a 64-year-old, self-employed business consultant. A left hemisphere stroke resulted in an infarct involving the white matter in the region of the superior temporal lobe and angular gyrus, with extension into the white matter in the left corona radiata. The WAB, the Auditory Comprehension Test for Sentences, and the Boston Naming Test were administered. A fluent aphasia, characterized by moderately impaired auditory comprehension, with paraphasic speech production, anomia, mildly impaired reading comprehension, and agraphia were revealed.

At the time of initial testing, BC successfully wrote his name but not his address. Only a portion of the alphabet and numbers to 20 were correctly written. Writing single words to dictation resulted in no correct responses. Letter substitutions and additions made words, for the most part, unidentifiable. Over the course of the next 2 weeks, however, spontaneous improvement was noted such that short sentence formulation was possible, with word-finding problems identical to those in oral speech.

Spelling errors were found mainly at the ends of words, where letter substitutions were noted. Irregularly spelled words occasioned the most errors. Further probing revealed that written naming was 50% successful using Grade 7 and Grade 8 polysyllabic, irregularly spelled words. Oral naming, followed by oral spelling, proved to be effective cues for BC to write the word correctly.

BC identified graphic expression as an important focus in treatment. His daily work activities relied heavily on written skills, particularly related to correspondence.

Because oral naming activities were being used in treatment, Area 5, Written Naming, was simultaneously developed. Once BC was able to write stimuli at the Grade 7 and Grade 8 levels successfully, including polysyllabic, regularly spelled nouns, and the difficulty level was increased by using nouns with irregular spelling, followed by other word classes, such as adjectives and verbs. Eventually, the vocabulary level was altered, along with grammatical form class, word length, and degree of imageability. Written naming activities were later incorporated into Area 7, Writing Complex Material, in preparation for the patient's eventual return to work.

Sample Activities

Level 1

Stimuli: Grade 7 and Grade 8 polysyllabic, regularly spelled nouns.

Procedure: A written sentence is presented with the stimulus word omitted. The patient orally provides the word, spells it aloud, and finally writes it.

Level 2

Stimuli: Grade 7 and Grade 8 polysyllabic, irregularly spelled nouns.

Procedure: A written sentence is presented with the stimulus word omitted. The patient orally provides the word, spells it aloud, and finally writes it.

Level 3

Stimuli: Grade 7 and Grade 8 polysyllabic, regularly spelled verbs.

Procedure: A written sentence is presented with the stimulus word omitted. The patient orally provides the word, spells it aloud, and finally writes it.

Compensatory Communication

Back to the Drawing Board is an approach that was designed as a tool for communication by patients with severe limitations in their oral expression abilities (Morgan & Helm-Estabrooks, cited in Helm-Estabrooks & Albert, 1991). Uncaptioned cartoons are presented for copying from memory until the patient is able to produce triple-panel sequences. The clinician provides coaching to elicit drawings that are recognizable, with productions including main ideas and essential details. During the later phase of treatment, practice in conveying information to significant others is incorporated.

Lyon (1995) considered drawing as an augmentative form of communication, not as a replacement for language, for those who have retained inner thought. Hypothetical situations are posed, with the patient encouraged to respond through drawing. The clinician aids in correcting or expanding portions that may be unidentifiable through questions and/or adding features to the drawings. As skills are developed, more complex topics are introduced, along with strategies to reflect different time periods. Involving significant others in communication exchanges through drawing and teaching them to interpret and probe for more information are viewed as a key components in this treatment approach.

The development of drawing in LOT may provide an avenue of communication for those who are unable to access communication through more conventional means. Some patients may encounter success in combining drawing with their limited written output to facilitate meaningful oral output. Because the drawings of patients with

aphasia initially may be simplistic (Lyon, 1995), implementation of a treatment hierarchy to improve the complexity of both the drawings and their communicative intents could be advantageous.

EFFICACY STUDY

The LOT subjects for whom the efficacy data are reported here were part of a larger project designed to study the efficacy of three different types of aphasia treatment. The LOT subjects were drawn from a population in London, Ontario, and the surrounding southwestern Ontario region in Canada. Table 28–1 shows the entry criteria that were met by all subjects. Only adult subjects were included (i.e., individuals between the ages of 18 and 85 years). The upper cutoff of 85 years was used to eliminate subjects at high risk of not being available for the 1-year treatment duration provided in the study. Only literate subjects and those with a single, unilateral stroke and whose symptoms had lasted for at least 5 days were included in the sample.

Subjects who had a medical condition that interfered with testing or survival were eliminated, as were subjects with a hearing impairment or blindness. Subjects were included if they were referred and tested within 2 to 4 weeks poststroke. Native speakers of English and competent bilinguals for whom treatment in English was appropriate were included. Subjects who achieved an initial WAB Aphasia Quotient score of less than 93.8, the cutoff score defining normal performance, were included in the study.

Random assignment to treatment type resulted in 28 subjects being assigned to LOT. To avoid an imbalance in terms of severity or type of aphasia, assignment was stratified for these variables. Because patients with hemorrhagic strokes appeared to behave differently from those with ischemic stroke, the subject with a hemorrhagic stroke was excluded from data analysis.

Demographic Data of LOT Subjects

Ages of the subjects with aphasia ranged from 28 to 82 years, with a mean age of 62.3 years (Table 28–2). Education ranged from 4 to 21 years of formal education, with a mean of 9.85 years. (In Ontario, 9 years represents completion of the first year of high school.) Socioeconomic status was measured using the Blishen Scale (Blishen & McRoberts, 1976), which rates 500 occupations based on income and education. The mean rating of 38.92 was similar to the mean for a group of 60 older, normal subjects gathered in the area (Shewan & Henderson, 1988). This suggested that the socioeconomic status of the LOT group was similar to that of the general older population. The LOT group was composed of 17 male subjects and 10 female subjects. This ratio of 1.7:1.0 was similar to ratios in other literature reports

TABLE 28–1

Entry and Exit Criteria for Aphasic Subjects

Criterion Variable	Entry Criteria
Age	18–85 years
Education	Literacy by history
Etiology	Infarcts Stable intracerebral hemorrhages Excluded hemorrhages because of: Arteriovenous malformation Subarachnoid hemorrhage Aneurysm Single unilateral strokes Transient ischemic attacks (≤ 5 days) excluded
Medical status	Excluded unstable medical illnesses interfering with testing or survival
Sensory status	Passed hearing screening for age appropriateness Blind patients (defined clinically) excluded Tactile dysfunction not excluded
Time post-onset	2–4 weeks poststroke
Language severity	Native speakers of English or competent bilinguals for whom treatment in English was appropriate Severe language barrier or accent excluded
Criterion Variable	Exit Criteria
Language recovery	Western Aphasia Battery Language Quotient of 94.0 or above
Death	Subject died
Second stroke	Neurologic deficit persisting longer than 5 days
Prolonged illness	Absence or illness longer than 3 weeks duration
Geographic relocation	Subject moved
Voluntary withdrawal	Subject did not wish further treatment and/or tests
Termination of project	Data collection terminated at end of funding period

Treatment of aphasia. A language-oriented approach (p. 246). Austin, TX: Pro-Ed.

(Abu-Zeid, Choi, & Nelson, 1975; Kurtzke, 1976). Most subjects were right-handed, with one left-handed and one ambidextrous person in the group. All subjects received treatment in English. For 22 subjects, English was their only language; five subjects spoke two or more languages, one of which was English.

TABLE 28–2

Demographic Data for 27 LOT Subjects^a

Variable	Value
Age (years)

Treatment of aphasia. A language-oriented approach (p. 249). Austin, TX: Pro-Ed.

Methods and Procedures

All LOT subjects met the entry criteria (Table 28–1) and were tested at periodic intervals by trained, reliable test administrators who were independent of the clinicians providing treatment in the study. Tests occurred 2 to 4 weeks poststroke (Entry Test) and at 3, 6, and 12 months after the first test. A follow-up test at 6 months after termination of treatment also was completed for as many subjects as possible.

The test battery included the WAB (Kertesz & Poole, 1974); the Auditory Comprehension Test for Sentences (Shewan, 1979), or ACTS; Raven's Colored Progressive Matrices (Raven, 1956), or RCPM; and a neurologic examination, with the site and side of lesion confirmed by computed tomography or isotope brain scan. Twenty-six subjects had left-sided lesions, and one had a right-sided lesion. Seventeen subjects showed some hemiplegia, eight were hemianoptic, and 11 demonstrated some hemisensory loss.

Speech and language treatment was initiated as soon after administration of the Entry Test as possible, and always within 7 weeks postonset of aphasia. Treatment was controlled for both duration and intensity. Subjects received treatment for 1 year unless they exited from the study before that time (for exit criteria, see Table 28–1). Intensity of treatment was controlled

by providing three 1-hour sessions weekly. The LOT subjects received a mean of 55.3 sessions, with a range of 1 to 118 sessions. Only subjects who received at least 3 months of treatment were included in the efficacy evaluation. Six subjects were lost to follow-up: One died, two relocated geographically, and three withdrew voluntarily.

Treatment was provided by trained speech-language pathologists. Each clinician was trained by C. M. Shewan, the developer of LOT. Before providing LOT in the study, each clinician demonstrated the competence to plan LOT. Competence was assessed by having each clinician design a 1-month LOT patient treatment plan, which passed evaluation by CMS and an independent, external evaluator. At 6-month intervals, each clinician was evaluated by a second independent, external evaluator to ensure that LOT was the treatment type being provided.

Efficacy Data

The efficacy of LOT was demonstrated by comparing the LOT subjects with a no-treatment control (NTC) group. The NTC group contained 22 subjects with aphasia who did not wish to or could not attend treatment. The NTC group was comparable with the LOT group for age, education, socioeconomic status, handedness, language, and etiology. Unlike the LOT group, however, the NTC group contained an equal number of men ($n = 11$) and women ($n = 11$).

Whether LOT resulted in significantly greater language gains compared with no treatment was examined using analysis of covariance, controlling for the initial severity of language impairment. The dependent variable in the comparison was the final test Language Quotient (LQ) score (LQLAST) on the WAB for each subject. The LQ score is a composite of the WAB oral and written language tests (Shewan, 1986). Initial severity was controlled through covarying for initial WAB LQ score (LQENTRY), because the LQ score was designed to be a measure of severity of language impairment, which, in turn, is known to affect language outcome. The LOT had significant positive effects compared with no treatment (Table 28-3) when the Entry Test and the Last Test were compared. The estimate of the difference between LOT and NTC group means, after adjusting for entry score and educational level, was 11.50, with a standard error of 4.71. When age and sex (variables that could possibly influence outcome results) were added as concomitant variables in the analysis of covariance, the results remained essentially the same.

To control for the effects of spontaneous recovery, additional analyses of covariance were performed comparing LQTEST 2 (3 months after the Entry Test) with LQLAST. Again, controlling for initial severity, the analysis of covariance indicated the gains for the LOT group were significantly greater than those for the NTC group (Table 28-3).

TABLE 28-3

Summary of Analyses of Covariance for Language Quotient (LQ) Outcome Measure for Language-Oriented Therapy (LOT) and No-Treatment Control (NTC) Groups^a

p	Estimate of Adjusted Mean Difference	Standard Error
	<i>Entry—Last Test</i>	
≤ 0.02	11.50	4.75
	<i>Entry—Test 2</i>	
≤ 0.43	3.93	4.90
	<i>Test 2—Last Test</i>	
≤ 0.02	5.86	2.19

Treatment of aphasia. A language-oriented approach (p. 254). Austin, TX: Pro-Ed.

The number of subjects within each aphasia type was too small to permit statistical comparisons among groups. Tracking the LQ scores over the course of treatment and through follow-up, however, showed some interesting recovery curves. Because the number of subjects who contributed to the mean LQ score at each test could be different as a result of subjects exiting from the group, the subjects were grouped according to the number of tests that they received and were followed accordingly in streams (Fig. 28-4). When the entire LOT group was considered, gains in the streams were greatest within the first 3 months of treatment. Substantial gains were noted at each test thereafter, and the gains were maintained for the most part for 6 months following treatment. The LQ mean at Test 5 (follow-up) was only 1.4 points lower than that at Test 4 (treatment termination).

Type of Aphasia

For subjects with global aphasia, gains were greatest during the first 3 months, although gains were substantial during the second 3 months as well. After this time, LQ scores plateaued. For the three subjects with follow-up tests, the gains from treatment were maintained. As seen in Figure 28-4, although those with global aphasia did make notable gains, these subjects both started and ended with lower LQ scores compared with those of subjects who had the other types of aphasia.

The subjects with Broca's aphasia made gains throughout the treatment period. As with other groups, the largest gains were during the first 3 months. At follow-up, scores were slightly lower than those at the end of treatment (2.4 points).

The group of subjects with Wernicke's aphasia contained only four subjects, who made substantial gains in the first 3 months of treatment. Because scores for only one subject were available beyond that point, no generalizations can be

Figure 28-4. Mean Language Quotient (LQ) scores at Tests 1, 2, 3, 4, and 5 for the total Language-Oriented Treatment (LOT) group and the five types of aphasia: global, Broca's, Wernicke's, anomic, and conduction. Patients have been grouped into streams according to the number of tests received. The numbers in parentheses refer to the number of patients included at each test. Termination of treatment (Rx termination) is represented with a dashed line. Test 5 is a follow-up test conducted 6 months after the termination of treatment.

made. This subject did make gains in all treatment periods and showed a slight decline during the 6-month follow-up period.

Subjects with anomic aphasia, as with the other groups, made their greatest gains during the first 3 months, although gains also were substantial during the next 3-month treatment period. The single subject remaining beyond that time made additional gains during the 6- to 12-month period, although no scores at follow-up were available. Overall, gains for the subjects with anomia were nearly 20 LQ points; in general, these subjects were less severely impaired than the subjects with Broca's, Wernicke's or global aphasia.

Individuals with conduction aphasia were among the less severely impaired subjects, as might be expected. In concert with other groups, they made the greatest gains during the first 3 months of treatment. The two subjects remaining at Test 3 (6-month test) were approaching complete recovery (LQ > 94). No scores were available beyond this point.

Severity of Aphasia

The subjects with aphasia were separated into mild, moderate, and severe groups on the basis of the initial test battery, and subjects in these groups were followed in streams,

Figure 28-5. Mean Language Quotient (LQ) scores at Tests 1, 2, 3, 4, and 5 for the mild, moderate, and severe groups. Patients have been grouped into streams according to the number of tests received. The numbers in parentheses refer to the number of patients included at each test. Termination of treatment (Rx termination) is represented with a dashed line. Test 5 is a follow-up test conducted 6 months after the termination of treatment.

similar to the analysis for type of aphasia (Fig. 28-5). The group with mild aphasia made visible gains throughout the treatment period, averaging 24.8 LQ points. The greatest gains occurred during the first 3 months of treatment. The single subject with aphasia remaining for the follow-up test showed only a slight decline from the termination of treatment.

Subjects with moderate aphasia showed the greatest LQ gains during the first 3-month period (at least 20 LQ points on average). Scores stabilized for the next 3 months and increased again for the 6-to 12-month treatment period. The mean overall gain for the group was 33.8 LQ points. The one subject available at follow-up showed a moderate decline in the LQ score from the termination of treatment.

The group with severe aphasia, despite obtaining the lowest scores overall, did improve an average of 24.8 points on the LQ. Although greatest in the first 3 months, gains also were seen during the second 3-month treatment period, after which scores leveled off. These gains were maintained at the follow-up test.

FUTURE TRENDS

Language Oriented Treatment was conceived at a time when detailed descriptions of language therapy and its efficacy were sparse. It evolved primarily out of a need to demonstrate that speech-language interventions served as more than just a vehicle for providing emotional and social support to those suffering from aphasia and that our treatment was, in fact, based on scientific principles. Over the last two decades, numerous advances have been made in our understanding of the complexities of the language system,

its interplay with cognition, and how it becomes altered in the face of neurologic insult.

Some of the most exciting discoveries in our field have occurred through the development of technology as it relates to neuroimaging. We are now provided with rich opportunities to better visualize brain lesions and determine how cortical and subcortical areas contribute to language. It remains critical that speech-language pathologists demonstrate a comprehensive understanding of the neural substrates and their relationship to speech and language processes, both in those with intact communication functioning and in those who have been affected by aphasia. As we implement various treatment methods with patients, we have come to observe more directly their impact on the brain's plasticity and the positive outcomes of our therapy.

The fundamental principles of LOT have not changed over time, although the content has become enriched by the proliferation of studies examining language in highly specified ways. An analytical framework continues to be imperative in breaking down the components that underlie the behavioral symptoms of aphasia so that we provide treatment that is customized to the needs of our patients. Most importantly, communication is a highly dynamic and intimate reflection of our personhood, which can and does remain at the forefront of our efforts, even within the context of this highly structured and systematic approach to treatment. Bridging the gap between therapeutic tasks and functional communication can be accomplished through flexibility, ingenuity, and successful engagement of our patients and their significant others in achieving mutually determined and achievable goals.

KEY POINTS

1. Aphasia represents impairment in the processes for understanding and producing language.
2. Language-Oriented Treatment is a psycholinguistic approach to intervention, applying research information about normal language processing and the impairments associated with aphasia.
3. Identification and understanding of the substrates affected by neurologic damage and their contribution to language are fundamental in developing a treatment plan that is customized for the patient.
4. The patient and significant others play central roles in determining treatment goals, activities and expectations.
5. Language-Oriented Treatment is organized according to content, reflecting potential areas of focus within five language modalities.
6. Activities incorporate a hierarchy of difficulty levels, both within and across areas, based on the analysis of strengths and deficits.
7. Treatment approaches that have proven to be beneficial in large and small group investigations as well as in single-case studies are incorporated when applicable to a particular patient.
8. Language-Oriented Treatment was proven to be efficacious in a full-scale clinical trial incorporating a NTC group.
9. Through systematic treatment of the underlying deficits, functional improvements in language can result from a LOT approach.

Chapter 29

Treatment of Aphasia Subsequent to the Porch Index of Communicative Ability (PICA)

Bruce E. Porch

OBJECTIVES

The major objective of this chapter is to demonstrate that the nature of response behavior is indicative of the status of the brain's circuits and systems. The following main arguments are presented to help the clinician appreciate the importance of this concept to the understanding of brain function and to the development of viable plans for treatment of aphasia.

1. The brain survives best when its circuits and systems function quickly and easily and when it stores information that is accurate. When these circuits and systems are damaged, information is processed more slowly and inefficiently, more circuits are required to do simpler tasks, and information is treated as tentative and not stored.
 2. The patient's response behavior reflects these changes in the brain circuitry's reduced efficiency. Because response changes, such as delayed responses, self-corrections, and requests for repetition of the stimulus, signal significant changes within the brain systems, the use of plus-minus scoring in testing or treatment is not appropriate, and multidimensional scoring or some other method of observing small behavioral changes is necessary clinically.
 3. Treatment planning based on this model therefore is directed at assisting the patient in achieving easy, immediate responses on progressively more difficult tasks.
 4. Decisions about the patient's potential for change as a result of treatment should be made on the basis of a psychometric sampling of the patient processing.
-

Before initiating treatment, and at various critical points during the therapeutic process, the clinician must answer a series of critical questions about the conduct of that treatment. The issues of major concern are how the brain lesion has affected

the communicative ability of the patient; whether those deficits are treatable; what modalities, tasks, and stimuli should be used in treatment; what behavior should be reinforced; and when should treatment be terminated. Traditionally, answers to these problems are evolved empirically during treatment through trial-and-error methods or are arbitrarily determined because of the clinician's bias for certain techniques and methods. In recent years, the tendency among clinicians who use the Porch Index of Communicative Ability (Porch, 2001), or PICA, to rely on the test results to help with the therapeutic decision making has been growing.

The discussion that follows will consider some of these treatment issues and will illustrate how PICA test results and PICA theory can assist the clinician in planning therapy. Much of this material is drawn from basic and advanced training courses that are designed to prepare the clinician for use of the test. Therefore, although it is hoped that the concepts presented here are useful to a general audience, the full application of some of these methods will necessarily be limited to PICA-trained clinicians who have demonstrated accuracy in the use of this multidimensional scoring system.

A SYSTEMS ANALYSIS APPROACH TO APHASIA TREATMENT

The principle of the brain as survival mechanism is fundamental to understanding the brain, why it does what it does in both normal and damaged states, and how to treat it. The ways in which the brain processes information, reacts to stimuli, and responds to damage are all biased by the ultimate effect of that moment on its capacity to survive. This principle pervades every aspect of treatment and must be used by the clinician to anticipate what must be done, and what must be avoided, while treating the patient.

A second principle essential to the development of an appropriate sequence of treatment is that all the systems of the brain and their components are intimately interrelated and that no part of a system can be affected positively or negatively without affecting all systems. A brief look at a hypothetical brain circuit might illustrate the practical

implications of these two principles and serve as an introduction to PICA theory as applied to treatment.

At the simplest level, a brain circuit may be viewed as being made of a series of modules, each of which processes data from the previous module and then sends the processed information on to the next module in the circuit. Each module has the capacity to enhance the information, reject it as inaccurate, or mark it as a survival message. For example, the auditory processing circuit shows three levels of modules between the input of each bit of raw data to the circuit and the output of the circuit to other circuits or integrators. When the input pathway sends basic data from the input transducers, such as the ears, or from other circuits to the feature detection modules, the data are stored temporarily in processing storage. The module then scans its data banks, or operational storage, to determine if the raw data have been processed before and if some information exists about the data that can further define that data, especially in terms of its significance to survival. This information is moved to the comparator to verify that the retrieved data explain or define the raw data stored in processing storage. If the comparator finds a good match between the input data and the retrieved data, it allows the combined product to be sent on to the next module in the circuit, which in this simple circuit is "pattern recognition." After storing the output of the features module in its processing storage, this next module scans its operational storage to see if the features coming in have a pattern that was processed previously as valid information. It then compares the retrieved information from its storage, compares it with the input data in processing storage, and if it matches, sends it to the signal processing module to determine if the recognized patterns have a specific significance, especially to survival. If the significance of the patterns is established, the processed information may now be sent on to other circuits, or to integrators that combine information from multiple circuits.

The storage units in this model are conceived of as an access core that defines the nature of the information stored around it, and each core has a "surround" made of data, subcores, and subsurrounds, all of which share a common relationship to the access core. The more important that information is to survival, and the more frequently that it is used, the closer it is to the core or subcore and, therefore, the more retrievable it is, because it requires less switching to reach it. Another interesting characteristic of these storage units (operational and permanent cores and surrounds) is that they tend not to store tentative or nonverified information. Processing storage and a general persistence in the circuit will maintain data temporarily. Only when a bit of data is processed immediately and accurately is it considered to be appropriate for operational, long-term storage. Usually, operational storage is achieved through processing a data bit enough times to verify it is both accurate and useable or when the data bit has high impact, in terms of survival, so

that it must be remembered after one exposure to it and trial-and-error learning is not conducive to survival. If a caveman with friends was walking down a path lined with bushes and a saber-toothed tiger jumped out and devoured one of the group, for example, it would be important to remember that path and those bushes after one exposure rather than repeating the walk and watching friends disappear over the next few days!

Feedback loops may be used when a module finds that it does not have sufficient information to complete the processing of a data bit sent to it and, therefore, needs the previous module to send more data. These feedback loops also can inform the previous modules that the information being processed is the first in a series that is well known, so no need exists to process the rest of the series. This frees the previous modules for processing new and less familiar data and reduces the circuitry necessary to process familiar data to a minimum. Thus, circuitry reduction results in more efficient, faster processing of familiar data and allows the circuit to use its energy on more complex, unique, or "danger" kinds of data. The immature brain uses many circuits to carry out relatively simple tasks. The mature brain reduces the number of circuits necessary to carry out a task to a minimum. The damaged brain is less efficient, must once again use its circuits to cope with less complex tasks, and is challenged by previously easy tasks. The goal of treatment is to restore circuitry efficiency.

A final important observation has to do with the interconnectedness of the brain's circuits and systems and why damage has such widespread implications in the brain. If, in our theoretic circuit, the processing storage in the pattern recognition module fails to function, the raw data enter the module, scanning in memory occurs, and the comparator attempts to match the retrieved information with the original input data. Nothing is stored in processing storage, however, and comparison is impossible. The comparator must then request that the input data be sent again from the previous module, or it must rescan memory in an attempt to verify the information. The comparator's other options are to simply stop functioning or to assume that the retrieved information is accurate and send it on to the next module. While all this is going on in the pattern recognition module, the features recognition module is waiting to send the next bit of data forward, and the signal processing module is waiting for the patterns module to send it some data. The entire circuit is locked up, because one small part of one module is broken. Furthermore, previous circuits are waiting for this circuit to accept information, and succeeding circuits are waiting for the output of this circuit. The entire system is affected, and this system is interlocked with all other systems.

In summary, this systems analysis model that we will be applying to treatment of aphasia suggests that the brain is made of complex, interlocked, interrelated modules and circuits that are survival biased. Survival is facilitated by

Figure 29-1. Multidimensional binary-choice scoring system.

maximizing the efficiency of these circuits by permanently storing only verified information that is not tentative. The efficiency of a circuit is further increased by circuitry reduction that allows fewer modules or fewer circuits to be necessary to quickly process accurate and familiar data entering the system. The clinical caution here is that both operational storage and circuitry reduction do not occur if any aspect of processing is not easy and immediate. What constitutes “easy and immediate” brings us to a consideration of the patients’ response behavior and why the use of plus-minus scoring during treatment of aphasia is both impractical and unproductive.

Multidimensional Scoring

The circuitry within the brain defies direct observation; therefore, the clinician must infer what is going on in a system by carefully observing the patient’s response behavior during a treatment task. A wide range of behavior is possible in a response to a given stimulus and task, depending on how the involved circuits are able to process the data. Several examples of response behavior to follow will illustrate this and will show how PICA multidimensional scoring is used to quantify behavior.

Returning to the theoretic circuit described earlier, when data move through each of the modules of a circuit both easily and immediately and produce an accurate, well-produced output from the circuit, those data are permanently stored in operational storage, and circuitry reduction may occur for those data. Use of the multidimensional, binary-choice PICA scoring system shown in Figure 29-1 would score such responses as accurate, responsive, complete, prompt, and efficient (score of 15). During treatment, it is these 15-type responses that are the target behavior the clinician strives for on every response.

In contrast to an “easy” response, a patient might retrieve inaccurate or incomplete information when scanning operational storage. When the retrieved information is sent to the

comparator, the discrepancy between this retrieved information and what is stored in processing storage is noted. This necessitates looping back to operational storage to retrieve a better match. When the comparator finds that the second information is accurate, it sends it on to the next module for processing. Such double looping appears, behaviorally, as a brief hesitancy or processing delay (score of 13) but is significant clinically, because that bit of information is still considered to be tentative by the circuit and, therefore, is not stored in operational storage (Aaronson, 1974). It still requires total, not reduced, circuitry for its processing. This is why any response other than an easy, accurate, immediate response (score of 15) means further treatment is necessary on that item.

Let us examine this double-looping example for other types of behavior that could have resulted. After double looping, a damaged comparator might accept incorrect information from storage and send it on to the next module. If this incorrect information produces an error response but the response reenters the circuit, is recognized as being inaccurate, and is then changed to be accurate, the clinician observes this use of an external comparator as a self-correction (score of 10). If the comparator recognized that the stored information in that module was inadequate, it might feed back to earlier modules or to sensory transducers a request for additional information about the data bit (score of 8) or for the same data to be sent through again (score of 9). If such information is not available earlier in the circuit, the comparator might just send on the erroneous information to produce an incorrect response (score of 6), or the comparator might stop all processing and accept that it cannot produce a response, with the patient rejecting the item by saying, “I don’t know” (score of 5).

Although this scoring system was developed for sensitively and reliably quantifying subtle changes in a patient’s test behavior, it has proven to be equally vital in documenting the response characteristics during treatment. A final benefit of multidimensional scoring is that it forces

the clinician to be sensitive to small, but important, changes in behavior.

Internal Consistency of Tasks

The PICA is designed so that all the subtests revolve around 10 common objects. This has the psychometric advantage of holding content constant across subtests and, therefore, making it possible to compare the patient's skill across modalities and tasks. It also produces subtests that have very high internal consistency, with all the items on a subtest being relatively equal in difficulty for the patient. Under these conditions, it is possible to detect patterns of response that normally are obscured by conventional aphasia tests beginning with easy items and getting progressively more difficult.

Table 29-1 shows how having stimuli that are relatively equal in difficulty will reveal various types of processing problems during testing or treatment. In this simple example, we see the scores for three different patients on a task involving 10 items of relatively equal difficulty. Patient A rejects the first item but is able to respond to the next few items after the stimulus is repeated or cued or after a significant delay. Eventually, he begins to respond at normal levels and receives scores of 15. With Patient A, it is apparent that he had trouble tuning into the task and adjusting his system to perform adequately during the first part of the task, but eventually, he reached fully operational levels. Patient B starts out with no difficulty but gradually has decreasing scores and tunes out on the task, suggesting that he lacks the ability to keep his system locked into the task or to handle cumulative noise that might build up during the task. Patient C has a performance that is very homogeneous and shows no variation from item to item.

TABLE 29-1

Examples of Patterns of Response

Stimulus	Patient		
	A	B	C
Cat	5	15	11
Dog	8	15	11
Boy	9	15	11
Apple	10	15	11
Cup	13	15	11
Shoe	15	13	11
Car	15	10	11
Soup	15	9	11
Ball	15	8	11
Pie	15	5	11
Mean score	11.0	11.0	11.0

We see in the bottom row of Table 29-1 that all three patients got a mean score of 11.0, indicating that they were all functioning at about the same communicative level on this task. Clearly, however, the type of processing difficulties that each manifests is quite different. In addition, patients A and B demonstrate several fully operational responses, suggesting that their circuits have the capacity to carry out the task once the processing problems are resolved. Although Patient C got all 10 items correct on a plus-minus basis, he showed no ability to do the task at operational levels. His system is indicating that, at least at this point in time, it is performing the task as well as it can.

Because the PICA has high internal consistency, it is able to give some indication about these types of processing problems, and it indicates potential levels of ability that a patient may have on a given task (Disimoni, Keith, & Darley, 1983). These same principles can be employed in treatment if the clinician will take the time to ensure that the stimulus items used on the task are relatively equal in difficulty.

DESIGNING A PLAN OF TREATMENT

Once the clinician has gained a thorough familiarity with the patient and his or her history, has completed comprehensive testing, and has found that the patient's condition is no longer changing dramatically from day to day, treatment planning can be initiated. The usual sequence of considerations at this point is to determine if the patient is a suitable candidate for treatment, to choose the tasks and stimuli to be used during treatment, to decide on which types of behavior will be reinforced on each task, and finally, to determine when treatment should be terminated.

Selecting Patients for Treatment

Determining whether a patient is treatable is a relatively new concern, arising in recent years as treatment has become more expensive and available funding for treatment scarce. During the 1960s, Schuell, Jenkins, and Jiminez-Pabon (1964) did some work on prognosis that assigned postrecovery, stabilized patients to one of five major or two minor prognostic groups. More recently, in an effort to develop earlier predictions, Porch, Wertz, and Collins (1974) as well as Porch, Collins, Wertz, and Friden (1980) have described other prognostic studies that attempted to develop more accurate predictions of eventual recovery levels; however, these studies employing multiple discriminate analysis have not yet been validated for clinical use.

Perhaps the most widely used clinical method currently is the high-overall-prediction (HOAP) method (Porch, 1970) that was developed during the late 1960s as an interim approach to prediction but proved to be reasonably accurate and simple to use and, therefore, has persisted for three decades. In this method, it was theorized that the capacity of

the patient's total communicative system was indicated by the highest scores or peak abilities. Therefore, the clinician could estimate the maximum potential for communication by using the average of the nine highest subtest scores achieved on the PICA or by using the highest modality score, whichever was the greatest. Appropriate tables or graphs enable the clinician to convert these scores into an estimate of the eventual outcome level and, thereby, make appropriate plans regarding treatment of the patient. Because this HOAP method may be applied as early as 1 month post-onset in most cases, and because it takes into consideration the normal recovery stages, the clinician is in a better position to select the patients who are most treatable and to counsel families and physicians regarding the eventual recovery levels (Porch & Callaghan, 1981).

For clinicians who use the PICA to test their patients early in the recovery process, another prognostic indicator is the acceleration rate of recovery. This is determined by subtracting the 1-month post-onset PICA Overall percentile from the 2-month post-onset PICA Overall percentile. Patients who improve more than 12 percentile points during this period tend to exceed the HOAP target percentile by the time they reach 6 months post-onset. Those with slower early recovery tend to not reach the early PICA predictions.

Estimating treatment potential is equally important later in the course of recovery. Eventually, the patient's condition seems to stabilize, and the clinician must decide whether to continue treatment. Once again, PICA scores are helpful in several ways for making this decision. First, discrepancies between the patient's overall score and the high modality score indicate the amount of potential change that remains. Second, after the patient is past the acute stage, it is expected that when he or she is at maximum recovery, his or her subtest percentiles will be approximately equal; therefore, differences between the nine highest subtest percentiles and the nine lowest subtest percentiles also will suggest a range of possible change or the lack of it.

These same principles hold true within subtests. The PICA scoring system provides 16 possible scores for any given response; therefore, it is not unusual for a patient to obtain a wide range of item scores. As a patient undergoes treatment for aphasia, the intrasubtest variability of scores gradually reduces until all the item scores within the subtests are quite homogeneous, indicating no peaks or depressions of ability on the task. This homogeneity suggests that the patient, at least at that point in time, is functioning at near-maximum ability on that particular task. The circuits necessary to carry that task are consistently performing at their highest current potential levels of efficiency: There are no low responses that might be brought up to the patient's average level, and there are no higher scores that might serve as a target level toward which to strive. When the patient demonstrates homogeneity in all modalities on the PICA, his or her brain is indicating that it is performing commu-

nicatively and cybernetically near its maximum potential level of functioning and that further treatment of the processing problems may not be fruitful. At that point, the clinician may evolve new treatment goals to maximize the patient's use of his or her functional systems, to modify the patient's environment to facilitate his or her communication, and to educate the people in his or her environment about the status of the patient's abilities and deficits and how to assist that patient.

In summary, an ideal treatment candidate is a cooperative patient whose medical condition is stable, who has a predicted overall percentile significantly above his or her present overall score, and who exhibits variation on item scores within subtests in some modalities.

Selecting Treatment Tasks

Before the discussion on treatment can continue, it is necessary to introduce some concepts and terminology related to PICA theory. As we see in Figure 29-2, we may visualize a continuum of communicative tasks, ranging from the most simple vegetative communicative processes to the most complex learned processes. The ordinate represents the response continuum, ranging at the top from the most complex levels of responses to the bottom of the continuum, where the patient fails to attend or give any type of response.

The PICA samples a test field somewhere in the middle of the task continuum. The tasks that were sampled range from relatively simple tasks in which only the most involved patients have difficulty to moderately challenging tasks in which even mild patients demonstrate some processing problems. The standard PICA test battery samples 18 points in the test field and establishes the subject's capacity to carry out tasks of varying difficulty.

The PICA tests have demonstrated that the interaction between the task and the response continua is best depicted by a sigmoidal function curve. If one were to test a normal subject longitudinally from infancy to adult levels of communication, this sigmoidal function curve would move from right to left on the task continuum and, finally, stabilize at some fairly high level of communicative ability. When a normal brain is damaged, its circuits are less efficient, it must use more circuits to carry out simpler tasks (the reverse of circuitry reduction), and it treats more entering data as tentative and, therefore, does not store it easily in operational storage. Because of these changes, the sigmoidal function curve shifts negatively to the right. The PICA locates the position of that response curve on the task continuum and, as indicated above, predicts how far positively that curve can be shifted with treatment.

Returning to our premise that aphasia represents a reduction in the processing efficiency of the brain, we can see that the sigmoidal function curve depicts the individual's processing abilities on a series of tasks that are ranked according

to their level of difficulty. The tasks to the right of the curve are all within the capacity of the individual's circuits and are carried out accurately, responsively, completely, promptly, and efficiently; therefore, they do not require treatment. As the tasks become a little more complex and require more communicative ability, the test responses are performed accurately but with some delays, self-corrections, or distortions, so the response curve begins to descend. As we will see, this area is referred to as the fulcrum of the curve, and it is the primary focus of treatment.

Referring again to Figure 29-2, note that as the tasks become increasingly complex, the curve begins to drop more precipitously as the person being tested begins to make errors and requires more information or more assistance to respond. To put it in terms of circuit theory, the circuits necessary for doing these tasks require the participation of more basic circuitry, such as those that are active at the fulcrum of the curve. These circuits are not yet operational, however, and cannot participate in more complex processing. Finally, as the tasks become even more complex, the sigmoidal curve bottoms out at the lower end of the response continuum, indicating that all tasks on the task continuum beyond this point are beyond the capacity of that person at that time.

Using this schema, the problem of task and modality selection is greatly simplified for the clinician, because the patient's system indicates precisely those tasks that need immediate attention. Once the PICA has been administered and the results plotted to indicate the patient's response curve, it is quite apparent which tasks are already operational and do not require treatment, which are on the fulcrum of

the curve and should be treated, and which are beyond the capacity of the patient's system at this time and should be excluded from the treatment format.

The reader should not confuse the concept of the fulcrum of the curve with the earlier suggestion that tasks on which the patient has the greatest item variability have the most potential for change and, therefore, assume that these tasks should be chosen for treatment. Tasks on which the patient has a large variety of scores, including high target scores and low scores that may be improved, have good potential for eventual change, but such tasks are too far down the curve. Attempts at treatment produce some errors, suggesting either that the circuits involved are getting insufficient information to perform the task or that more efficiency in the circuit needs to be developed by using tasks more within the capacity of the circuits (i.e., farther up the curve). In general, errors during treatment usually suggest either that the task selected is too difficult at this point in time or that the stimuli have been poorly chosen. The patient does not have enough information to monitor the developing processing before responding by using internal comparators or to evaluate the output after responding using external comparators.

Selecting Treatment Stimuli

After the tasks in various modalities have been selected from the fulcrum of the curve, it is necessary to select appropriate treatment stimuli to serve as vehicles for resolving the patient's processing problems on those tasks. Although it is common practice for clinicians to select stimuli on some a

priori basis and then proceed with treatment, expecting the patient to do as well with whatever stimuli are selected is dangerous, because it does not take into consideration the specific type of processing problem the patient has. Stimuli that are too difficult and overdrive the patient’s system, or those that are too “noisy” and interfere with processing, not only may reduce the amount of positive results from treatment but actually may produce problems rather than resolve them.

The danger of using inappropriate stimuli can be obviated by testing their appropriateness on selected tasks. The PICA score sheet may have already indicated to the clinician that the patient has more difficulty on certain types of stimuli, such as polysyllabic words, words with consonant blends, or words that are too short to provide adequate clues for decoding. This type of information might be used in assisting in the selection of the repertoire of stimuli that the clinician plans to use for the treatment tasks. It remains important, however, to verify the selected stimuli under the actual treatment conditions.

Stimulus verification is done through the use of PICA scoring, because the classic plus-minus scoring is relatively insensitive to processing disorders. Having selected 20 or 30 stimuli that seem to be appropriate for the task, the clinician explains to the patient what the task is and what he or she is expected to do. It also is useful to explain to the patient that the clinician will be scoring the responses so as to determine which stimuli will be the best to use in subsequent treatment sessions. Each stimulus, which has been listed on a treatment score sheet, is presented in order, and the patient’s responses are scored for later analysis. After all the stimuli have been presented once, it usually is informative to present them again after a brief rest period to see how consistent the patient’s processing is on each stimulus.

Table 29–2 shows how a few stimuli might be scored during a stimulus verification session. The clinician has selected some common nouns for treatment stimuli and has presented the list twice. In addition to the specific item scores the patient received, some other, more general observations may be made about these two trials. First, the patient tends to improve slightly on the second trial, demonstrating a good potential for improving after repeated trials. Second, it appears that the patient does somewhat better on polysyllabic words, thus suggesting that the auditory system may not be able to decode short stimuli rapidly enough and that the longer duration and increased information in longer words makes it easier to process them. Finally, it does not appear that, as one scans down the column of scores for both trials, that any orderly changes occurred. It is not unusual to find some patients whose scores gradually increase during a trial, suggesting that it takes several items for them to make the necessary adjustments to carry out the task. Other patients may start out a given trial with high scores and then, suddenly, have decreasing scores as the trial proceeds, indi-

TABLE 29–2

Verification of Treatment Stimuli

Stimulus	Trial	
	First	Second
Apple	8	9
Hammer	13	15
Shoe	10	13
Cup	6	6
Baseball	15	15
Hat	9	9
Bicycle	15	15
Car	7	10
Window	13	13
Bus	9	10

cating that they are unable to lock their system into the task, and they gradually tune out on the succeeding stimuli. In the example in Table 29–2, these types of trends are not seen; therefore, the variation in scores probably is attributable to the stimuli themselves.

Having made these general observations, the clinician is now ready to decide on which stimuli he or she will use in subsequent treatment sessions. The first rule here is to drop any stimuli on which the patient received errors (i.e., scores of seven or below). The fact that the patient got error scores on one of the trials on those stimuli indicates that they are either too noisy or too difficult to be used in treatment and can only interfere with processing and progress. Too often, the inexperienced clinician will attempt to “teach” these words to the patient but, instead, ends up putting more noise into his or her system along with practicing errors. A second consequence of using error-type responses is that not only do you prohibit the facilitation of good switching on these stimuli, the effect spreads to other stimuli on the list, and it creates a spread of poor processing to other stimuli in the treatment trial (Brookshire, 1976). When a clinician is treating the processing problems of the patient, no given stimulus can be considered as sacred, and whenever one presents a problem, it should be dropped out of the program.

This concept of dropping error items or stimuli also should be incorporated into the stimulus verification process, because items that are too difficult may have an interaction effect on other items. It generally is a good policy when running such trials to eliminate any error items from second and third trials to rule out possible interactions. In addition, the items that produce errors should be analyzed carefully for characteristics that are in contrast with items that invariably elicit 15-level responses. Such an analysis will give the clinician important information about what variables affect

the circuits involved and what type of stimuli should be avoided in treatment.

It should be apparent that plus-minus scoring is too gross to yield meaningful information about the patient's system, and that PICA scoring should be used if possible. Clinicians who are not trained in PICA methods, however, may achieve similar results by sorting stimuli into three categories: "easy"—items that the patient has responded to accurately, without effort or delay and in a manner that might be referred to as "normal"; "medium"—items that are responded to accurately, but only after processing delays, self-corrections, or repeats of the stimuli or after cues or additional information are given; and "hard"—items that yield error responses. When using this system, it is customary to designate the type of response as E, M, or H (or as 3, 2, and 1), or the stimuli may be sorted into three separate piles if card-type stimuli are used.

At this point, after all the sorting and analyzing of stimuli is complete, it would seem that the selection of tasks and stimuli is complete and the actual treatment might begin, but one more preliminary step is quite informative. Having selected a treatment task on which the patient gets 9- to 15-type scores (easy and medium responses), the clinician, instead of simply presenting the task multiple times to eventually achieve all "easy" responses, should manipulate some single variable of the task in a way that will immediately produce higher scores. If a particular manipulation does, in fact, improve responses, the clinician has discovered an important factor about the patient's system and what helps it to function successfully. By the same token, if the manipulation produces lower scores, evidence is obtained as to what variables have negative effects on the system. No change in responses as a result of the manipulation signifies that variable is not a relevant factor in the patient's performance of the task.

A simple auditory task might illustrate how one carries out this probe technique. The clinician has selected a task that involves placing six pictures of common things in front of the patient and having him point to the one that is named. The clinician on the initial presentation obtained three easy responses (scores of 15), a correct response after a repeat of the stimulus (score of 9), a self-correction (score of 10), and a delayed response (score of 13). The question now is how may the task be modified to produce all easy-type responses immediately? Several possibilities exist—reduce the number of items from six to four to simplify the task and reduce visual loading, use a carrier phrase before the noun (e.g., "Point to the . . .") to negate rise-time problems, add the printed word for the noun (e.g., "car") to the picture to add visual information to assist the auditory system, give an arousal signal (e.g., "Ready? . . . Car") for system activation or attention problems, and so on.

Gradually, as various modifications of the task succeed, the patient is able to come to all easy responses until he or

she finally achieves all scores of 15. During the process, the clinician learns what factors make the patient's processing more or less efficient, which is information that will assist in this and future therapeutic tasks. In addition, possible tasks for subsequent treatment have been documented. As the original probe task that started out down the curve was manipulated, it gradually moved up the curve until it reached the all-15 level. With each change, the clinician documented the location of the various modifications of the task on the curve during this upward movement. Therefore, the clinician may, by working in reverse order down the curve, move from one task to the next in that sequence documented during the probe. As each task is raised to the all-easy level, the circuits under treatment become available for assisting the processing of other tasks down the curve, and the entire response curve moves toward the more complex end of the task continuum.

Treatment Format

Once the tasks and the stimuli have been selected for treatment, the clinician is now ready to organize them into a treatment format that is designed to present a consistent presentation of tasks that will facilitate the patient responding at the all-15 level. In other words, the goal of the clinician and the patient, working as a team, is to have the patient eventually respond to every stimulus on the task without requiring cues, repeats, self-corrections, or significant delays. Not only is this type of treatment designed to be error free, but as much as possible, it tries to facilitate the patient's responses so that they are produced easily and without any processing difficulty.

All these principles discussed thus far are roughly what is meant by "treating on the fulcrum of the curve." Processes in which the patient demonstrates delays and self-corrections are tentative processes that break down when used in more complex tasks employed farther down the curve. If these minor processing problems are cleared up and the patient reaches the all-15 level in carrying out the processes, then these become available farther down the curve, and all the more complex processes can take advantage of the now normal, simpler processes. This phenomenon may explain, in part, why so many times we see tasks improving in the clinic that have not been treated directly during the therapeutic process. This schema also makes clear why it is so inappropriate to treat tasks too far down the response curve—because we are expecting the patient to carry out complex processes that require other basic processes that are not yet available to him or her.

Finally, in connection with this issue of the dangers of overdriving the patient's systems, we should note how different the fulcrum of the multidimensional curve is from the plus-minus curve. If you refer again to Figure 29-2, you will note that the response curve for the average patient with

aphasia is in the middle of the test field. This response curve, however, is a multidimensional response curve that drops off on the tasks on which the patient first begins to have some delays, self-corrections, or repeats. In plus-minus scoring, these behaviors are ignored; therefore, the plus-minus response curve would not begin to drop until the patient gets some responses wrong. The plus-minus fulcrum of the curve would be equivalent to a point far down the multidimensional curve, a point at which tasks tend to be beyond the capacity of the patient's circuits.

When setting up the sequence of presentation for treatment activities, realize that the goal of treatment is to assist the patient in mastering noisy, inadequate circuits and switching. Because sudden changes in tasks, target behavior, or methods of reinforcement invariably produce distraction and noise in the patient's communicative system, it is advisable to establish an orderly and fairly fixed treatment format. If patients can anticipate the treatment events and have time to make leisurely transitions from task to task, they will maintain a more efficient, quieter system.

A useful format for ensuring adequate stimulation of the patient's system without producing noise or overload might be summarized as follows:

1. Adjustment period (clearing out)
2. General activation (warmer upper)
3. Consolidation (old stuff)
4. Modification (new stuff)
5. Consolidation (old stuff)
6. Modification (new stuff)
7. Conclusion (winder upper)

Adjustment Period: Checking and Clearing Out Circuits

The adjustment period that initiates the treatment session is a brief, but important, time. After the patient enters the room and sits down at the treatment table, the clinician greets him or her and simply asks a broad, nondirective question, such as "How's everything?" or "What's new?" This is designed to give the patient the opportunity to clear out his or her system and to tell the clinician about any special occurrences, problems, or questions that may have arisen since the last session. It also gives the patient an opportunity to try out, in a free-speech situation, some of the processes that he or she has been working on previously. The clinician, on the other hand, is trying to observe several things about the patient.

First, any significant difference between how the patient currently appears compared with how he or she appeared in previous sessions should be noted. If he or she is markedly improved, it may be necessary to redesign the treatment session or to retest the patient to determine his or her new level of functioning. If the patient is functioning poorly compared with previous sessions, it may be necessary to probe into the

cause of the problem or to discuss the matter with the family to see if there has been an exacerbation of the patient's medical problem. Sometimes, the patient has less serious problems, such as headache, shoulder pain, or some psychological or social issue that produces a depression in his or her ability and may make it necessary to be somewhat less adventurous in the treatment session on that day. Finally, while the patient is gradually adjusting his or her system to the room and to the clinician and is getting prepared for more difficult treatment tasks, the clinician is carefully noting the quality of the patient's communication and observing how much carryover has occurred from those processes that are being attacked during treatment to a spontaneous speech situation.

General Activation: Turning On and Warming Up Systems

Once it is certain that the patient is functioning adequately and has cleared his or her storage systems in preparation for treatment, the clinician can begin to focus the patient's attention on treatment-type tasks. For this purpose, a task is selected from the highest, or consolidated, part of the patient's response curve. This fairly easy, all-15-type task is for activating the patient's communicative systems and warming them up and for furnishing the patient with a gradual transition into the more difficult tasks. This activation period also will provide the clinician with a second check on the patient's general level of functioning on that day, and it gets the patient off to a successful start in the treatment session.

When initiating treatment with a new patient, information about what might be suitable warm-up tasks might be obtained from the PICA score sheet if one looks at the all-15 items on the easiest subtests. In the case of a patient who has been treated for a period of time, the clinician may elect tasks that, at one time, were on the fulcrum of the curve but that, eventually, become fully operational. Selecting these old tasks serves to verify that the patient is maintaining skills that were worked on formerly.

If, after a short period of general activation, the patient seems to be responding easily to simpler processing tasks, the clinician is ready to move on to the next step in treatment.

Just as in testing, where making a definite and clear transition in between tasks is important, the change between one step in treatment to the next should be made obvious to the patient so that he or she can clear out his or her system and make the necessary switching adjustments for the new task. This is done by giving the patient a general positive reinforcement for his or her efforts on the previous task and then suggesting that the patient just relax for a moment while the clinician makes notes about what has occurred in the session until that point. Then, the clinician announces to the patient that they are going to be doing something different. The clinician should explain what the task will be and

what the patient is expected to do, and then the first item of that task should be demonstrated for the patient. When it is apparent that the patient understands the task, that task should then be started with the demonstration item so that the patient's system is gently eased into the task. Generally, following this type of transition will minimize the amount of noise in the patient's system and greatly reduce his or her anxiety and fatigue.

Consolidation: Pushing for All "Easy" Responses on Old Stuff

Having moved through the adjustment and activation steps, the patient and clinician now are ready to begin the first of several treatment modules. A treatment module is a series of tasks directed at a given modality or process. Depending on how many steps are in each module and how much time the total program takes, there may be two or three modules in a 1-hour treatment session. For instance, the first module might be devoted to consolidating and modifying auditory processing, and the clinician may then move on to the second module for consolidating and modifying verbal processing and, finally, turn to work on reading or writing as a third module. A module usually is begun with a task that the clinician is trying to consolidate and make fully operational. This task is quite high on the fulcrum of the curve, which on the first presentation has occasional delays in it but by the second or third presentation is all scores of 15. If, in a given session, it is found that this task is done at the all-15 level on the first presentation, the clinician might consider using that task as a warm-up in the future. If, on the other hand, the patient has continuing difficulty and cannot get to the all-15 level even after several presentations, it generally means that he or she is not ready to proceed to new tasks in that module. If, after a few presentations, the patient is able to get all 15s, the clinician should do the task several times to consolidate those 15s and then prepare to move on to the next step in the module.

Modification: Moving Down the Curve to New Tasks

As the patient approaches the point at which he or she is fully operational on a given task, it becomes appropriate to think about modifying that task slightly so that it involves some new aspect of switching or storage. For instance, if, on an auditory task that requires the patient to point to one of four pictures after the clinician says the noun, the task might be modified by using six pictures, by having the patient point to two pictures instead of one, or by not allowing the patient to see the pictures while the clinician is saying the noun. Any of these changes probably would produce an increase in the number of delays or self-corrections that the patient might have on the task. The goal then would be to increase the patient's performance until he or she achieves all 15s on the new task. If the clinician makes what is considered to be a

small modification in the task and the patient begins to make errors or requires multiple repeats and cues before he or she gets a correct response, the modification is larger than expected, and the task should move more in the direction of the consolidation task.

If the patient does fairly well with the new material and seems to understand it after several trials, he or she should be given a brief rest period in preparation for the next module. Usually, shifting to a new modality means shifting to new stimuli and treatment materials, but once again, the transition should be verbalized to help the patient readjust his or her system for the new task. This same general procedure is then followed, beginning with old material in the modality that needs to be consolidated and then, if appropriate, moving on to some new modifications of the task to increase the patient's processing capabilities.

Conclusion: A Positive Wind Up to the Treatment Session

The final step in the treatment format should involve a fairly easy task at the all-15 level. The patient and the clinician have moved through a variety of fairly arduous tasks during the previous hour and have just completed a relatively new modification task that has been somewhat difficult, and concluding the treatment session on that note would be psychologically undesirable. Therefore, the clinician should select a task from the easy, consolidated part of the curve, which will assure winding up the session on a successful note. The clinician also may use this final step as a verification that the patient is maintaining his or her skills on one of the earlier treated processes. In addition, it is a nice technique to use wind-up tasks from one day's session for a warm-up task on the next day's session. This helps the patient to get back to the same point at which he or she was at during the previous session, and it reduces intersession regression.

To summarize this section on the treatment format, the tasks are selected and sequenced in such a way as to maximize the efficiency of the patient's communicative systems and to minimize noise. Treatment of a given process or modality is begun with tasks selected from the consolidated, all-15 part of the curve to prepare those circuits for the more difficult tasks. Next, slightly more difficult tasks are selected from the fulcrum of the curve, and these are worked on until the patient eventually reaches the all-15 level. At that point, these newly consolidated processes are available for use on other tasks; therefore, the patient's response curve moves positively toward the predicted target level.

TREATMENT PRINCIPLES

Patient–Clinician Team

Implicit in the treatment method being described here is the involvement of the patient in the conduct of the treatment

process. The patient should understand that the clinician is not trying to teach the patient words but, rather, is attempting to return him or her to “easy” processing—that is, free of self-corrections, repeats, and delays. The patient must be taught what this behavior feels like. It sometimes is helpful in teaching what is meant by “easy” processing to present the task using all “medium” items first and then to repeat the task with all “easy” items so that the patient can get the feel of the contrast between the two levels of performance. Once this distinction is clear to the patient, he or she also must be taught to advise the clinician when a response is tentative or slightly off-target so that it can be consolidated. In this sense, the two people become a team in which the patient relies on the clinician to assist with selecting the tasks and stimuli and in which the patient keeps the clinician informed as to the impact of those items on his or her system.

Setting Treatment Priorities

The establishment of the specific modalities and processes to be treated is facilitated by careful examination of the PICA score sheet. All-15 tasks are selected for warm-up and wind-up tasks, 13- to 15-level tasks should be treated, and 9- to 13-level tasks, when slightly simplified, may soon be appropriate as modification tasks in the format.

In general, it is best to first treat processing problems that are not stimulus related. This includes difficulty in shifting tasks, tuning in, cumulative noise, and tuning out. These problems are diagnosed when a series of homogeneous items are presented on a task and the patient always has trouble (e.g., repeats, self-corrections, or delays) with the first few items or tunes out the last few, regardless of the order of stimulus presentation. When these temporal problems occur, a specific program may be designed to overcome them. For instance, the goal of eliminating tuning out might be achieved by discussing the problem with the patient and then presenting stimuli that generally elicit 15-type responses. At first, only a few stimuli are used, and these are worked on until the patient achieves all 15s. The number then is gradually increased until the patient can keep his or her system locked in to the task for a full complement of stimuli.

If the patient has problems that are more random or are stimulus related, those problems are overcome by getting the circuits necessary for the task to the 15 level and then processing multiple times at that level. The circuits for the task are facilitated and will store processing information once the 15 level is achieved. Therefore, as treatment proceeds, those items on which the patient scored below 15 should be repeated until a score of 15 is achieved and then repeated some more so that the circuit can sense what 15-level processing entails and can store that information.

Very often, clinicians move through a series of stimuli and score responses without repeating items enough for success to occur. This is essentially testing rather than treating, because the patient's circuits never have the opportunity to experience the target behavior and achieve fully operational circuits. It probably is more beneficial to move lower scores to 15 and then practice the 15s if stable improvement is desired.

Criteria for Shifting Tasks

By this point in the discussion, it should be apparent that plus-minus scoring is completely inadequate for carrying out this type of treatment and that a more detailed type of scoring, such as a PICA scoring system, must be used. Second, the clinician must mentally score every response of every task to decide whether he or she should repeat the item or move on to the next one. Some clinicians like to write down every score for every response during the session so that they have a running account of exactly what happened in the patient's system. In that way, they can make the correct adjustments in the program, and they can document the patient's change very precisely over time. Another approach is to record the scores on the first presentation of the task to establish a baseline, then to work on the task for a period of time, and then rescore to measure change. Still other clinicians, who plan their treatment for a longer period of time and change the format less frequently, prefer to score the responses at the beginning of the treatment week and then rescore them at the end of the week to see what changes have taken place. Specific application of PICA scoring has been described by Bollinger and Stout (1974) in their discussion on response-contingent, small-step treatment; by LaPointe (1974), who gives examples of PICA scoring as used in Base 10 Program Stimulation; and by Brookshire (1973) in his general consideration regarding treatment of aphasia.

Some of the major differences between these types of programs and the PICA program described here are the criteria for selecting tasks and stimuli and the criteria for shifting to new tasks or terminating tasks. Many programs suggest a criterion of 80% or 90% correct as an indication that the patient is ready to proceed to more difficult tasks. This is undoubtedly too low, because this would allow the patient to have repeats, self-corrections, or delays on every item and still meet the criterion. Even a standard of 95% 13s (delays) or better allows the patient to have significant problems with 5% of the items. When this amount of interference in processing occurs, the information being processed probably is considered by the system as being tentative and, therefore, is not stored for long-term use. In turn, this means that the process being treated is not fully consolidated and is not available for use on tasks farther down the curve.

The PICA theory, therefore, suggests that the target for changing or terminating tasks is all-15 responses. This may seem to be overly idealistic but, in fact, is realistic and essential. Such a goal is attainable, because the tasks and the stimuli used have been carefully chosen and verified through the patient's system.

The second reason that all-15 responses are an appropriate treatment goal is that this type of processing seems to transfer better and is more resistant to regression. Unless a task is fully consolidated, it will tend to deteriorate in a normal life situation or in a more difficult treatment task. Cued (8) to self-corrected (10) responses often become errors, and delayed responses (13) shift to lower, more tentative scores. For this reason, transfer of these skills rarely occurs, because they are not operational. Conversely, if the patient develops a good awareness of what "easy" responses are and achieves them on all the items on the task, transfer can be maximized and regression prevented.

REINFORCEMENT OF RESPONSES

One of the advantages in using an error-free program is that the focus of the patient and the clinician is on achieving an "easy" 15-type response as opposed to delays, self-corrections, and so on. As the clinician presents stimuli, all responses are correct but may or may not be easy. Whenever either the patient or the clinician feels that the response was not easy, it should be repeated until the response is easy, and it should be reintroduced into that module later to verify that the response is still easy. Unlike doing plus-minus treatment, in which the use of tangible reinforcements, verbal praise, and so on are necessary because the stimuli are too complex for the patient to evaluate, such rewards are not required, useful, or even desirable, because they tend to interrupt processing and to distract the patient, who must concentrate on improving processing. When the clinician simply presents the next stimulus, this indicates to the patient that the last response appeared to be easy. If the stimulus is repeated, the patient knows that the response was not easy and needs more effective processing.

FUTURE TRENDS

The treatment methods based on PICA test results and multidimensional scoring described in this chapter offer several advantages over less structured approaches. In starting treatment, the clinician and the patient are offered a specific target level of overall communicative ability to work toward, and this can be computed quite early during the course of recovery. The treatment, once initiated, focuses on modalities and processes that the patient's own

communicative systems have indicated are appropriate to modify at that point in time, and the exact difficulty levels of the tasks, the stimuli, and the target behavior are prescribed and verified by the level of multidimensional scores the patient achieves. All this evolves naturally out of a treatment format that maximizes the patient's processing efficiency yet minimizes the possibility that the clinician is misdesigning the treatment. Finally, the predictive formulas and the measures of intrasubtest variability indicate when the patient is at last functioning at his or her highest possible levels so that plans for terminating treatment may be made.

In contrast to these advantages, the PICA approach to treatment has disadvantages. It requires training to see the response behavior in detail and to convert the behavior into scores: It requires careful preparation and planning based on the patient's responses at every stage of treatment; necessitates accurately recording and analyzing of the response scores; and because of the emphasis on systems analysis rather than on language per se, requires that the clinician always be sensitive to the many variables that affect the patient's processing.

To clinicians who have not been trained in using the PICA, these approaches to treatment of aphasia can seem both demanding and complicated. In fact, it recently was suggested by Odekar and Hallowell (2005) that using such multidimensional methods is cumbersome, time-consuming, and may not be efficient and cost-effective within many current service-delivery contexts. Those authors recommend plus-minus scoring as a faster, less expensive method. Perhaps, someday, someone will demonstrate that it is not clinically important to recognize and quantify all the types of behavior that the patient with aphasia can show during a treatment task. Goldstein (1945) may have been wrong when he said, "If the results are viewed as so many pluses and minuses, as often is the case, no real insight is gained as to what the patient can still do and what he can no longer do." It may be that Schuell and colleagues (1964) erred when they considered the necessity to have a stimulus repeated, a response behavior that generally was ignored at the time, as being so significant that they scored it as an error. It could be that the treatment using multidimensional scoring described in this chapter will be superseded by other methods that use less complicated scoring. It appears, however, that the current trend is not toward simplified scoring. If one peruses the literature, not only in aphasiology but in many other fields, one will discover that an increasing number of multidimensional scoring systems or category scoring methods are replacing simpler scoring systems that have been found to be imprecise. In the future, the PICA scoring system probably will be just one of many multidimensional scoring systems the clinician will find in the clinical armamentarium.

KEY POINTS

1. An efficient brain processes information both quickly and accurately and only stores information that it can trust for survival.
2. The inefficient brain must use its circuits for simpler tasks, and it does the tasks less quickly and efficiently.
3. This reduced processing efficiency is evident in the response behavior of the individual.
4. The clinician must be able to discern and document all the behaviors that distinguish an easy, immediate response, which is the goal of treatment, from less efficient responses.
5. Multidimensional scoring, or some other method that distinguishes easy responses from less efficient responses, is necessary in treatment of aphasia, because both the patient and the clinician must make these distinctions. Plus-minus scoring fails to make these distinctions and is not useful in treatment.
6. Treatment should focus on those tasks and stimuli on which the patient produces accurate but not easy responses. Error responses suggest that that item, task, or stimulus is beyond the capacity of the patient's circuits at that time and is not appropriate now.
7. Once tasks and stimuli that are appropriate for the patient's circuits and systems have been selected, a treatment format should be organized to maximize the probability that the patient will achieve easy responses on items that previously were tentative.
8. Decisions about the reasonableness of treating or continuing to treat a patient should be made on a psychometric basis, which samples the patient's processing potential.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Discuss how a cybernetic, systems analysis view of aphasia contrasts with the one using the classic subtypes of aphasia (e.g. Wernicke's or Broca's).
2. Why would it be impossible for a clinician to do the kind of treatment described in this chapter using plus-minus scoring?
3. What is the danger in having a clinician select tasks and stimuli a priori without verifying that they are appropriate for the patient?
4. Several psychometric reasons exist for an aphasia test having high internal consistency. Can you describe some clinical reasons why using homogeneous items in testing or treatment might be preferable to using items of undetermined difficulty or items going from easy to difficult?

5. Considering this discussion on PICA treatment, how should you react to these clinicians' statements:
 - "I like to make my therapy sessions interesting by doing a variety of different things and by always trying new activities to surprise my patients."
 - "I don't go on to a new task in treatment until he gets them all right."
 - "He's doing pretty well on that task. I think I'll go on to something else."
 - "When he has to point to one of six pictures I name, I use poker chips as reinforcement so he knows if he's right or wrong."
 - "I don't have time to test my patients. I can find out how the patient is doing while I'm doing treatment."
6. Improving your clinical skills: Have a group of students and/or clinicians watch a videotape of a patient with aphasia doing some test or treatment tasks. For a short period of time, score each response using plus-minus scoring. Next, replay the same responses, but use the multidimensional scoring system shown in Figure 29-2 to score each response. Saying the scores out loud as they occur will give everyone some immediate feedback as to what response behavior is occurring and how well each person is seeing delays, self-corrections, rule breaking, repeated stimuli, related errors, distorted responses, and so on.

D. Specialized Interventions for Patients with Aphasia

Chapter 30

Communication-Based Interventions: Augmentative and Alternative Communication for People with Aphasia

Karen Hux, Kristy Weissling,
and Sarah Wallace

OBJECTIVES

This chapter introduces readers to the variety of augmentative and alternative communication (AAC) options available to support the communicative interactions of people with aphasia. Readers will learn about barriers and assets regarding the incorporation of AAC into communication-based interventions for people with aphasia; partner-dependent, transitional, and partner-independent communicators within the population of adults with aphasia; various types of assessment procedures that allow practitioners to match cognitive and linguistic strengths and challenges with AAC methods; and various AAC techniques and strategies for use with people with aphasia.

“In all but the most transient of aphasia, and perhaps its mildest forms, there is little reason to believe that aphasia therapy ‘removes’ the aphasia” (Holland & Beeson, 1993, p. 582). This statement highlights a major problem with which aphasiologists have long struggled: Existing interventions do not always restore the abilities of people with aphasia to their premorbid levels and, hence, leave some people with unmet communication and social needs (LaPointe,

2005). This does not mean that therapy for aphasia is ineffective in facilitating linguistic improvements in many people with aphasia (Holland, Fromm, DeRuyter, & Stein, 1996; Robey, 1998). Months or even years of speech and language intervention services, however, do not spare some people with aphasia from facing futures in which communication challenges repeatedly prevent or impede full participation in the social roles, activities, and relationships that they enjoyed previously.

The Holland and Beeson (1993) statement also reinforces another well-known phenomenon concerning aphasia recovery: People with mild aphasia typically have better outcomes and are more likely to regain functional communication skills compared to people with severe aphasia. Those with initial aphasia severity levels that are moderate or worse may make gains in recovering some aspects of language functioning, but they frequently experience a degree of chronic aphasia. The persistent struggles these people face demand a flexible clinical approach that takes into account the complexities of augmenting impaired symbolic processing systems.

Despite these phenomena, a strong inclination to restore impaired language underlies the efforts of many speech-language pathologists working with people who have aphasia. Traditional therapy for aphasia has, at its core, the notion that providing systematic and extensive language stimulation to people with aphasia, especially during the acute stage of recovery, will help to re-establish language processing, either through recovery of language-specific brain regions or through recruitment of alternate brain

regions to assume language functions. Indeed, the rapid changes observed in many people during the first several weeks or months following the onset of aphasia support the notion that language restoration is a viable goal. Total restoration may not be realized, especially by those who are faced with moderate or severe aphasia. For them, additional compensation-oriented interventions, such as those associated with augmentative and alternative communication (AAC) devices, strategies, and techniques, are needed.

We believe that practitioners can improve the long-term outcomes of people with aphasia by providing early supplementation of restorative intervention approaches with ones that are compensatory in nature. Early introduction of compensatory AAC strategies and techniques supports the residual verbal comprehension and expression of people with aphasia. The alternative strategy—namely, providing only restorative intervention initially and, when insufficient gains signal that natural speech will not reach functional levels, belatedly introducing AAC interventions, or even dismissing clients from therapy altogether—is unlikely to support functional communication. Given the limited reimbursement that insurance companies currently provide for speech and language services, the early introduction of AAC interventions is important to allow adequate time for people with aphasia to adjust to, practice, refine, master, and begin to generalize compensatory strategies to a variety of communication situations.

To compensate for the persistent communication challenges they face, people with aphasia need instruction about multi-modal communication strategies that include the use of residual speech and language as well as compensatory strategies and techniques that support communicative interactions across diverse settings and with multiple partners. Speech-language pathologists have the challenging job of designing and implementing intervention programs to assist people with aphasia in mastering these compensatory behaviors. The purpose of this chapter is to provide speech-language pathologists with the information they need to make informed decisions about the types of AAC devices, strategies, techniques, and applications most likely to benefit people who display various communicative capabilities and needs associated with differing types and severities of aphasia.

Information in this chapter is organized into five sections. First, we provide an overview of the relation between AAC and aphasia, highlighting the complexity of implementing AAC interventions with individuals who have weakened symbol processing abilities. Second, we address AAC assessment issues by providing guidelines for determining the clinical profiles of people with aphasia regarding their communicative capabilities and needs. This includes distinguishing partner-dependent, transitional, and partner-independent communicators and aligning them with traditional types of aphasia classification. Third, we present interven-

tion procedures associated with communication-based AAC strategies and techniques that support the residual speech and language capabilities of people with aphasia. Fourth, we discuss the generalization and application of AAC systems, techniques, and strategies to the variety of communication situations and interactions encountered by people with aphasia. Finally, we address future trends concerning the integration of AAC interventions into standard clinical practice for people with aphasia. Throughout this chapter, we provide case examples to illustrate the application of specific aspects of AAC systems to people with varying types and severities of aphasia.

RELATION BETWEEN AAC AND APHASIA

Rehabilitation professionals have long recognized the potential for exploring AAC interventions for people with aphasia (Beukelman, Yorkston, & Dowden, 1985; Jacobs, Drew, Ogletree, & Pierce, 2004; Kraat, 1990; van de Sandt-Koenderman, 2004). Discussion about adapting existing AAC interventions or creating new strategies and techniques to meet the needs of people with aphasia has appeared periodically in professional journals. A consistent theme across these discussions is that AAC holds considerable promise for supporting individuals with aphasia. Improved communication outcomes for people with chronic aphasia are likely as speech-language pathologists increasingly (a) introduce compensatory techniques as early supplements to restorative approaches, (b) develop and refine AAC interventions to address the specific needs and capabilities of people with aphasia, and (c) promote greater AAC acceptance by other practitioners both within and outside the profession, the lay public, and people with aphasia.

The successful development and implementation of AAC interventions for people with aphasia requires that speech-language pathologists have accurate information regarding two issues: the nature of AAC interventions for people with aphasia as multifaceted systems geared toward maximizing functional and effective communication, and the symbolic processing weaknesses that underlie aphasia and that influence the design and application of AAC interventions. These issues are discussed separately in the following sections.

Multifaceted AAC Interventions

As stated in the American Speech-Language-Hearing Association Technical Report, “AAC is best thought of as a system, as opposed to a single entity” (2004, p. 4). The development and maintenance of successful AAC systems for people with aphasia almost invariably require multi-modal approaches that combine several strategies, need frequent updating to meet changing needs, and provide a means of facilitating ongoing partner support of communicative

interactions. For people with aphasia, AAC is most effective when it is multifaceted, dynamic, and adaptable.

By viewing AAC as a combination of strategies and techniques geared toward minimizing barriers to successful communicative interactions, speech-language pathologists can create systems that address the multiple challenges faced by people with aphasia when they attempt to participate in activities. For example, to communicate during a social gathering of friends, a person with severe, chronic aphasia may need compensatory strategies to assist with understanding verbal statements made by others as well as with relating details about recent personal experiences. This may mean using a combination of spoken and written language, gestures, self-generated drawings, and references to pre-stored information or remnants. Because multiple challenges associated with aphasia (e.g., auditory comprehension limitations, word retrieval problems, production of jargon, verbal perseveration, and agrammatism) could potentially contribute to communication breakdowns, reliance on only one communication modality or a single type of compensatory strategy or device is unlikely to foster sufficient success for a person with aphasia to engage in this type of social event. Hence, it is crucial that speech-language pathologists teach people with aphasia and their communication partners multiple strategies that they can employ systematically to minimize communication breakdowns interfering with either transactional (i.e., transmitting specific information from one person to another) or interactional (i.e., developing and maintaining interpersonal relationships) communication goals (Simmons-Mackie & Damico, 1997).

Viewing Aphasia as a Symbolic Processing Weakness

One of the biggest challenges to designing and implementing AAC interventions for people with aphasia relates to the nature of aphasia as a symbolic processing weakness. Aphasia is not simply a language disorder; rather, it is a problem that limits an individual's ability to process all types of symbolic information. McNeil (1988) provided a definition of aphasia highlighting the symbolic nature of the underlying deficit that is experienced: "Aphasia is a multi-modality physiological inefficiency with verbal symbolic manipulations (e.g., association, storage, retrieval, and rule implementation). . . . It is affected by and affects other physiological information processing and cognitive processes to the degree that they support, interact with, or are supported by the symbolic deficits" (p. 739).

Certain features of this definition have particular importance regarding AAC applications. First is the stipulation that people with aphasia are inefficient, rather than deficient, in manipulating verbal symbols (McNeil & Pratt, 2001). People who are inefficient in verbal symbol manipulation are not totally devoid of this ability. Hence, they are likely to benefit from compensatory strategies that provide

redundancy through the presentation of information in multiple modalities. The devices, strategies, and techniques of AAC can provide this type of informational redundancy.

A second important feature of McNeil's (1988) definition concerns the notion that people with aphasia have information processing challenges that not only include language but also extend beyond language to the processing of all types of symbols (McNeil & Pratt, 2001). The fact that people with aphasia have difficulty processing all symbol types means that simply substituting one symbol for another (e.g., substituting the written word *drink* or a line drawing of a person lifting a cup to his mouth for the spoken word, *drink*) will not provide sufficient support or compensation. The problem stems from the fact that many existing AAC systems designed for people with disabilities other than aphasia resemble "language in a box"—that is, the systems have isolated and decontextualized representations of language concepts (i.e., individual verbal symbols) arranged in separate compartments of a grid for use to construct linguistic structures (Light et al., 2004). This occurs because, when designing a system, AAC specialists rely on their own fully developed, unimpaired language systems as the basis for organization and structure. Hence, many current AAC technologies reflect how people without language impairments use language. This strategy does not work well for most people with aphasia precisely because they are inefficient in accessing and using symbolic elements, and their challenges extend across all symbol systems. For AAC to benefit people with aphasia, professionals need novel approaches to system design, organization, and structure that extend beyond the mere substitution of one symbol system for another and that do not use normal language processing as the underlying framework.

In summary, the need for improved outcomes in overall communication—including goals relating to interactional as well as transactional functions—has been a driving force behind the development of AAC strategies for individuals with aphasia. Within the realm of designing and teaching compensatory strategies, two types of approaches exist for using AAC to support the residual speech and language capabilities of people with aphasia. First, professionals can design systems that supplement a person's inefficient language processing by providing informational redundancy. This means that, through the use of multiple modalities and contextual supports, people with aphasia and their communication partners promote redundancy by presenting a single message through simultaneous or sequential use of speech, gestures, written language, drawing, or reference to environmental cues, low-tech communication books, or high-tech communication devices. Such informational redundancy increases the likelihood of accurate comprehension and expression of intended meanings. Second, professionals can design systems that minimize reliance on linguistic or symbolic processing. This approach will be discussed in the

portion of this chapter that explains the incorporation of visual scenes into low-tech and high-tech communication systems. The basic premise with this approach is that people with aphasia communicate most effectively when relying on cognitive processes that are non-symbolic in nature, such as visual perception, memory for important life events, and holistic processing of contextual information.

To date, AAC professionals and aphasiologists have succeeded primarily in developing treatment approaches corresponding with the first of these strategies—that is, by uncovering innovative ways of supporting the weakened language systems of people with aphasia through provision of informational redundancy. Recent advances, however, also have revealed new possibilities for bypassing sole dependence on linguistic elements and symbolic processing by, instead, increasing reliance on other, relatively preserved cognitive processes. By combining existing knowledge about systems supporting language processing with development of systems minimizing reliance on symbolic processing, AAC and aphasia specialists have an array of communication-based treatments from which to choose when supplementing the restorative intervention approaches commonly used to assist people with aphasia. The remainder of this chapter provides information to assist speech-language pathologists in deciding which AAC techniques and strategies are most likely to be effective with people displaying different aphasia characteristics and severities as well as information about how to design and implement a variety of communication-based AAC intervention strategies.

ASSESSING PEOPLE WITH APHASIA FOR SELECTION OF AAC INTERVENTIONS

Attempting to determine which of the many possible AAC intervention techniques will help a particular person with aphasia is a complex undertaking. The primary goal during AAC assessment for people with aphasia is the development of a clinical profile of capabilities and needs. This profile, once developed, can be matched against clinical trials with various AAC strategies and devices to determine those that hold the most promise for generalization into real communication contexts.

Capability Profile

Historically, constructing a capability profile of a person with communication needs is a starting point for developing an AAC treatment plan. Often, scores reflecting previous administration of a standard aphasia battery are available to begin formulation of the capability profile; if not, clinicians may wish to administer such a battery. In addition, if desired, clinicians can supplement these scores with administration of additional measures looking at specific cognitive functions

and/or specific AAC assessment measures to provide a more complete profile of a client's capabilities.

Aphasia Batteries

Speech-language pathologists can choose from several standardized assessment tools to help determine current linguistic and symbolic processing abilities of a person with aphasia. Some of the more commonly used options include the Boston Assessment of Severe Aphasia (Helm-Estabrooks, Ramsberger, Morgan, & Nicholas, 1989), or BASA; the Boston Diagnostic Aphasia Examination—3rd Edition (Goodglass, Kaplan, & Barresi, 2001), or BDAE-3; the Western Aphasia Battery (Kertesz, 1982), or WAB; and the Porch Index of Communicative Ability (Porch, 1967), or PICA. Clinicians may find the BASA particularly useful for people displaying very limited communication behaviors, because this tool provides a means of acknowledging non-spoken responses, assessing both linguistic and paralinguistic skills, and observing and identifying some AAC strategies spontaneously used by the person with aphasia (Nicholas, Helm-Estabrooks, Ward-Loneragan, & Morgan, 1993). For individuals who retain greater linguistic processing abilities, clinicians may prefer assessment measures that provide a means of observing behaviors across the modalities of listening, speaking, reading, writing, and gesturing. Most standardized aphasia batteries allow clinicians to identify areas of preserved strength relative to overall linguistic functioning.

Many comprehensive aphasia tests allow the classification of aphasia by type. Classification of aphasia types has a long history and broad appeal among speech-language pathologists and other rehabilitation medicine professionals. In particular, the clinical applicability of the Boston Classification System has made it popular among clinicians (Kertesz & Poole, 2004). In part, this appeal is because this provides a consistent vocabulary for discussing the clinical features of subgroups of people. Terms such as Broca's aphasia, Wernicke's aphasia, and anomic aphasia convey information about the status of a person's retrieval of words, fluency in speaking, comprehension of auditory messages, and repetition of utterances produced by others. These labels, however, may provide little practical information to guide practitioners in selecting and applying appropriate AAC interventions.

Beukelman and Garrett (1998) and, more recently, Garrett, Lasker, and Fox (2007; see also Garrett & Lasker, 2005a; Lasker & Garrett, 2004) suggested an alternate classification system placing greater emphasis on the partner-independent/dependent status with which a person who has aphasia communicates and less emphasis on the modality-specific language characteristics that he or she displays. For AAC purposes, this type of classification system can be a beneficial supplement to help speech-language

TABLE 30-1

Characteristics of Partner-Independent and Partner-Dependent Communicators

Partner-Independent Communicator	Partner-Dependent Communicator
• Initiates communicative interactions with others frequently and independently • Uses both natural modalities (e.g., speaking and gesturing) and AAC strategies to communicate • Experiences frequent communication breakdowns leading to inconsistent success communicating messages • Recognizes when communication breakdowns occur • Combines some symbols (e.g., spoken words, pictures, written words) to create simple and some complex messages • Displays relatively good pragmatic behaviors during conversational interactions • Has relatively good comprehension skills	• Needs assistance from a partner to initiate and maintain communicative interactions • Does not use AAC strategies without support and may not search, or searches ineffectively, for ways to communicate • Relies on a partner to interpret most, if not all, intents to others • Does not consistently recognize errors in communication • May have difficulty using symbols of any kind • May not engage in appropriate turn-taking during conversation • May require support for comprehension and/or expression of messages

Key: AAC = augmentative and alternative communication.

pathologists make decisions about communication-based treatment approaches. As implied by the label, partner-independent communicators are ones who communicate independently in many situations, without the need for assistance from others. Some partner-independent communicators use pre-stored messages, whereas others generate their own novel messages. In contrast, partner-dependent communicators require assistance from others to convey and comprehend messages and to reveal their communicative competence. Table 30-1 summarizes some of the common characteristics distinguishing partner-independent and partner-dependent communicators (Garrett & Lasker, 2005a).

Clinicians familiar with the Boston Classification System may find it helpful to consider how the corresponding aphasia types relate to partner-independent and partner-dependent communicators. Over the years, many aphasiologists have come to view the Boston Classification System as a severity continuum (Kertesz & Poole, 2004). This, in fact, is the underlying premise of the Aphasia Quotient score derived from administration of the WAB (Kertesz, 1982). Similarly, aphasia severity has a large impact on a person's classification as a partner-independent versus a partner-dependent communicator; however, severity by itself is an insufficient indicator (Garrett & Lasker, 2005a). Other factors, such as awareness of production errors and motivation to communicate, also contribute to determination of a person's partner-dependency status. Specifically, people exhibiting those types of aphasia identified through the Boston Classification System as being severe (e.g., such as global or mixed transcortical aphasia) or people having those aphasia types that correspond to severe comprehension problems and limited awareness of production errors (e.g.,

Wernicke's, transcortical sensory, or subcortical sensory aphasia) tend to be partner-dependent communicators. People with less severe types of aphasia and good awareness of their challenges, such as those with Broca's, conduction, or anomic aphasia, tend to be partner-independent communicators.

Of note, many individuals with aphasia fall somewhere in the middle of the partner-independent/dependent continuum. These individuals may be independent communicators in some instances but, at other times, may rely heavily on partner support to convey intents, comprehend others, and engage in meaningful communicative interactions. The label transitional communicator serves to describe the communicative competence displayed by these individuals. Indeed, many partner-dependent communicators evolve into transitional communicators as they gain skill and confidence applying AAC strategies and techniques to a variety of situations and with multiple communication partners.

Supplemental Cognitive Assessments

In addition to determining aphasia characteristics, clinicians may wish to assess cognitive skills if they feel this information will add meaningfully to a client's profile. Tools such as the Cognitive Linguistic Quick Test (Helm-Estabrooks, 2001), Raven's Progressive Matrices (Raven, Raven, & Court, 1998), and Wisconsin Card Sorting Test (Heaton, 1981) may be useful for assessing such skills. These measures give clinicians information about nonverbal processing and executive functions.

Helm-Estabrooks (2002) attempted to determine the correspondence between aphasia battery scores and scores

Box 30–1**Case Study 1**

Tom sustained a left hemisphere cerebrovascular accident (CVA) 9 years ago, at the age of 52 years. Before his stroke, he lived by himself and worked as a photographer. As an adult, he had traveled throughout much of the world, both for his own enjoyment and as part of his vocation.

Following his stroke, Tom had frequent word finding difficulties, used several stereotypic phrases repeatedly during conversational interactions, and perseverated on certain ideas and verbal responses. His language production was nonfluent in nature, with poor verbal repetition skills. Tom's auditory comprehension skills surpassed his verbal expression abilities. A typical utterance follows, illustrating the nature of Tom's stereotypies and word retrieval challenges: "Well / let's see / I see a / I see a / you know I have a problem / I really do / I am bad / it's really bad / I see a / no that's not it / well it floats / and kids and things / you know I really have a problem / I really do."

Tom's language characteristics are consistent with moderate to severe Broca's aphasia, a diagnosis confirmed by his achieved scores on subtests of the Western Aphasia Battery (Kertesz, 1982) (i.e., Fluency = 4; Comprehension = 7; Repetition = 0.9; Naming = 2.3), yielding an Aphasia Quotient of 38.4. Tom's performance on Raven's Colored Progressive Matrices (Raven, Raven, & Court, 1998) placed him at the 25th percentile, and his performance on the Test of Nonverbal Intelligence (Brown, Sherbenou, & Johnsen, 1997) placed him in the 39th percentile. According to Garrett and Lasker's (2005a) classification system, Tom is a partner-independent, generative communicator.

Tom uses multiple AAC materials to support his communicative interactions. These include (a) two low-tech communication books differing in size and complexity; (b) a business card organizer for discussion of health care, financial concerns, and other matters involving interactions with professionals; (c) remnants about current events/activities in the form of news articles, advertisements, restaurant napkins, and so on that he stores in a shoulder pouch; and (d) paper and pencil for writing first letters or partial words and for drawing simple pictures. His ongoing intervention goals include (a) further development and expansion of use of low-tech communication books; (b) refinement of an organizational strategy for business cards and remnants; (c) expansion of his use of writing, including introduction of a spelling board for cueing production of more content words; and (d) mastery of conversational repair strategies related to misunderstandings by communication partners.

on assessments of non-linguistic functions. She found no consistent pattern of performance regarding the relation between linguistic and non-linguistic skills. Instead, individuals with aphasia appear to have unique profiles of cognitive strengths and weaknesses that are not predictable based on language test results. Helm-Estabrooks postulated that differences in the long-term outcomes of individuals with similar aphasia severities may stem from discrepancies in their cognitive abilities—specifically, within the realm of executive functions that allow flexibility and performance of goal-directed behaviors. Therefore, administration of assessments to measure the status of these functions may provide additional important information for consideration when developing a profile of a person with aphasia.

Aphasia-Based AAC Assessments

The specific assessment of the AAC strategy as used by people with aphasia is a relatively new undertaking. In recent years, some tools for examining these skills have emerged. For example, Garrett and Beukelman (1998) originally developed—and Garrett and Lasker (2005b) later updated—a communication assessment measure relating specifically to use of AAC by people with aphasia. This assessment, the Multi-Modal Communication Screening Task for Persons with Aphasia (available at <http://aac.unl.edu/screen/screen.html>) assesses a person's ability to communicate with an external system, search pictures, categorize, combine symbols, combine communication modalities, and use symbols for story telling or to convey a message (Garrett & Lasker, 2005b; Lasker & Garrett, 2004). Information gathered through administration of this tool assists clinicians in making decisions about the viability of using aided communication systems with specific individuals who have aphasia. The tool includes eight activities:

1. Selecting a symbol to request a basic need or provide a response to a biographical question.
2. Selecting two or more symbols to convey a specific message.
3. Choosing symbols that are exemplars of a given category.
4. Using symbols to complete a transaction and to converse with another person.
5. Pointing to sequential pictures to tell a story.
6. Listening to a clinician tell a story, and then retelling it using pictures or other available materials.
7. Using a map to provide information about places.
8. Spelling to supplement communication attempts.

When administering the tool, a clinician marks the type and frequency of cueing that a person needs to perform specific tasks. A summary score sheet allows clinicians to interpret test results with regard to an individual's communication partner-dependency.

Another way of collecting this partner-dependency information is to engage the person with aphasia in spontaneous communication using activities such as responding to open-ended questions (e.g., *What is your typical day like?*) or describing contextually rich pictures. While eliciting such a sample, the clinician provides alternative means with which the person who has aphasia can communicate by making tools, such as pencil and paper and a spelling board, readily available. Then, by watching and listening as the person with aphasia engages in the communication process, the clinician can make a judgment about partner-dependency, paying particularly attention to spontaneous uses of speech, gestures, drawing, writing, and spelling as well as to the person's overall comprehension level. This information, combined with results from other assessment procedures, may provide a sufficient basis for determining partner-dependency during communication attempts.

Needs Profile

A needs profile involves identifying all the contexts and interactions in which a person desires to communicate; the term should not be limited to requests for objects or actions. A needs profile include both transactional (i.e., transmitting specific information from one person to another) and interactional (i.e., developing and maintaining interpersonal relationships) activities. Beyond meeting basic needs, people communicate for a variety of purposes, including sharing information, establishing social closeness, and maintaining social etiquette (Light, 1988). Communication checklists and informal interviews are common ways of obtaining this type of information.

Checklists completed by caregivers provide a means of obtaining information about the needs and abilities of people with aphasia regarding use of AAC. Although experienced clinicians may prefer to gather such information through informal interviews, checklists provide a systematic way of collecting information about a person's functional and routine behaviors and needs. In particular, checklists provide clinicians with a means for amassing information about the communication roles, functions, and modes routinely used. For example, the Aphasia Needs Assessment (Garrett & Beukelman, 1997) (available at <http://aac.unl.edu/screen/screen.html>) includes items relating to a variety of communication needs that an individual with aphasia may experience. Administering the Partner Skill Screening Form and Partner Attitudinal Survey (Garrett & Beukelman, 1992) to family or caregivers may assist in delineating strengths of the communication partners regarding the facilitation of comprehension and expression by people with aphasia. Additionally, having a family member complete the Inventory of Topics (Garrett & Beukelman, 1992) may assist clinicians in identifying potential communication topics.

Strategy and Device Trials

The final aspect of assessing people with aphasia for AAC interventions involves the implementation of communication strategy and device trials. To perform such trials, a clinician first must identify a cluster of potentially useful strategies for exploration by matching a person's clinical profile to available strategies. This can be guided by identification of the person's independent-, transitional-, or dependent-communicator status. If initial trials are unsuccessful, alternate strategies should be explored. (Approaches that are appropriate for independent and dependent communicators are summarized in Communication-Based Interventions for People with Aphasia.)

Once a clinician has generated a list of potential strategies, he or she introduces them to a person with aphasia to determine which are used with ease, which are viable options for further training, and which the person with aphasia is not yet ready to attempt. People with aphasia and the professionals working with them sometimes require only a single session to decide whether a particular strategy or device has potential value; more frequently, however, experimentation and implementation over multiple sessions is necessary. Clinicians should judge the usefulness of particular strategies based on the person's responsiveness in terms of ability, engagement, willingness, and comfort.

Additional Considerations

Most people with aphasia have sustained strokes or acquired brain damage from other types of acute incidents. A subgroup of individuals, however, has a progressive form of aphasia—primary progressive aphasia (PPA)—associated with a decline in communicative function over time. These people have unique needs regarding AAC assessment, because over time, they will show the opposite shift regarding their partner-dependency status compared to people with acutely acquired aphasia. Specifically, during early stages of the disease process, people with PPA function as independent communicators. As the disease progresses, however, people with PPA become transitional communicators and then, eventually, partner-dependent communicators. This deterioration in communication independence has implications regarding the introduction and application of AAC strategies and devices that differ from those relevant to people with aphasia resulting from acute events. An overriding strategy regarding people with PPA is to provide instruction early during the disease process, when the individual still has adequate language and cognitive skills to understand and master compensatory strategies. The same philosophy extends to instruction regarding AAC strategies, techniques, and device usage (King, Alarcon, & Rogers, in press). Specifically, to maintain maximum communicative performance for as long as possible, practitioners

should teach AAC strategies that are appropriate for transitional and partner-dependent communicators while the individual with PPA is still functioning as an independent communicator.

COMMUNICATION-BASED INTERVENTIONS FOR PEOPLE WITH APHASIA

This section presents information about multiple AAC interventions designed to promote successful interactions among people with aphasia and their communication partners.

Augmented Input/Augmented Comprehension

Augmented input, also called augmented comprehension, refers to a set of compensatory strategies that speech-language pathologists can teach to family, friends, and caretakers of partner-dependent and transitional communicators. The purpose of augmented input is to increase the ease and accuracy with which a person who has aphasia understands the verbalizations of others (Beukelman & Garrett, 1998; Garrett & Beukelman, 1992). Thus, the focus of augmented input is on improving receptive, rather than expressive, aspects of language processing, although it is easily paired with other AAC techniques, such as the written choice communication strategy, targeting the expression of communicative intents. Augmented input is appropriate for use with any individual who has reduced auditory-verbal comprehension.

Augmented input is multi-modal by nature. Communication partners of people with aphasia use drawing, writing key words, gesturing, referencing readily available contextual information in the environment, and providing prosodic emphasis to supplement spoken words as a means of communicating. These multiple-input modalities typically occur in combination with spoken messages.

The following example shows augmented input in an interactional exchange. Note that the communication partner uses augmented input to verify the person's response as well as to convey the initial question. As is typical of augmented input, the communication partner verbalizes the question in its entirety but only augments key elements:

Communication partner Did you go to your sister's [writes, *sister*?] on Sunday [points to *Sunday* on calendar]?

Person with aphasia [nods head]

Communication partner So, yes [nods head], you did go to your sister's [points to word, *sister*] on Sunday [points to *Sunday* on calendar].

Person with aphasia [nods head vigorously]

Communication Books

Communication books are used with many populations of people who have communication disorders. Regarding people

with aphasia, communication books can be helpful to individuals across the spectrum of partner-dependency, although the type, complexity of information, and format will vary substantially based on capabilities, needs, aphasia severity, and partner-dependency status. Dependent communicators are most likely to benefit from communication books that include instructions to others about ways to foster communicative interactions along with relatively simple, contextually organized pages providing information about frequently discussed topics as well as topics of high interest. Independent communicators benefit from access to multiple types of conversational supports, such as maps of buildings or local areas, places for collecting and storing important remnants from recent events (e.g., newspaper clippings, ticket stubs, and business cards), and pages for drawing or writing to supplement verbalizations. Regardless of content or organization, communication books are relatively inexpensive ways of allowing people with aphasia to communicate about subjects that a clinician, caretaker, or family member anticipates will be frequent or desirable topics, and they are ways of providing tools for generative communication. They are among the most commonly used of all AAC strategies for people with aphasia, although the success that individuals experience when using them varies widely, depending on the content, organization, and instruction provided.

Communication Book Content

Inexperienced clinicians may believe that the intent of communication books is to provide people who have aphasia with a method of requesting attention to basic wants and needs. Although some people with aphasia require an AAC strategy to express basic needs, staff and family members often anticipate these needs, thus eliminating the necessity for communicating directly about them. For example, a person residing in a long-term care facility may have meals delivered at routine times and water available at all times on a bedside table, thus eliminating the need to request food or liquids; a person living at home may not need assistance dressing, toileting, or grooming, thus eliminating the need to communicate with another person about these activities. Because of this, not all people with aphasia use communication books to express basic needs, and communication books that solely provide a means of expressing such information generally are unsatisfactory.

Communication books have many potential uses other than the expression of basic wants and needs and, depending on their content, can be used to assist with communicative interactions in a wide variety of contexts. For example, a communication book may include content specifically targeting communication with grandchildren while babysitting, requesting directions to sale items in a store when shopping, or relaying personal information about an individual, his or

her family, and interests when meeting new acquaintances. Determination of content and the context for use of communication books stems from careful consideration of an individual's needs and communication desires. Interviewing key people and reviewing information in the case history are good ways to make initial decisions about content and context.

Among the major goals of communication books are the provision of means to establish social closeness through small talk and storytelling, share information through generation of unique messages, make communication repairs, and use a variety of communication registers to indicate different social relationships with others (Stuart, Lasker, & Beukelman, 2000). The failure of clinicians to include ways of engaging in communication acts beyond requesting assistance to provide for basic wants and needs is one of the prime reasons that people with aphasia sometimes reject their communication books. Communication is about forming social relationships with other people, and communication books need to allow people with aphasia to do that through the development of conversations, the exchange of information, the opportunity to tell stories, and the chance to relate personal experiences and opinions.

Another important aspect of communication book content is to provide instructions about methods of facilitating communicative interactions to people who are not familiar with aphasia. Inclusion of simple messages explaining why an individual struggles with speaking or ways of helping to determine communicative intents can minimize the embarrassment that people with aphasia may experience when their communication attempts are less than perfect or the discomfort that others may feel when they do not know any strategies for facilitating communication. A sample message might be "I have aphasia, and I use this book to help me communicate. I can understand what you say if you speak slowly. Please be patient." Specific directions to write down words or repeat utterances also may be helpful in setting the context for a communication exchange.

As more pages and additional types of information are added to a communication book, the clinician may need to divide it into sections to foster easy location of material. Organizational strategies need careful consideration and adjustment, however, to ensure that they are logical to the person with aphasia and do not require symbolic or linguistic processing beyond the person's capabilities. (Ideas about how to organize books are provided in *Communication Book Organization*.)

Finally, communication books need to be dynamic in nature—that is, they should change in content and complexity to meet the changing needs of a person with aphasia. Once use of a communication book has been established, a family member, staff member, or other person should assume responsibility for updating the book as needed after

Box 30–2

Case Study 2

John had severe Broca's aphasia resulting from a stroke. He could say only a few words, although he often understood comments made by others when the topics were familiar and predictable. He used a communication book along with a collection of remnants to support many of his communicative interactions.

John lived with his wife in a small, rural community. One of his favorite activities was accompanying his wife to town to purchase groceries or run errands. John used these trips as an opportunity to catch up with friends and acquaintances by sitting in the car while his wife shopped. Because John had spent most of his adult life living and working in the town, he knew most of the people who passed by, and he enjoyed hearing the latest news about their families or projects at work.

Unfortunately, John's chats with friends frequently were followed by difficult conversations with his wife. Having visited with several friends and acquaintances, John was eager to share the latest news with his wife. Although he could often use his communication book and remnant collection to indicate the topics of his conversations, he struggled to tell his wife with whom he had talked—a problem exacerbated by the fact that John knew many people who his wife knew by name only. To solve this dilemma, John's clinician added a sign-in sheet and written instructions to the front of John's communication book. After talking with someone, John simply presented his communication partner with the sign-in sheet so that the person could write his or her name and the topic discussed.

the termination of formal speech and language intervention. For this to be successful, a speech-language pathologist must teach the designated individual how to make such additions and changes to the existing book.

Communication Book Organization

Categorical organization, based on either semantic or syntactic features, is common in AAC devices for people with communication disorders other than aphasia. Comprehension of traditional categorical organization may be difficult for people with aphasia, however, because organization by category requires symbolic abilities that often are impaired following strokes to the language-dominant hemisphere. For this reason, communication books in which pages are organized according to topic (e.g., eating, playing, or getting ready for work) or location (e.g., office at work or

bedroom at home)—as is common for some children needing AAC materials—or according to syntactic categories (e.g., nouns, verbs, or adjectives)—as may be appropriate for literate adults—are not beneficial to some people with aphasia. These strategies require rather complex linguistic processes involving the recall of specific lexical items and the association of those items with either semantic or syntactic categories. Because these types of semantic and syntactic associations are difficult for people with symbolic deficits, communication books using semantic or syntactic categorical organization, regardless of the pictorial or lexical nature of individual items, may not provide as much benefit as communication books using other organizational schemes to people with aphasia.

Because of the nature of aphasia, an alternate organizational strategy not reliant on symbolic or linguistic processing may help when structuring communication books and other AAC devices for people with aphasia. The use of contextualized photographs and visual scene displays are ways of accomplishing this. A contextualized photograph shows an activity or experienced event in which familiar and personally relevant people, animals, and objects appear in a setting

that is congruent with the depicted activity or event (McKelvey, Dietz, Hux, Weissling, & Beukelman, 2007). Contextualized photographs contrast with portraits or isolated pictures of objects in that they include contextual or environmental content, show an ongoing activity or important life experience that is conducive to relating a story, and suggest the type or nature of relationships among people. For comparison purposes, consider the photographs displayed in Figure 30–1. Figure 30–1a shows a typical portrait in which a person not engaged in an activity appears against a neutral background. Although the image is clear and the pose is typical of static portraits, the photograph is of little use communicatively other than to identify the individual. Similarly, Figure 30–1b shows a family picture with little meaningful contextual information and no action or implied story. Again, the communicative potential relating to the image is limited. These pictures contrast with the contextualized photograph shown in Figure 30–1c. Here, a considerable amount of informational content is available to foster communication about the depicted individuals, the relationship among them, and the activity in which they are engaged.

Figure 30–1. Examples of non-contextual and contextual photographs.

Using contextualized photographs to organize communication books can be an effective strategy for people with aphasia. Incorporating one or more contextualized photographs into the display of a visual scene that incorporates digital reproductions of personally relevant photographs from an individual's private collection, written words, phrases, or sentences relating to the content depicted, as well as supplemental organizational strategies such as color coding or highlighting, can result in highly personalized support to the conversational interactions of a person with aphasia. An example of a visual scene display for incorporation into a low-tech communication book of a person with aphasia appears in Figure 30–2. Templates providing potential layouts for making visual scene displays to include in low-tech communication books are available at <http://aac.unl.edu>.

Recognizing pictures of familiar people and events is a relatively preserved cognitive skill for most people with aphasia (Fox & Fried-Oken, 1996). Using highly contextualized photographs in visual scene displays capitalizes on the intact visual processing and memory skills of people with aphasia as well as on the holistic nature of contextually rich pictures to organize content information and support conversation (McKelvey et al., 2007). As noted by Wilkinson and Jagaroo (2004), consideration of visual processing abilities is important when determining what type of AAC layout will best support

an individual's attempts at communication. A potential advantage exists in using visual scene displays, rather than the traditional grid layouts common to many AAC systems, when dealing with people with aphasia, because grid processing requires individuals to evaluate all items in a grid both individually and equally, without the benefit of contextual support. In contrast, processing information contained in a visual scene display allows recognition of natural relations among objects displayed in a cohesive, holistic, and familiar context. People process visual scenes in a “gist” format that does not require full comprehension of all depicted elements to interpret meaning; hence, people with aphasia may benefit more from AAC systems that use visual scene displays compared with those that use traditional grid formats.

Instruction in Using Communication Books

Introducing the concept of using a communication book early in the treatment process may improve overall communication as well as allow a person with aphasia and his or her family to become accustomed to the idea of using AAC strategies to support natural speech. Delays in implementing communication books may contribute to their eventual rejection, both because the person with aphasia has not had sufficient time to master use of the book and because the clinician has not had sufficient time to make the necessary adjustments to maximize communication. Success most often occurs when practitioners introduce and teach the use of communication books in therapeutic activities that mirror real contexts. This allows the clinician to gauge an individual's feelings about using the communication book as well as to monitor his or her success. It allows the person with aphasia to practice using the book in a supportive setting and to participate in decision making about changes or additions to its structure and content.

High-Tech Devices

In the past, the use of high-tech AAC devices by people with aphasia has met with only limited success. A few anecdotal reports and case studies exist suggesting that some individuals—often those with motor speech challenges masking relatively intact residual language abilities—are successful in using high-tech devices to support communication attempts in real-life situations extending beyond the therapeutic environment (Garrett & Lasker, 2005a; Lasker & Garrett, 2003, 2004). The most common scenario, however, is that such a device is used only for a limited number of situational contexts (e.g., ordering at a restaurant or getting tickets at a box office). The goal of using high-tech AAC to support spontaneous generative communication remains elusive to most people with aphasia. The problem that people with aphasia face when attempting to use high-tech communication devices is circumventing their symbolic processing challenges.

Figure 30–2. Sample visual scene display from a low-tech device.

Simply substituting an alternate symbol system for spoken language does not change the underlying symbolic processing problems. Hence, although people with aphasia may benefit from the multiple modalities that are presented on displays with written words, pictures of items, or alphabet letters, using such symbols to construct linguistically based generative messages remains difficult. Furthermore, the expense associated with purchasing and maintaining high-tech devices persuades most clinicians, family members, and people with aphasia to select low-tech options providing comparable features.

Despite the challenges experienced in the past, new advances incorporating visual scene displays hold considerable promise for facilitating the use of high-tech AAC devices by people with aphasia. As with low-tech communication books, high-tech devices displaying personally relevant, highly contextualized photographs along with related words or phrases and color-coding to assist recognition and navigation emphasize reliance on the intact visual processing and memory skills of people with aphasia while simulta-

neously minimizing the need for symbolic processing. In addition, high-tech applications of visual scene display offer advantages over their low-tech counterparts in that they allow digitized or synthetic speech output and increased amounts and complexity of included information. Use of miniaturized pictures (i.e., signature pictures) revealing the content/topics of hidden levels and touch-screen technology simplify organization, navigation, and access within the device. Researchers working on the development and implementation of high-tech AAC devices using visual scene displays have reported success by people with chronic aphasia in navigating their systems, using them to communicate stories to unfamiliar communication partners, and improving the overall quality of their communicative interactions as reported by family members (Dietz, McKelvey, & Beukelman, 2006; Dietz, McKelvey, Beukelman, Weissling, & Hux, 2005; McKelvey, Dietz, Hux, Weissling, & Beukelman, 2005, 2007). An example of a screen from a high-tech device showing a visual scene display appears in Figure 30-3. The large pictures in the center region of the

Figure 30-3. Sample visual scene display from a high-tech device. Printed with permission. Copyright Beukelman, 2007.

screen correspond with the selected topic, written text, and available digitized speech. The icons, when touched, allow navigation to higher or lower levels within the selected topic as well as triggering production of digitized messages, and the signature pictures around the perimeter of the screen, when touched provide access to screens relating to other conversational topics or other supplements to convey communicative intents or resolve communication breakdowns (e.g., maps, calendars, rating scales, or instructions to communication partners).

Basic guidelines for introducing high-tech AAC devices to people with aphasia are available (Garrett & Lasker, 2005a; Lasker & Garrett, 2004). First, the optimal size and number of symbols per page needs specification. Second, a practitioner needs to explore the impact of using devices with synthetic versus digitized speech. Third, the clinician should develop a scenario to assess the person's use of the device to relate stories and communicate novel messages, such as placing a phone call to order clothing from a mail-order catalogue or asking a stranger for directions to locate a store. Because people with aphasia have difficulty using symbols to encode and represent content, they may have difficulty with complex encoding strategies. When assessing the usefulness of a high-tech AAC device, it has been suggested (Garrett & Lasker, 2005a; Lasker & Garrett, 2004) to record information about the number of times that a person (a) uses the device successfully to communicate part or all of a message, (b) initiates communicative interactions, (c) integrates aided and unaided communication strategies, (d) navigates from one section or level of the device to another, (e) uses organizational strategies to search for items, and (f) resolves communication breakdowns. Clinicians also need to observe the competence with which the person handles control features for turning the device on and off, adjusting the volume, and troubleshooting unanticipated problems.

Virtually all people with aphasia who use high-tech AAC devices also employ multiple other strategies to support their communication attempts. These include both spontaneous, natural communication strategies, (e.g., gesturing and using facial expressions) as well as more formal, augmentative communication strategies, (e.g., referring to remnants, low-tech communication books, and lists). When used in combination, the multi-modal nature of these strategies is paramount in making them beneficial to people with aphasia. Limiting AAC strategies to a single device or modality does not maximize a person's use of residual cognitive recognition and problem-solving skills.

Drawing

Given appropriate instruction, people with aphasia can learn to use drawings to express simple thoughts and ideas, make requests, and gain social closeness; drawings also are beneficial when used by communication partners as a type of

augmented input. The value of communicative drawing stems from two features: first, its provision of a permanent or semi-permanent record, providing additional time for people with aphasia to co-construct messages or revise communication attempts, and second, its lack of reliance on the processing of linguistic symbols (Lyon, 1995a, 1995b). Although drawings are symbolic in nature, people with aphasia may interpret the non-linguistic symbols used in drawings more easily than the linguistic symbols used in spoken and written messages.

Effective communicative drawing by people with aphasia requires good visual attention, relatively intact visual memory, and the ability to copy one-dimensional shapes (Helm-Estabrooks & Alberts, 2004). Despite frequent preservation of these skills, however, many people with aphasia do not spontaneously use drawing to convey ideas (Lyon, 1995a, 1995b). This is not surprising, because most people without communication challenges do not routinely incorporate drawing in their communication attempts. Hence, people do not automatically recognize the potential for communicative drawing, and direct instruction often is necessary to encourage its use. In particular, clinicians need to allay the concerns of both people with aphasia and their communication partners relating to limited artistic ability or coordination challenges resulting from use of the nondominant hand. Because of the simplistic nature of drawings required for communicative purposes, neither concern should limit exploration of the potential benefits of using drawing to supplement other modes of communication.

In addition to the creation of simple illustrations, communicative drawing can include graphic elements. Graphic elements are non-text symbols that do not convey meaning in isolation but that, when added to illustrations, can extend or clarify an intended meaning (Boling, Eccarius, Smith, & Frick, 2004). For example, a drawing of a car might connote a stopped car or one that is moving at either a fast or a slow rate of speed. The addition of three lines (i.e., movement lines) behind the vehicle provides the impression that the car is moving quickly. Movement lines, as well as other examples of graphic elements that people with aphasia and their communication partners can use to supplement drawings, are presented in Figure 30-4.

People with aphasia may initially benefit from a drawing program specifically geared toward improving communicative drawing (see, e.g., Helm-Estabrooks & Albert, 2004; Lyon, 1995, 1995b). Because communicative drawing typically uses simple line drawings and stick figures, drawing intervention programs for people with aphasia are not expected to increase artistic talent. Instead, the prime objectives of drawing programs are, first, to correct or expand drawings so they better convey their intended meaning and, second, to augment unrecognizable portions of drawings through clinician feedback and implementation of additional drawing strategies, such as enlargement of main ideas and inclusion of graphic elements.

Box 30-3

Case Study 3

Mary acquired severe Broca's aphasia as a result of a cerebrovascular accident when she was 58 years old. Following the stroke, Mary's verbalizations were limited primarily to automatic speech and stereotypic and perseverative responses; she sometimes was successful in writing simple words or the first few letters of the words she wished to say.

Because of the severity of her expressive language challenges, Mary and her speech-language pathologist devoted a portion of their individual therapy time to improving Mary's generation of drawings as a means of supplementing her limited verbal and written output. First, Mary practiced identifying key shapes (e.g., square, circle, or triangle) in simple line drawings. Then, she traced these shapes, and after demonstrating adequate tracing skills, she copied shapes of increasing complexity. Eventually, the copied shapes became sufficiently complex so that they resemble objects. The next treatment step involved Mary's completion of drawings made by her clinician but lacking key elements. Only after repeated success with this activity did Mary's clinician engage her in communication-based tasks during which Mary had to use drawing to convey information displayed on cards visible to her but not to her communication partner.

Eventually, Mary independently initiated drawing as a supplement to verbalizations and/or written words or parts of words to convey communicative intents to others. She generated the drawing shown below to express her frustra-

tion with not being included in a women's discussion group following a recent church service.

Communicative drawing serves to augment communication, not replace it. People with aphasia may shift between drawing and using other forms of communication, such as speaking, gesturing, and writing. As with many aphasia treatments and supports, use of communicative drawing during therapeutic contexts does not guarantee its use during natural communication settings. Only when others are supportive of the inclusion of drawing in communication attempts and encourage and embrace its use are people with aphasia likely to generalize it to natural settings.

Particularly for dependent communicators, communicative drawing is highly dependent on the ability of a communication partner to interpret a drawing. Some communication partners and people with aphasia find that using a drawing as a basis for a dynamic communicative interaction is beneficial. This means that each person intermittently contributes features or details to a shared drawing during the course of an interaction. In this manner, communication partners draw, interpret, correct, and probe while jointly creating an image along with a person who has aphasia. Especially when a person with aphasia does not draw to ini-

tiate communication of an intended message, the partner may need to start the process by making a guess about an intended message. By describing details while they draw, communication partners foster comprehension through provision of information in multiple modalities. Then, the person with aphasia may add to a partial drawing or answer simple yes/no questions to confirm the drawing's accuracy or appropriateness concerning the intended message. This approach also provides a way for the communication partner to model the use of drawing as a supplement to other modes of communication.

Written Choice Communication

Garrett and Beukelman (1992) developed the written choice communication strategy as a means for partner-dependent individuals with severe aphasia to express personal ideas, preferences, and opinions. The strategy capitalizes on the observation that people with aphasia benefit from informational redundancy and comprehend better when information is presented through multiple modalities rather than a

single modality. Residual skills and competencies of partner-dependent communicators become evident when communication partners present spoken questions simultaneously with written key words and followed by possible responses, again presented both in spoken and written modalities. To initiate an interaction, a communication partner and person with aphasia determine a topic of mutual interest. This is achieved by the communication partner asking a question such as *What topic would you like to talk about?*, printing and underlining the word *Topic* at the top of a piece of paper visible to the person with aphasia, and suggesting several possible topics. As the partner suggests each topic, he or she prints a key word or phrase relating to that topic and preceded by a bullet on the piece of paper. For example, as shown in Figure 30-5, the partner might suggest talking about events that occurred the previous weekend during a family visit, the performance of a favorite team in a recent

sporting event, or plans the individual has for returning home after completing his or her stay at a rehabilitation hospital. Usually, a communication partner presents three to five options from which the person with aphasia can choose, with one option being *Something else* or *Other*, in case the person with aphasia has a topic in mind other than those initially suggested. The person with aphasia responds to the question by pointing to one of the printed options. The communication partner then confirms the selection by circling it on the piece of paper and verbalizing it (e.g., *You want to talk about your family's visit last weekend*). The communication partner presents subsequent questions and potential answers relating to the selected topic in the same manner, with the interaction continuing until the topic is exhausted.

Many variations in applying the written choice communication strategy make it adaptable to the needs of a particular person with aphasia. For example, the number of possible responses that a communication partner proposes for questions can vary according to a person's ability to manage multiple potential answers (Garrett, 1993; Garrett & Beukelman, 1995). Also, some people with aphasia do not need the support of written key words and can use the strategy by having the communication partner simply write numbers or signal, with his or her fingers, a number to correspond with each verbalized option (Lasker, Hux, Garrett, Moncrief, & Eischeid, 1997). In addition, the strategy works well to elicit opinions or ratings corresponding to a continuum of responses presented on Likert-type response scales (e.g., a scale ranging from 1 to 5, with 1 corresponding to a very negative response and 5 corresponding to a very positive response). Other variations involve altering the pace of an interaction through inclusion of additional repetitions by a communication partner of questions or response choices. Finally, a communication partner or person with aphasia can supplement the written choice communication strategy, with drawings or gestures serving as forms of augmented input or alternative forms of expression.

As shown in the example illustrated in Figure 30-5, a key advantage of the written choice communication strategy is that it allows a person with severe aphasia to express personal desires and opinions—a communication skill that often eludes such patients. The quality of interactions using the written choice strategy, however, largely is dependent on the skill of the communication partner. Speech-language pathologists must ensure that family members, friends, and caretakers of a person with aphasia receive instruction and structured practice using the technique.

Gestures

Gestures are a standard supplement to most people's natural speech production. Although some people with aphasia retain some spontaneous use of gestures as supplements to speaking, most struggle with using gestures, comparable to their challenges with other forms of linguistic and symbolic

Communication partner: What restaurant do you want to go to?
Do you want to go to Old India, Italian Kitchen, Rudy's Steak House, or somewhere else?

Restaurants

systems. In general, practitioners need to provide direct instruction to encourage use of gestures as an AAC strategy for people with aphasia (Collins, 1986).

Gestures can serve many purposes during interactions. Common examples include:

1. Waving a hand, touching another person's arm, or establishing joint eye contact to gain a person's attention.
2. Pointing to a desired object to replace a verbal request for the item.
3. Using iconic or charade-like movements to express needs or transfer information (e.g., raising a hand to the mouth in imitation of holding a glass and drinking from it).
4. Affirming or refuting statements made by others through head nods and shakes.
5. Indicating feelings, opinions, or reactions through facial expressions and standardized gestures (e.g., raising the eyebrows to indicate surprise, shrugging the shoulders to indicate indecision or doubt, or pointing the thumb up or down to indicate approval or disapproval, respectively).

Clinician- and researcher-developed treatment programs exist that specifically target the use of gestures by people with aphasia. One such training program is Visual Action Therapy developed by Helm-Estabrooks, Fitzpatrick, and Barresi (1982). The intent of Visual Action Therapy is to decrease the effects of apraxia of speech, improve verbal expression, and improve the use of gestures for communicative purposes by people with severe aphasia (Helm-Estabrooks & Albert, 2004). The program includes three phases, focusing on development of proximal limb, distal limb, and oral gestures. Various stimuli (e.g., real objects, line drawings, and pictures) are presented to elicit responses following a hierarchy that begins with matching objects to pictures and concludes with independent use of gestures to represent objects unknown to a communication partner.

Coelho and Duffy (1986) developed another gesture training program that included levels of imitation, recognition, and production. During the imitation level, a practitioner shows a person with aphasia a picture and a corresponding gesture or sign for imitation. During the recognition level, the clinician signs a referent, and the person with aphasia matches the gesture to the appropriate picture given a group of four choices. During the production level of training, the person with aphasia practices making appropriate signs or gestures when presented with a pictures of referents.

Concerns exist about the generalization of gesture use to communicative interactions outside of structured treatment sessions both for Visual Action Therapy (Helm-Estrabrooks et al., 1982) and Coelho and Duffy's (1986) gesture-training program (Coelho, 1990; Coelho & Duffy, 1987). To address this concern, Cubelli, Trentini, and Montagna (1991) used Promoting Aphasic's Communicative Effectiveness (Davis & Wilcox, 1985), or PACE, procedures in which, given a picture of an object or action, a person with aphasia pantomimes an intended message to his or her communication partner or clinician. Questions and cues from the listener prompt the person with aphasia to provide increasingly specific gestures. After successful conveyance of the intended meaning, a review of distinctive features, function, or form provides a platform for refinement and practice generating appropriate gestures, although the emphasis remains on message communication rather than on perfection in performance of gestures.

Although the various gesture training programs differ somewhat in their instructional methods, they face similar challenges regarding effectiveness. The success of gesture use by people with aphasia depends on factors such as the amount of contextual support available; the presence of limb apraxia, facial apraxia, or other motor impairments; and the iconicity of selected gestures. Context affects how people interpret gestures. For example, two fingers held in a "V" shape can mean *peace* or *two*, depending on the context. Gestures used without a pre-established topic may be

ambiguous to communication partners because of multiple possible interpretations. Also, attempts at gestural communication relating to previous or future activities or objects not physically present are considerably more difficult than gestural communication about current events (Glennen & DeCoste, 1997). In addition, motor impairments in the form of paresis or apraxia complicate the acquisition and use of gestures for communicative purposes. Clinicians typically find that gestures requiring only simple motor movements are the easiest for people with aphasia to master (Coelho & Duffy, 1986). In addition, clinicians should consider location, hand shape, movements associated with the sign, spatial orientation, and handedness of the person with aphasia when selecting gestures for training. Finally, iconicity is an important factor for consideration when selecting gestures to include in an intervention program. Iconicity refers to how apparent the meaning of a gesture is based on its resemblance to a physical entity. For example, pantomimes are highly iconic movements designed to be direct, concrete portrayals of an intended message; socially or culturally recognizable gestures, such as waving or saluting, also have a high degree of iconicity for members within a society or social group (Glennen & DeCoste, 1997). Highly iconic gestures typically are easier for people with aphasia to master as compared to those with low iconicity (Coelho & Duffy, 1986). Again, however, motor impairments may impede acquisition and use of even highly iconic gestures.

As a rule, dependent and transitional communicators use gestures less frequently and less effectively compared with independent communicators. For most individuals with aphasia, spontaneous gesture use is roughly comparable to residual verbal output (Glosser, Wiener, & Kaplan, 1986); hence, dependent communicators with limited effective verbal output also may have a limited repertoire of interpretable gestural communication. Because of this, direct instruction in use of gestures is particularly important for dependent and transitional communicators. Independent communicators who routinely rely on gestures as a communication supplement may find it helpful to carry a dictionary of gestures with them to help partners interpret specific, idiosyncratic gestures.

Aphasia-Friendly Environments

In addition to the specific AAC strategies and techniques described in the previous sections, the notion of aphasia-friendly environments warrants attention. The development of aphasia-friendly environments is an overarching principle governing the incorporation of AAC strategies, techniques, and devices into communication-based interactions involving people with aphasia who function as partner-dependent, transitional, or partner-independent communicators. Aphasia-friendly environments refer to settings that are conducive to maximizing the effectiveness of people with aphasia by

increasing situational supports and decreasing barriers interfering with the success of communication attempts (Howe, Worrall, & Hickson, 2004). Howe and colleagues (2004) relate the components of aphasia-friendly environments to the five domains identified in the International Classification of Functioning, Disability, and Health Environmental Factors Model (World Health Organization, 2001):

1. Support and relationships
2. Attitudes
3. Products and technology
4. Natural environments and human-made changes to the environment
5. Services, systems, and policies

Regarding the first two domains, aphasia-friendly environments are ones in which partners acknowledge the competence of people with aphasia by including them in decision-making activities and by using simple, adult language with extended processing time for language comprehension and formulation. Members of society demonstrate accepting attitudes by facilitating the participation of people with aphasia in novel as well as established activities and by encouraging people with aphasia to interact with familiar as well as unfamiliar partners. The third domain—products and technology—affects the establishment of aphasia-friendly environments through the development of programs and products that are easily accessed by people with aphasia, minimize challenges associated with aphasia, and serve to educate others about aphasia. This includes a wide diversity of items, ranging from specially adapted computer applications to public-information materials describing the strengths and challenges experienced by people with aphasia. Regarding the domain of the natural environment and human-made changes to the environment, aphasia-friendly settings are conducive to optimizing communicative interactions through strategies such as eliminating competing background noises and distractions. The final domain—services, systems, and policies—is evident in aphasia-friendly environments through the availability of support groups, transportation services, and communication services to aid people with aphasia as they participate in daily activities, such as running errands, attending meetings/appointments, placing telephone calls, and responding to written correspondence.

For dependent communicators, two domains are of particular importance: support and relationships, and the natural environment and human-made changes to the environment. These domains are especially important because dependent communicators rely heavily on family members and friends to modify various aspects of the environment for facilitation of effective communication. Hence, professionals must ensure that communication partners of people with aphasia are adept in supporting conversation. A skilled communication partner must know how to use strategies such as

writing key words (i.e., providing augmented input), providing written choices, and referencing contextually rich pictures to present information through multiple modalities and to enhance comprehension and expression. Elaboration about implementing each of these strategies is provided in the following sections.

Independent communicators may rely on some of the same types of supports that are used by dependent communicators; in addition, however, they benefit from attention to the domains of attitudes, products and technology, and services, systems, and policies. Changes in these domains reflect modifications affecting the whole of society rather than individual people. For example, as society becomes more accepting of and educated about people with communication challenges, more support groups and services in the community will become accessible and, hence, more widely used. Given proper support, independent communicators may even be the individuals responsible for organizing support groups or rallying for services not otherwise provided. In addition, technologic advances may provide the basis for environmental supports, allowing independent communicators to maintain their independence. Independent communicators are the subset of people with aphasia most likely to benefit from traditional high-tech communication systems. Other AAC strategies that are particularly helpful for independent communicators (and reviewed in the following sections) focus on the incorporation of multiple communication modalities through drawing, gesturing, writing, and accessing low-tech and high-tech communication books incorporating visual scenes.

Computer-Based Treatment Approaches

A final issue warranting attention concerns the development and use of computer-based treatment approaches. Compensatory, communication-based, AAC interventions differ from computer-based treatment approaches in important ways. Computer-based treatment approaches allow the provision of intervention services in a manner that contrasts with or supplements traditional aphasia intervention services in which a professional interacts during individualized or group therapy sessions with one or more people who have aphasia. A professional's goal when applying a computer-based treatment approach is to facilitate language restoration by providing opportunities for massed practice, non-judgmental feedback, the possibility of practicing outside formal speech-language therapy sessions, real-time task modification to meet individual needs, and reduced time pressure (Wallesch & Johannsen-Horbach, 2004). In contrast, a professional's goal when applying AAC interventions is to teach people with aphasia and their communication partners the strategies that will support communication in diverse settings and with a wide variety of people. By teaching AAC techniques, strategies, or device usage, a professional strives to

help a person with aphasia compensate for persistent communication challenges. Both computer-based treatment approaches and AAC have important contributions to make in the field of aphasiology and warrant the attention of speech-language pathologists and other rehabilitation specialists; however, recognition of the differences between the two approaches is important.

As covered more extensively in this book's chapter about computer-based treatment approaches, professionals have designed several types of technology-based programs to support treatment of aphasia. Computer-based interventions vary in their status as sole methods of treatment or as parts of comprehensive programs, in the extent to which they are client- or therapist-directed, and in the type and number of treatment goals that are targeted. For example, some programs are designed to function as replacements for spoken language (Steele, Kleczewska, Carlson, & Weinrich, 1992), although people with aphasia often do not have sufficient linguistic competence to use such systems in multidimensional ways that extend beyond treatment settings. Other computer-based treatments support only one aspect of language performance, such as word retrieval (Adrian, Gonzalez, & Buiza, 2003; Fink, Brecher, Sobel, & Schwartz, 2005) or sentence-level auditory comprehension (Crerar, Ellis, & Dean, 1996). Differences regarding client/therapist direction and support during practice sessions range from programs allowing people with aphasia to engage in independent practice using specific linguistic structures (Mortley, Wade, & Enderby, 2004; Petheram, 1996) to programs requiring professional input to guide intervention and monitor progress (Aftonomos, Steele, & Wertz, 1997; Crerar et al., 1996).

A major concern expressed by some aphasia specialists is that computer-based treatments provide little opportunity for generalizing learned skills to communicative interactions and limited, if any, improvement in functional communication. Instead, observed improvements following application of computer-based treatment approaches almost invariably take the form of higher scores on formal aphasia assessments (Aftonomos et al., 1997). Although such a change may indicate overall improvement in language processing, it does not ensure generalization to conversational interactions with other people. The opposite, however, is true of AAC interventions: By definition, AAC interventions aim to support a person's real-life communicative interactions in diverse settings and with multiple partners.

Recognizing potential limitations associated with computer-based treatments is important. Computer-based systems can be expensive and time-consuming, with mastery only occurring after many hours of work with a speech-language pathologist over a period of weeks or even months (Wallesch & Johannsen-Horbach, 2004). In addition, computer-based approaches that emphasize massed practice may have the unintended negative effect of increasing isolation

and reducing time spent engaging in other activities or interacting with others (Wade, Mortley, & Enderby, 2003; Wallash & Johannsen-Horbach, 2004). Given the large investment in time and/or money needed to pursue computer-based approaches and the lack of evidence documenting generalization to real-life conversational interactions, careful and individualized weighing of the risk-benefit ratio is necessary before embarking on extensive programs using computers solely for treatment purposes. As long as professionals recognize that computer-based treatment approaches have limitations as well as advantages, however, and that they are distinct from AAC interventions, people with aphasia and those who interact with them are likely to benefit from advances regarding both types of treatment.

GENERALIZATION OF AAC STRATEGIES AND TECHNIQUES

The generalization of AAC systems into everyday, meaningful communication activities is the desired outcome of such intervention. Generalization is unlikely, however, unless a therapist strategically plans for it from the inception of treatment. Conceptually, generalization is a four-step process involving (1) planning, (2) providing intervention services to a person with aphasia and instruction to family members or caretakers, (3) designing a home program, and (4) performing monitoring activities to make adjustments as appropriate.

Generalization planning involves identifying immediate, short-term, and long-term goals that a person with aphasia can achieve through application of specific AAC techniques and strategies. By engaging in a planning process, clinicians construct ideas about generalization at the outset of treatment. For example, regarding instruction about using written choice as a communication strategy, a clinician first might plan activities that require a small number of exchanges and for which family members may have preexisting knowledge about probable preferences. To achieve this short-term goal, the clinician might teach family members to use written choice as a communication strategy when providing choices to a person with aphasia about the day's meals. Initial activities such as this are ones in which people with aphasia and their caretakers are likely to experience success, thus encouraging continued use of the AAC strategy to attempt more substantive interactions. The clinician's plan for long-term generalization of the written choice strategy might involve progress toward using it for more generalized and conversational purposes, such as talking about an upcoming grandchild's dance recital or discussing events of the past week. The long-term goal is to facilitate expression of intents to a variety of familiar and unfamiliar communication partners across multiple settings to enhance an individual's formation and maintenance of relationships with others. The key to the planning stage is that the clinician considers generalization

issues at the start of strategy instruction rather than waiting for mastery first.

After the planning stage, intervention targets both family and client development of the skills needed to meet treatment goals. The combination of skilled intervention for a person with aphasia and instruction to family members about AAC strategies is important for successful generalization. Although such dual instruction is well-established when treatment involves children with AAC needs (Bruno & Dribbon, 1998), the concept of providing instruction to family members often is overlooked when dealing with adults with aphasia.

Once both family members and a person with aphasia can successfully implement AAC strategies and techniques to perform tasks presented within structured therapeutic settings, home assignments encourage generalization of the learned skills. Not waiting too long to transfer skills to settings outside of therapy is important. Otherwise, people may view the techniques as only applying to therapy and may not attempt their use in real-world situations. In addition, to facilitate generalization, therapists need to model AAC strategy use whenever possible before, during, and after treatment sessions and not restrict it to treatment time devoted specifically to practicing AAC techniques. Regarding home assignments, specific instructions about when and where to implement certain techniques is initially beneficial. For example, a clinician might instruct a person with aphasia to use drawing to facilitate his or her communication during dinner with a granddaughter the following evening or when having coffee with a neighbor the next morning. Later, the clinician can provide more generalized instructions, such as telling the person with aphasia to find two people with which to use the drawing strategy within the next week.

Arranging outings and accompanying people to specific locations are other ways of providing highly structured homework tasks. Examples include planning a trip to a local store to allow interaction with a clerk, using an AAC device to place a phone call, or interacting with a receptionist or other employee of a health care facility with which the person with aphasia is familiar. As people with aphasia experience success, they often think of additional ideas on their own and report back about their independent success.

The last step in establishing a generalization program is to arrange a method for monitoring progress and refining AAC skills as needed. Adjustments to the home program and overall plan may be necessary if a person with aphasia experiences multiple communication breakdowns or encounters resistance from others in certain settings. Again, clinicians must keep in mind the goal of providing ways for people with aphasia to convey communicative intents, allowing the formation and maintenance of relationships with others.

FUTURE TRENDS

Advances in AAC and in aphasiology largely have occurred independently from each other. Few AAC specialists consider themselves to be experts in aphasia, and few aphasiologists feel comfortable implementing a wide variety of AAC strategies and techniques. Likewise, few empirical research articles appearing in aphasia journals have addressed the application of AAC interventions, and equally few articles appearing in AAC journals have reported the effectiveness of implementing such interventions for people with aphasia. The melding of assessment and intervention strategies that support both restoring speech and language functions to the greatest extent possible and compensating for persistent challenges holds considerable promise regarding the development of innovative and effective communication-based approaches for people with aphasia. For this to occur, however, practitioners need to maintain their focus on designing and implementing strategies and techniques that apply to interactions extending beyond the confines of treatment sessions and that address the day-to-day interactional and transactional needs of adults with aphasia. In particular, interventions must be directed toward decreasing the social isolation that people with aphasia commonly experience. A goal of all aphasia-based interventions—whether they involve AAC strategies, devices, and techniques or rely on other language restoration strategies—must be greater social reintegration of people with aphasia through increased opportunities and participation in social activities.

New interventions are likely to include the development of new AAC devices and strategies specifically taking into consideration the preserved and impaired aspects of cognitive functioning displayed by people with aphasia. These applications will exploit relatively preserved cognitive skills, such as memory and visual perception, while minimizing reliance on linguistic and symbolic processing. In addition, these applications will foster the provision of communicative information through multiple modalities to maximize the likelihood of comprehension and expression by people with aphasia.

Clinical professionals have a responsibility to be familiar and comfortable with the notion of AAC for people with aphasia, with existing communication-based AAC strategies and devices, and with new AAC applications as they become available. With this knowledge, early introduction of compensatory and communication-based AAC interventions will be more likely, in turn promoting greater skill acquisition and acceptance of compensatory strategy use by people with aphasia, their family members, other rehabilitation professionals, and society in general. This type of treatment advance, coupled with increased attention regarding the training of communication partners for people with aphasia and the establishment of aphasia-friendly environments, could substantially impact the overall effectiveness of aphasia intervention.

KEY POINTS

1. Many people with aphasia—particularly those with more severe forms of the disorder—experience chronic communication challenges that negatively impact their participation in social roles, activities, and relationships.
2. In addition to restorative treatment approaches, people with aphasia can benefit from exposure to AAC interventions during all stages of recovery—including the acute stages—to ensure sufficient time and opportunity to practice and refine strategies that will help them to compensate for persistent communication challenges.
3. For people with aphasia, AAC is most effective when it is conceptualized as a combination of procedures and processes that are multi-modal, compensatory, adaptable, and geared toward minimizing communication breakdowns.
4. Aphasia is a weakness of symbolic processing and, as such, requires innovative and non-symbolic approaches to the design, organization, and application of AAC interventions.
5. Two types of approaches exist for using AAC to support the communication efforts of people with aphasia:
 - a. AAC systems can supplement a person's inefficient language comprehension and production by providing informational redundancy through the use of multiple modalities and contextual supports.
 - b. AAC systems can minimize reliance on linguistic or symbolic processing by incorporating contextual scenes or visual scene displays into low-tech or high-tech devices.
6. Practitioners can obtain important information about a person's communicative capabilities and needs as well as their potential to use various AAC strategies and techniques effectively by administering and interpreting results from aphasia batteries, supplemental cognitive assessments, communication checklists, and aphasia-based AAC assessments and by implementing strategy and device trials.
7. For AAC purposes, practitioners need to consider the partner-dependent, transitional, or partner-independent status of the communication attempts of individuals with aphasia.
8. Specific AAC strategies and techniques for people with aphasia include the use of augmented input, high- and low-tech communication books and devices, drawing, written choice communication, and gestures.
9. Computer-based treatment approaches differ from AAC interventions, and although they provide for massed, non-judgmental, and untimed practice, they may not necessarily generalize to communication used for interactive purposes.

10. Aphasia-friendly environments are crucial to the successful incorporation of AAC strategies, techniques, and devices into communication-based treatments for people with aphasia.
11. AAC approaches hold considerable promise for supporting individuals with aphasia, but professionals need to continue working on generalizing use of AAC to natural contexts and everyday settings.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Why are AAC systems that provide symbols (in any form) as substitutions for spoken words only partially beneficial to people with aphasia?
2. How does partner-dependency status impact a practitioner's selection of AAC strategies and techniques to try with a person who has aphasia?
3. What are the key characteristics of an aphasia-friendly environment?
4. How can augmented input facilitate comprehension by a person with aphasia?
5. What distinguishes a portrait from a contextual scene?
6. Why should family members and caretakers of people with aphasia learn AAC strategies and techniques?
7. What are the characteristics of a person with aphasia who might benefit from written choice communication?
8. What AAC strategies and techniques provide informational redundancy to support either the receptive or expressive communication attempts of people with aphasia?
9. What are the relatively intact cognitive processes retained by many people with aphasia that allow them to benefit from communication book or device organization using contextually rich photographs or visual scene displays?

Chapter 31

Melodic Intonation Therapy

Robert W. Sparks

OBJECTIVES

The objectives of this chapter are to instruct the clinician in the technique of melodic intonation, describe the verbal behavior of both good candidates and poor candidates for melodic intonation therapy (MIT), discuss the administration of the MIT hierarchy, offer suggestions for involving the families of those with aphasia who are selected for exposure to this language intervention strategy, and suggest future trends in further development of MIT.

Numerous studies have indicated that an unimpaired right cerebral hemisphere is dominant for music in right-handed persons. This explains why persons with aphasia can sing the melody of a familiar song. Their accurate emission of the words of the song is of greater interest, however, because of its contrast with their inability to communicate the most basic needs. This preserved skill also includes recitation of prayers, some social gesture phrases, and premorbid use of profanity. Jackson (1931) classified such utterances as non-propositional language, because they do not involve encoding of a message that contains specific information. He theorized that such utterances are processed in an undamaged, so-called nondominant hemisphere of a person with aphasia. Today, we can produce no better word to describe such language, although we no longer label the right hemisphere as being a nondominant one. Indeed, research indicates that the right hemisphere is involved in processing the prosody of propositional language.

Sparks, Helm, and Albert (1974) reviewed some of the literature on right hemisphere processing of the prosodic elements of speech. Their analysis suggests that, in normal right-handed persons and many left-handed persons, the right hemisphere functions in a tandem relationship with the left hemisphere both for encoding and for emission of propositional language. The final integrative process, however, takes place in the temporal lobe of the left hemisphere.

Reorganization of this interhemispheric process with increased participation of the right hemisphere probably occurs only when recovery is slow and incomplete. Of equal importance in this reorganization are preserved interhemispheric pathways for language. Indeed, Gordon (1972) states that a long period may be involved in increasing the function of the right hemisphere. The reader is referred to Code's discussion of the role of the right hemisphere in the treatment of aphasia. The probability that this is increased by melodic intonation therapy (MIT) is even more likely when we consider the right hemisphere's dominance for music. Studies of adult aphasia that have described language performance from a phonologic model have included Blumstein (1973), Martin and Rigrodsky (1979), and Whitaker (1970).

Melodic intonation therapy involves singing, and the specific techniques that we call intonation are described in some detail later in the chapter. This type of singing is an ancient form, dating back at least to the Judeo-Christian period. It is distinct from other forms of singing in that each intoned utterance is based on the melody pattern, the rhythm, and the points of stress in the spoken model. Use of an intoned utterance that resembles a familiar song may produce disastrous results, therapeutically speaking. The familiar melody will stimulate recall of the nonpropositional words of that song.

PRINCIPLES OF LANGUAGE THERAPY AFFECTING MIT

Objectives of MIT

The original intention for developing MIT for those with severe nonfluent aphasia was to achieve at least a basic recovery of the ability to use some language accurately. Good candidates demonstrate extreme paucity of speech and show concern about such an incapacity. Reasonable priorities of therapeutic purpose for such patients would relegate the quality of articulation and syntax to secondary consideration. Emphasis on the linguistic or semantic aspects of verbal utterances for these persons with aphasia is the primary goal of MIT. Some clinicians, however, are using the

technique as a more phonologic intervention for verbal apraxia. A review of our physiological model implies that the right hemisphere controls prosody. This, then, justifies the use of MIT for the phonologic defects of such patients.

Speech Pathology Principles Applied to MIT

The Examination

A preference as to standardized aphasia examinations that are used to evaluate a potential candidate for MIT is not an issue. Sparks (1978) has presented guidelines for supplementary para-standardized examination of persons with aphasia that make it possible to investigate more specific language skills in addition to those sampled by standardized examination batteries. In any event, MIT depends on evidence from the examination that the aphasic candidate has a distinct potential for some recovery of language.

Eight Principles of Language Therapy Involved in MIT

1. The first principle is concerned with gradual progression of the length and difficulty of the tasks in the therapeutic hierarchy. Such progression involves the type of linguistic material used, a gradual withdrawal of participation by the clinician in that are purely repetition, and reduction of reliance on melodic intonation in the last level of the MIT hierarchy.
2. The second principle—one endorsed by Schuell, Jenkins, & Jimenez-Pabon (1964)—maintains that direct attempts to correct the verbal errors of the person with aphasia fail because he or she cannot recall the specific nature of his errors. Attempts to correct errors accomplish little, and even may do some harm, if they detract from the smooth progression of the hierarchy. The person severely handicapped by aphasia who is considered to be a candidate seldom can effectively correct his or her verbal errors by retrieval. Such retrievals often result in a perseverated repetition of the error, which thus reinforces it. During MIT, attempts are made to achieve correct responses by means of a second trial that involves the technique of “backup.” Specifically, when the person with aphasia fails a step, he or she is immediately guided through a repetition of the previous step and then a second attempt of the step that he or she failed. The person with aphasia may or may not be aware of the purpose of this procedure, but it is not drawn to his or her attention. A second backup retrieval is never attempted if failure occurs again.
3. The third principle maintains that repetition is a highly effective therapeutic device. Repetition serves as the core of MIT. Actually, repetition involves a rather complex process. The fact that normal persons can repeat familiar or simple sentences more efficiently than they can more difficult sentences suggests that a process of decoding the stimulus and then re-encoding it for emission is involved. Accurate repetition deteriorates in longer units. The paraphrased repetition of the longer sentence, however, does not alter the meaning. The stimulus has been accurately received and decoded, but some word substitutions have been used for the restatement. Perhaps the most difficult repetition task involves unknown words of another language or nonsense syllables. In this task, the usual decode–encode process is less efficient. As stated previously, the use of repetition in MIT gradually decreases as the level of difficulty of tasks increases.
4. The fourth principle is concerned with latencies of response. One such control is use of latency between completion of stimulus presentation by the clinician and permission for response by the person with aphasia so that the complete stimulus is received and decoded. Another use of latency is between the completion of one sentence-item progression in the hierarchy and the beginning of the next.
5. The fifth principle is avoidance of practice effect by using the same material or carrier phrases repeatedly. This often is tedious and not therapeutically effective. A well-constructed program of intervention will include many useful high-probability utterances that trigger recall of premorbid language skills. Language that is alien to the person with aphasia should not be used. Therefore, enough variety of meaningful material is encouraged for MIT so that no utterance is used more often than every ninth or tenth session of therapy.
6. The sixth principle maintains that the clinician should pay scrupulous attention to the purpose and semantic value of each of his or her verbal utterances. For example, exuberant reinforcements within a sequence of steps are disruptive. A smile of encouragement will serve just as well or better. This is not an indictment of a warm, holistic approach to therapeutic intervention in general; however, clinicians should practice restraint during MIT.
7. The seventh principle maintains that written or pictorial materials should not be used as added stimuli. We believe the presumption that such material is supportive to the auditory stimulus is very suspect. Our premise is that these materials actually distract rather than support the MIT therapeutic process. This is particularly true of good candidates for MIT who have auditory comprehension that permits them to understand and retain spoken stimuli in a variety of contexts. Persons with aphasia and severe auditory deficits may respond better to auditory stimuli when they are accompanied by pictures; however, such patients are not candidates for MIT.
8. The eighth principle pertains to the frequency of therapy sessions. Twice-daily treatment sessions are essential for the person with aphasia and severe impairment

of language. When restrictions of time, resources, or transportation are involved, the training of family members to function as assistants in the MIT program may be very effective.

CANDIDACY FOR MIT

Assessment regarding the efficacy of MIT has proved that no single language intervention strategy for aphasia is a panacea. Indeed, MIT is effective for only a portion of the aphasic population. This, then, implies a need for careful evaluation of each person with aphasia who is being considered for exposure to this method. Chapter 3 of this text described computed tomographic findings of cortical and subcortical lesions as predictions of candidacy for MIT. Such studies contribute much. Language profiles of both good and poor candidates are presented here as guides for selection. Emphasis is placed on auditory comprehension, several aspects of verbal expression, and nonlanguage behavior.

The Good Candidate

Auditory Comprehension

Examination of auditory comprehension indicates that the good candidate's understanding and retention of spoken language are essentially normal in a variety of contexts. It is simplistic to presume that the process of monitoring one's own verbal utterances is solely through auditory feedback. Actually, kinesthetic feedback probably alerts us to phonologic or semantic errors immediately before the auditory feedback has commenced. In any event, evidence of preserved self-criticism in the good candidate is important.

Verbal Language

The clinical impression of the good candidate is that of a person with aphasia and a marked paucity of any kind of verbal output. In other words, he or she is a nonfluent aphasic. This is accompanied by demonstration of frustration and despondency concerning his or her language impairment. A curious and enigmatic perseveration of a neologistic utterance has been observed in some persons with aphasia who have subsequently responded well to MIT. It is enigmatic because it is similar to the stereotypical jargon utterances of some patients with global aphasia, but two points of difference are notable. First, good candidates will modify the prosody of the utterance so that it reflects their intention to make a declarative, interrogative, or forceful imperative statement. Second, they < will be annoyed by the meaningless morphology of the utterance. With the exception of such stereotyped jargon utterances, little speech is initiated except for an occasional, single substantive word that is always an appropriate communication.

Phonologic performance by the good candidate who has no language impairment other than speech production includes effortful but indistinct speech that is interrupted by pauses for attempted initiation of each utterance and attempts to correct himself or herself. Speech is phonologically distorted. When the articulation is analyzed, a systematic reorganization of sound patterns may seem to occur.

A summary of the results from examination of verbal expression produces a profile of the good candidate as follows:

1. Almost no responses occur in confrontation naming, responsive naming, word and phrase repetition, or sentence completion. An occasional response, however, will be poorly articulated but accurate enough to indicate correct encoding of the target word.
2. Effort at self-correction often is vigorous. This is to be expected in persons with aphasia who are acutely aware of making errors in their verbal output. Unfortunately, the product usually is not improved by this effort.

Nonverbal Behavior

Good candidates often are reasonably depressed, but they almost always are emotionally stable, with a mature response to counseling by the clinician. They manifest a strong desire to enter into intensive efforts to rehabilitate their speech, and they accept MIT.

Concurrent Abnormalities

The good candidate usually demonstrates a significant buccofacial apraxia and has a hemiplegia that is more severe in the arm than in the leg.

Language Profile after MIT

A diagnosis of "classical" this or "classical" that usually is careless, but it is tempting to describe the verbal output of the person with aphasia after MIT as having evolved into that of a person with classical Broca's aphasia. Some of the person's utterances continue to be poorly articulated and agrammatical but telegraphically appropriate. An example is "Home—weekend—Saturday and Sunday. Hospital—you;—Monday." Considering the graduate's almost total inability to communicate before the therapy, this telegram is a triumph.

Further Improvement after MIT

The question as to whether achieved language improvement will be retained by the person with aphasia following successful MIT produces some concern for clinicians. Fortunately, follow-up examinations of MIT graduates have shown that not only do they maintain their new competency, they also continue to improve in their own home environment.

Syntactic substance begins to appear in their verbal output. Graduates of MIT and their families should be advised that a review of the final steps of the hierarchy will be beneficial in the continuing improvement. The clinician should discuss the extent of the family's participation and be available as a continuing consultant.

The Poor Candidate

Three aphasic syndromes are not responsive to the present form of MIT—namely, Wernicke's, transcortical, and global aphasia. The labels are not as important as brief reviews of the verbal behavior involved in each of the three types. All are clearly distinct from the profile of the good candidate that has been presented.

Wernicke's Aphasia

Achieving therapeutic success in those with Wernicke's aphasia is a very difficult and challenging task. Concerted effort by some speech pathologists to produce more effective language therapy for persons with this type of aphasia is essential. The following characteristics of those with Wernicke's aphasia are in marked contrast to those of the good candidate:

1. Auditory comprehension is poor and variable. Those with Wernicke's aphasia show no evidence of being aware that they fail to be understood. In fact, they usually reject language therapy, and their reaction to MIT is either explosive or one of amused condescension.
2. Verbal utterances are overly fluent, syntactically normal, and clearly articulated. They include abundant paraphasic errors for the substantive words, however, and the end result is bizarre and meaningless.
3. Those with Wernicke's aphasia are often emotionally unstable, often hostile, but sometimes extremely cordial. The application of MIT techniques to patients with Wernicke's aphasia has produced poor results. These patients accurately duplicate intonation patterns, including the melody, rhythm, and points of stress. This is in contrast to their replacement of the words in the stimulus model with their own paraphasic jargon.

Transcortical Aphasia

The person with aphasia demonstrating this profile may be similar in some ways to the good candidate and in other ways to the person with Wernicke's aphasia. The important feature of this form of aphasia is an isolated skill at accurately repeating long phrases and sentences, seemingly without the normal decoding process mentioned earlier. The person with aphasia performs perfectly in MIT, but no carryover to improved functional language occurs. Investigation of repetition skill as a candidacy factor would

suggest that the ability to repeat even single words may be a negative prognostic factor for MIT candidacy.

Global Aphasia

The history of language therapy for persons with global aphasia indicates that such therapy has been unsuccessful in improving their functional verbal language. This was pointed out by Albert and Helm-Estabrook (1988); by Sarno, Silverman, and Sands (1970); and by Schuell and colleagues (1964). In fact, MIT is no more effective than other language therapy in reestablishing any useful verbal communication.

MELODIC INTONATION

Sparks and Holland (1976) briefly describe the difference between songs and melodic intonation. Specifically, songs have distinct melodies. In contrast, melodic intonation is based solely on the spoken prosody of verbal utterances. The latter uses a vocal range that is limited to three or four whole notes; this is all that is necessary to achieve an adequate variety of melodic patterns. The range is about the same as that of the melodic line of speech.

This limited range of sung notes is comfortable for the untrained voice of adults. It is important to point out the necessity of avoiding melodic intonation patterns that are similar to those of long-lasting popular songs.

The Form of Melodic Intonation

Melodic intonation is based on three elements of spoken prosody:

1. The melodic line or variation of pitch in the spoken phrase or sentence.
2. The tempo and rhythm of the utterance.
3. The points of stress for emphasis.

Certainty regarding the appropriateness of the intonation pattern is essential in MIT. The need for this appropriateness becomes essential in the final level of the hierarchy, when intoned utterances gradually are transposed back to spoken prosody.

Some exaggeration of the three elements of a spoken prosody model occurs when that utterance is intoned. First, the tempo is lengthened to a more lyrical utterance. Second, the varying pitch of speech is reduced and stylized into a melodic pattern involving the constant pitch of intoned notes. Third, the rhythm and stress are exaggerated for emphasis; this usually involves increased loudness and elevation of intoned notes. These three modifications of spoken prosody serve as a means for emphasizing the prosodic structure of the utterance.

Figure 31-1. Prosodic patterns of speech. H indicates higher pitch; L indicates lower pitch. A single-syllable word is indicated by a single vertical bar. Vertical bars that are connected represent multi-syllabic words or clusters of words. An arrow preceding a vertical bar indicates stress on that word or syllable.

Acceptable Variety of Melodic Patterns and Regional Differences

Several alternative prosody patterns exist for any verbal utterance. The clinician must exercise his or her judgment as to which one will be used for a phrase or sentence in any one session of language therapy. Using a different intonation pattern in a subsequent session is a means for achieving variety of stimulation. Two such variations are illustrated in Figure 31-1.

Regional differences of speech prosody sometimes are quite pronounced. This is not a matter of concern if the clinician and the person with aphasia come from, and are in, the same region. The emigration of a clinician from one prosodically distinct area to another, however, implies that he or she must make an adjustment when MIT is involved. Samples of regional differences are presented in Figure 31-2.

Plotting Spoken Prosody Patterns

Two illustrations of the method of graphically plotting verbal utterances along with an explanation of the plotting technique are presented in Figure 31-1. This method, an adaptation of the one developed at the Kodaly Musical Training Institute and presented by Knighton (1973), will be used in all subsequent illustrations.

Figure 31-2. Two equally acceptable spoken prosody patterns. H indicates higher pitch; L indicates lower pitch. A single-syllable word is indicated by a single vertical bar. Vertical bars that are connected represent multi-syllabic words or clusters of words. An arrow preceding a vertical bar indicates stress on that word or syllable.

Figure 31-3. Regional differences in patterns of spoken prosody for one sentence.

In the first phrase shown in Figure 31-1, “cup of coffee,” the utterance starts on a lower pitch for “cup,” but the substantive importance of the word places it alone. This is followed by the cluster of words, “of coffee.” Emphasis stress is on the first syllable of “coffee,” along with the higher pitch that such stress produces. The last syllable of this declarative phrase has the customary drop in pitch. In the second illustration, “Go for a walk,” the stress is on “go,” with an accompanying higher pitch, then a drop in pitch for the two functor words in the cluster, then a return to the higher pitch along with stress for the substantive word, “walk.”

Figure 31-2 plots the difference of two variations for the phrase “Go for a walk.” The first is as illustrated in Figure 31-1. The second illustrates a model in which the word “for” is detached from the rest of the cluster that follows. This may be desirable as the person with aphasia improves and the clinician thinks that therapy should begin to attack the absence of functor or relational words in the patient’s speech.

In Figure 31-3, a comparison of prosody for the social gesture utterance “good morning” shows a rise-fall melody pattern of the northeastern parts of the United States and a gradually rising inflectional pattern of at least some parts of the South.

Transposing Speech to Intonation

Illustrations of the transposition of plotted speech prosody models into melodic intonation are presented in Figure 31-4

Figure 31-4. Transposition of spoken prosody models to melodic intonation. Key of C in treble cleff is used for illustration. No attempt is made to present accurate musical tempo.

using the phrases illustrated in Figure 31-1. The placing of the notes on a musical staff in these illustrations does not imply that ability to read music is a prerequisite to administering MIT, although such skill is an advantage. The primary purpose here is to duplicate graphically the pattern of spoken prosody that has served as the model. Considerable musical license has been taken—and musicians are requested not to take issue. For those who are interested, however, the key of C is used in the illustrations so that variations of sung note combinations may be demonstrated.

Sprechgesang

The fading of melodic intonation and a return to spoken prosody occurs in the fourth level of the MIT hierarchy. It is a technique that lies halfway between speech and singing. It is used in choral reading but more lyrically by Schoenberg in his *Ode to Napoleon* and *Pierrot Lurairé*. Schoenberg defined the technique as *sprechgesang*, or “spoken song.”

The exaggerated tempo, rhythm, and points of stress in *sprechgesang* are the same as in the intoned model. The more variable pitch of speech, however, replaces the more constant pitch of intoned notes. The utterance is lyrical but spoken rather than sung.

The senior author lays claim to the use of this art form as a bridging technique in the MIT hierarchy after having heard a performance of *Ode to Napoleon* by the Boston Symphony Orchestra in 1973. He will furnish a cassette sample of *sprechgesang* on request, provided that the request is accompanied by phrases to be illustrated and a cassette.

LINGUISTIC CONTENT

The importance of a linguistically sophisticated control of the grammatical structure of phrases and sentences used in MIT depends largely on the severity of the individual person with aphasia's inability to communicate and the usefulness of the verbal material. The selection of phrases and short sentences should be high-priority communication. This involves investigation of basic aspects of the patient's premorbid milieu that may be used and then some creativity on the part of the clinician to produce stimulating material. In other words, all material should be egocentric for the individual person with aphasia. This should be the case in all therapy for the traumatized person with aphasia, but it is particularly important as a counterbalance during MIT, in which the technique is so atypical of normal verbal behavior. Information about such things as basic family routines, family relationships and customs, personal needs, and personal likes and dislikes will suggest an abundance of material with both universal and individual appeal. Clusters of sentences that have a spherical relationship add an even greater significance. This is illustrated in Figure 31-5, which

Figure 31-5. Four thematic, three-item illustrations of melodic intonation material using the same figure legend presented in Figure 31-1.

presents four three-item themes as an illustration of the thematic relationship of therapeutic material along with further illustration of melodic intonation plotting. Additional illustration of the thematic arrangement of material presented by Sparks and Holland (1976) is included here with the permission of the senior author of that article:

3. Look at the Sports Page 6. Time to Go to Bed

Sample Material for Level II

- | | |
|--------------------|------------------|
| 1. twelve o'clock | 6. apple pie |
| 2. time for lunch | 7. glass of milk |
| 3. bowl of soup | 8. I am sleepy |
| 4. salt and pepper | 9. take a nap |
| 5. ham sandwich | |

Sample Material for Levels III and IV

- | | |
|-----------------------------|------------------------|
| 1. Sit down in a chair. | 6. I am very tired. |
| 2. Read the newspaper. | 7. It is getting late. |
| 3. Look at the sports page. | 8. Time to go to bed. |
| 4. Turn on the TV. | 9. It is ten o'clock. |
| 5. Go for a walk. | |

Meaningful stimulus items for the aphemic candidate who has no impairment other than phonologic errors should, in addition to being meaningful for the individual patient, focus on facilitating more intelligible speech. The creative clinician will meet with the candidate and family and explain the importance of gaining information about specific linguistic preferences that the patient used in his or her premorbid speech. Therapeutic concern for consistent phonologic errors makes it more difficult to select meaningful material. Table 31-1 illustrates the use of phonologic patterns in selecting stimulus materials.

TABLE 31-1

Sample Phonologic Patterns for Melodic Intonation Therapy Stimuli

Facilitation of Velar Production		
cup of coffee	corn on the cob	piece of cake
calico cat	good cookie	call a cab
make music	big lake	can of coke
Facilitation of Cluster Production		
ask the man	pass the salt	small price
stamp please	go back home	last street
deep snow fall	spare room	sports coat
Facilitation of Syllable Sequencing		
build a snowman	light the Christmas trees	more ice cubes
it's a democracy	open the refrigerator	fix the machine
read it in the paper	time for breakfast	play the music box

MELODIC INTONATION HIERARCHY

The hierarchy of MIT is highly structured for gradual progression of difficulty. Therefore, it is presented in explicit detail, because attention to every specification has contributed to its success. We are sympathetic with those clinicians who prefer less structured language intervention strategies, and we assure them that their reservations about using hierarchies is understood. Sparks and Holland (1976) referred to the dilemma of presenting a hierarchy in a way that is too detailed and seemingly dogmatic for some clinicians and, perhaps, not explicit enough for others. The presentation here will include a description of the technique of intoning, a detailed and illustrated discussion of the four levels of the hierarchy, and a suggested method of scoring each MIT session.

Specific Aspects of the Technique

Discussion of the hierarchy will be made more explicit by first describing the several techniques that are involved.

Use of Verbal Cueing

Phonemic cues, along with their important visual components, are used in the second level of the program and, to a lesser extent, in the subsequent levels. The use of such cues is limited to assisting those with aphasia in the initiation of their responses when it is apparent that they are having difficulty. It is never used as a means of repeating the task for purposes of correcting errors in the responses of the person with aphasia.

Backups and Patient's Failures

A means of attempting indirect correction of errors, called "backups," is used in the third and fourth levels of the program. If the response of the person with aphasia in any step is not considered to be adequate, the clinician has the person repeat the preceding step and then attempt the failed step again. This second trial often is effective in producing the correct response without distracting the patient or making him or her directly aware of the error. As illustrated, if the third step of a level is failed, the second is repeated and the third is then attempted again. If the fourth step is failed, the third is repeated as a backup, and so forth. If the person with aphasia again repeats the error or produces a different one after a backup sequence, the clinician terminates any further effort with that sentence-item and proceeds to the first step of the level with a new sentence. This is consistent with the concept that overt attempts to correct errors are not useful with the type of aphasia that indicates a patient is a candidate for MIT.

Hand Tapping and Control by Hand Signals

It is recommended that the clinician seat himself or herself across the table from the patient with aphasia so that his or her participation is visible to the patient and the patient's performance is clearly visible to him or her. The clinician grasps the patient's left hand so that he or she can engage it in tapping out the rhythm of the stimulus as it is presented and then the rhythm of the responses. Many subjects begin to exercise some control of the hand tapping. This should be encouraged provided that it is accurate. The clinician's participation may then be faded to that of monitoring accuracy while continuing to hold the patient's hand. Hand tapping has proved to be an important and effective supportive stimulus. It has a cueing value that often seems to be as effective as the verbal component it accompanies.

The clinician's use of his or her left hand as a means of controlling onset of the patient's responses is recommended as a nonverbal and nondistracting means of exercising such control. Held up, the left hand advises the patient to remain silent and listen. Dropped with a finger pointed at the patient, it signals him or her to respond. This method is useful in enforcing latency if it is used consistently. The clinician may feel like a traffic officer and may wish that he or she could develop a means of also using his or her feet.

Unison Repetition and Fading Participation by the Clinician

An early step in all levels of the hierarchy involves clinician—patient unison repetition of the stimulus that the clinician has just presented. The clinician fades his or her participation, first the audible and then the visible component, so that the patient is repeating the sentence "solo." It often is necessary for the clinician to rejoin the patient when it is

evident that the patient is not quite ready to proceed in the repetition on his or her own.

Adapting to the Patient's Modification of Melody Patterns

The clinician should be prepared to change the key of the melody to that of the person with aphasia's inadvertent modification. Attempts to correct such modifications is an unnecessary distraction. Rather, accurate repetition of the verbal material is the primary goal. Modification of the rhythm or number of intoned syllables, however, cannot be permitted because of their effect on the substance of the sentence.

MIT Session Scoring

The best way to judge the effectiveness of any highly structured form of language therapy for aphasia is to use or develop an objective system of scoring each therapy session. This principle is recommended for MIT as a means of measuring the efficiency of the method for producing steady improvement by any one patient. The method suggested here involves a two-point score for an accurate response that has not required a phonemic cue to initiate a response or a backup, a one-point score for an accurate response achieved with cueing or after a backup, and a reduction of the maximum possible score for any sentence-item if steps have not been completed.

The Hierarchy of MIT

The discussion of each of the four levels of the MIT hierarchy will include a fully detailed description, and Table 31-5 will provide a quick reference. A second table for each level presents a sample therapy session that includes management of errors and scoring, and a review of the types of errors most frequently encountered.

Level I

The first level is a one-step, preliminary means of establishing a set for holding hands and, as far as the person with aphasia may see it, singing odd little nothings. The melodies are those that are used for intoning phrases and sentences. They should increase in length and complexity of melody and stress points as the person with aphasia adapts to the technique. A good candidate usually can be introduced to the idea by a simple description of the process and its purpose. The clinician hums a melody twice while hand tapping the rhythm-tempo-stress pattern with the patient. Humming is suggested rather than a vowel of "la-la" because of its less distinct phonemic quality. Melody patterns similar to those illustrated in Figure 31-5 should be used. Second, the clinician signals the patient to join him or her in unison humming of the melody along with the hand tapping. The patient may

use a more phonemic verbal utterance when he or she joins in with the clinician. This is acceptable in this first nonverbal level. When the clinician thinks the patient is ready for a solo effort, the clinician fades his or her vocal participation but continues hand tapping with the patient. When the patient has completed his unaccompanied repetition, the clinician reinforces the performance by saying "good" and proceeding to the next melody pattern. No scoring takes place in Level I. The time required to complete this first level varies from 15 minutes for some patients to two full therapy sessions for others. In any event, moving to the second level occurs as soon as the patient is comfortable in the set of intoning, hand tapping, and complying with the hand-signal controls of the clinician.

Level II

In Level II, linguistic material is added to the type of intonation patterns introduced in the first level. Each of the four steps in the level is presented in detail below. The model presented by Sparks and Holland (1976) had five steps. The present model has combined the first two steps of that model. The use of phonemic cueing is indicated when applicable. Scoring involves two points for a response from the patient that does not require a cue to initiate it and one point if the response is acceptable when initiated by a cue from the clinician. Hand tapping by the clinician and the patient occurs in all stimuli and responses.

Step 1

The clinician hums the melody-tempo-stress intonation pattern that is to be used with the sentence while hand tapping it with the patient, then repeats it with the sentence added. The clinician pauses briefly and then repeats it again. Next, the clinician signals the patient to join him or her in unison repetition of the intoned sentence. If the patient's performance is acceptable, the clinician proceeds to Step 2. If the patient's performance is not acceptable, the clinician pauses for several seconds to produce decay of the strength of the stimulus and then proceeds to the next sentence. The maximum score for an acceptable performance by the patient is one point.

Step 2

After a brief pause, the clinician and the patient begin a unison intoning of the same sentence along with hand tapping. The clinician then fades his or her verbal participation in the manner described earlier but continues to hand tap the rhythm stress pattern with the patient. An acceptable performance implies progression to the third step, and the maximum score is again one point. An unacceptable performance terminates further progression; the clinician pauses for several seconds and then proceeds to the next sentence to be attempted.

Step 3

The patient is signaled to listen. Then, the clinician presents the same intoned sentence. This is accompanied by the hand tapping. Next, the patient is signaled to repeat it, unaccompanied by the clinician except for the clinician's participation in the hand tapping. If the patient has difficulty initiating the repetition, the clinician gives a phonemic cue for the first phoneme of the sentence. Again, this is accompanied by the hand tapping, and hopefully, the patient will respond to the cue accurately. If this third step is completed without cueing, the score is two points; if it is unacceptable only after cueing for initiation, the score is one point. Failure to initiate the utterance after one cueing effort or to produce it accurately enough to be acceptable terminates progression to the fourth step. After a suitable pause, the clinician proceeds to the next sentence.

Step 4

In the final step of the second level, the clinician, without hand tapping, intones the question "What did you say?" immediately after successful completion of the third step. The clinician then signals the patient to repeat the intoned sentence. Cueing along with the hand tapping is offered once if the patient is having difficulty initiating the repetition. Occasionally, the patient may modify the sentence slightly by omitting a functor word or by a slight paraphrase of the sentence. This may be acceptable to the clinician. We maintain that any appropriate near-target response is evidence of progress. Scoring is the same as that of the third step. Two points are given for an acceptable uncued response; only one point is given when a cue was necessary for initiation. The patient is reinforced if he or she successfully completes the four steps for the sentence.

Level II Accomplishment

The patient who succeeds in Level II has acquired the skill of repeating intoned sentences immediately after hearing the model and then in response to a question. The latter is more difficult, however, because the question not only acts as a masking intrusion but also initiates the process of reencoding the stimulus for responsive speech. Attention to this becomes progressively more active in the subsequent levels.

The Most Common Errors Occurring in Level II

First, the patient may be so surprised by his or her solo repetition when the clinician fades his or her participation that the patient will falter. The clinician should be generous in reentering the unison repetition as much as he or she considers it to be useful in producing improvement of the patient's performance. Second, increasing repetition skill may disclose significant evidence of poor articulation, and this will continue throughout the MIT program for that patient. As stated previously, we give greater priority to increasing linguistic skill.

Sample MIT Session and Scoring for Level II

A brief, five-item therapy session and its scoring is presented in Table 31-2 to illustrate management of errors in the patient's performance.

Level III

The third level actually is a liaison between the recovery by the patient with aphasia of his or her ability to repeat during participation in Level II and the return to speech prosody and responsive speech in the fourth level. Latency of permitted responses and less specific questions in the last step

TABLE 31-2

Sample Melodic Intonation Therapy Level II Session With Step and Summation Scores

Patient Performance	Scores			
	Step 1	Step 2	Step 3	Step 4
First sentence: Patient succeeds in all steps. Maximum scores attained.	1	1	2	2
Second sentence: Patient succeeds in all steps but requires a cue to initiate response in Steps 3 and 4.	1	1	1	1
Third sentence: Patient succeeds in Steps 1 and 2, requires a cue to initiate response in Step 3, and fails Step 4 because of an unacceptable response after backup.	1	1	1	0
Fourth sentence: Patient succeeds in Steps 1 and 2, requires a cue to initiate response in Step 3, and requires a backup to initiate Step 4.	1	1	1	1
Fifth sentence: Patient succeeds in Step 1 but fails in Step 2. Progression is stopped, and no scores are given for Steps 3 and 4.	1	0	—	—
Scores	5/5	4/5	5/8	4/6
Total	18/24 (75%)			

begin to put more stress on the encoding of responsive speech. In this level, phonemic cueing by the clinician is replaced by the backup system already discussed. In addition to their use as an aid for initiation of responses, backups also are used as an indirect means of correcting an error in a response. As in cueing, only one backup and retrieval of a failed step is permitted if the hierarchy is followed without modification. Again, the Sparks and Holland (1976) hierarchy has been modified by combining their first and second steps into one. The detailed description of this third level follows.

Step 1

The clinician presents the intoned sentence with the usual hand tapping once, then signals the patient to join in unison intoning and hand tapping the sentence. As the patient shows evidence that he or she can continue, the clinician fades his or her verbal participation, returning briefly if necessary and then fading again until the patient can continue alone. The maximum score is one point for acceptable performance, and the clinician proceeds to Step 2. It would be unusual for the patient to fail this step, but if he or she does, the progression for that sentence is discontinued.

Step 2

The clinician intones the same sentence once with the usual patient-clinician hand tapping. The patient's response will be intoned repetition, but delay in his or her response of 1 or 2 seconds is imposed by a hand signal from the clinician. Then, the clinician signals the patient to repeat the intoned sentence. Failure involves an immediate backup to Step 1 (i.e., unison intoning with clinician fading) and then retrieval of the second step. If the step is completed without a backup, the score is two points. One point is given for an adequate response following a backup if it is necessary. Failure after one retrieval terminates progression to the third step for that sentence.

Step 3

No hand tapping is performed in this step. The clinician intones a question asking for a substantive response concerning some element of information in the sentence that has been presented. For instance, if the sentence used in the preceding steps was "I want some pie," the question for Step 3 could be "What kind of pie?" Perhaps the encouraging early indications of language recovery during MIT are the occasional appropriate, but nondirected, responses to the question. Such responses seem to be ahead of any other evidence of recovery in the patient's functional language. Such responses please and surprise the patient and reward the clinician. These responses usually are uttered in normal speech prosody, and they certainly should be accepted. Failure to respond appropriately to the question implies an immediate backup to Step 2 (i.e., delayed repetition) and then a retrieval of

Step 3. The clinician should not solicit some response of his or her own choosing. Scores are the same as for Step 2: two points without a backup, and one point after a backup.

Level III Accomplishment

Satisfactory completion of this third level of MIT has begun the modification of the patient's responses from simpler repetition that is well supported by the clinician's participation to more difficult responses involving some retrieval and a beginning of attempts at encoded responses to specific questions.

The Most Common "Errors" Occurring in Level III

The patient's burgeoning confidence and enthusiasm may prompt him/her to respond before the clinician has signaled him/her to do so, particularly when delayed response is required. This is not, strictly speaking, a verbal error, but because of the increasing difficulty of the tasks, the clinician must insist on compliance with his or her controls. The patient also may omit an occasional functor word. Perhaps this is an error of omission, but we believe that any improvement should be free of criticism and should not be inhibited by too much attention to syntax at this point in the progression of the hierarchy. Finally, the variety of appropriate but unanticipated responses to the question in Step 3 should be praised even though they may not be what was expected. They are not errors, particularly if the questions are open-ended enough to make it possible for a variety of responses to occur.

Sample MIT Session and Scoring of Level III

As in Level II, a brief, five-item therapy session and its scoring are presented in Table 31-3 to illustrate management of errors.

Level IV

In this last level, the return to normal speech prosody by way of the *sprechgesang* technique described earlier occurs for each sentence used, longer delays are imposed by the clinician before he or she permits the person with aphasia to respond, and more spontaneous and appropriate verbal intrusions by the person with aphasia may be expected.

Step 1

The clinician signals the patient to listen, then intones the sentence. The clinician then pauses briefly and presents the sentence twice in *sprechgesang* accompanied by hand tapping with the patient. He or she then invites the patient to join him or her in unison *sprechgesang* repetition of the sentence with continued hand tapping. Failure of the patient to respond appropriately calls for a backup to the clinician's solo presentation accompanied by hand tapping, then a second trial of the unison repetition. A second failure terminates

TABLE 31-3

Sample Melodic Intonation Therapy Level III Session with Step and Summation Scores

Patient Performance	Scores		
	Step 1	Step 2	Step 3
First sentence: Patient succeeds in all steps. Maximum scores attained.	1	2	2
Second sentence: Patient succeeds in all steps but requires backups for Steps 2 and 3.	1	1	1
Third sentence: Patient succeeds in Step 1, requires a backup to initiate Step 2, and succeeds in Step 3.	1	1	2
Fourth sentence: Patient succeeds in Step 1, requires a backup for Step 2 because of inaccurate response, and fails to initiate response in Step 3 after a backup.	1	1	0
Fifth sentence: Patient succeeds in Step 1, fails to repeat accurately in Step 2, and fails after a backup. Progression is stopped, and no score may be given for Step 3.	1	0	—
Scores	5/5	5/10	5/8
Total	15/23 (65%)		

further effort with that sentence. If the step is completed without a backup, the score is two points; the score is one point if a backup is necessary.

Step 2

The clinician again signals the patient to listen. Then, the clinician presents the same sentence in *sprechgesang* with hand tapping, delays permission for the patient to respond for 2 or 3 seconds, and then signals the patient to repeat it in *sprechgesang* with hand tapping. Failure involves an immediate backup to the first step (i.e., unison repetition in *sprechgesang* with hand tapping and fading participation by the clinician) and then a retrial of Step 2. If the step is completed without a backup, the score is two points; if a backup is necessary to get an acceptable response, the score is one point. Failure to respond appropriately after one backup terminates progression to the third step for that sentence.

Step 3

Hand tapping is now discontinued for the remainder of Level IV for each sentence. The clinician signals the patient to listen, then presents the same sentence twice but now in normal speech prosody. After delaying permission to respond for 1 or 2 seconds, the clinician signals the patient to repeat the sentence as presented in normal speech prosody. The length of the delay may be lengthened as the patient develops proficiency. Failure involves a backup to the second step (i.e., delayed repetition in *sprechgesang*, with hand tapping) and then a retrial of Step 3. Scoring is the same: Two points without a backup, and one point after a backup that produces an acceptable response. Failure after a backup terminates progression to the fourth step for that sentence.

Step 4

As in the last step of the third level, the clinician asks questions concerning substantive information contained in the same sentence immediately after successful completion of Step 3, but the number of such questions may be increased. Then, the clinician asks questions that are more associative in nature. As illustration, the following example is given:

Sentence

I want to watch TV.

- (a) What do you want to watch? (b) Who wants to? (c) When do you like to do that? (d) What programs do you enjoy most?

The guidelines for decisions regarding what may be considered to be acceptable responses and when a backup should be used are less specific as this last step in the hierarchy becomes less rigidly structured. One suggested solution is to demand accurate responses to the specific questions based on material in the sentence and reward the patient with extra credit for appropriate responses to the less specific questions. Backups should be used only for failures to initiate responses to the specific questions or when such responses are inferior to the patient's current ability. Principles of suggested scoring are modified to conform to the above guidelines for acceptability of responses. If a backup is used, it will be Step 3 (i.e., delayed repetition of the sentence in normal speech prosody) and then a retrial of this fourth step. Backups should be restricted to use with the first specific questions, because responses to the less specific questions are bonus items. Response to the specific questions yields two points for each one, but only one point if a backup was necessary. Response to one or more of the less specific questions would yield a single score of three

points, an added bonus that is a nice reinforcement the patient will enjoy.

This last level of the MIT hierarchy is more permissive than the first three and demands significantly more from the patient because he or she has recovered enough speech to reach it. The somewhat less stringent form lends itself to transition to any other language therapies that the clinician may want to employ after completion of MIT.

Level IV Accomplishments and Post-MIT Therapy

The patient who has completed the MIT program has maintained the skills that he or she acquired earlier in the program and has carried them over to normal speech prosody, along with an ongoing recovery of ability to encode and emit at least basic verbal communication. Perhaps this recovery now exceeds, or will exceed, the limits of what MIT currently is designed to offer. Some clinicians may think that the goals should be expanded to help the patient with aphasia and less severe impairment, whose language profile is essentially that of the good candidate but with less acute impairment. This would place the method alongside other techniques that are concerned with improving syntax, articulation, and efficiency of retrieval. The MIT might be used concurrently with these techniques in post-MIT language therapy. Many of us have modified the hierarchy for limited use after completion of the four levels. The issue could be raised as to how long language therapy should continue when the improving patient reaches a point at which he or she can experience some continuing recovery in his or her own milieu. That discussion, however, does not belong here.

A fifth, less structured postgraduate step has been used to retire melodic intonation. Its design includes only sprechgesang and normal speech prosody repetition, along with an increased emphasis on answering questions, such as those used in Step 4 of the last level. It is useful to encourage the patient to use sprechgesang as an auto-therapy when he or she is experiencing difficulty with word finding and the phonemic structure of words. Most MIT graduates find it difficult to use the technique unless some prompting takes place before final discharge from the realm of MIT.

Sample MIT Session and Scoring for Level IV

A five-item therapy session with scoring for the fourth level is presented in Table 31–4.

Quick Reference Guide for the Hierarchy

The four levels of the MIT hierarchy are presented in Table 31–5 for the convenience of the clinician during administration of the therapy.

Concurrent Language Therapies

Because MIT involves a marked departure from normal speech, and because of its carefully planned program of progression, we recommend that no other therapy that is directed specifically to improved verbal output be used concurrently. The patient may easily be confused if one form demands intoning all verbal output, and another uses a procedure involving normal speech prosody. The gradual transition in MIT to therapy that involves normal prosody makes it

TABLE 31–4

Sample Melodic Intonation Therapy Level IV Session with Step and Summation Scores

Patient Performance	Scores			
	Step 1	Step 2	Step 3	Step 4
First sentence: Patient succeeds in Steps 1 and 2 requires a backup to initiate normal prosody in Step 3. Patient succeeds in Step 4, but no bonus because of failure on last associative question.	2	2	1	2
Second sentence: Patient succeeds in Step 1 but requires backups for Steps 2 and 3. Patient succeeds with bonus in Step 4.	2	1	1	3
Third sentence: Patient requires a backup to succeed in Step 1 and then succeeds in subsequent steps.	1	2	2	3
Fourth sentence: Patient succeeds in Steps 1, 2, and 3 but requires a backup for Step 4 and fails to answer any associative question.	2	2	2	1
Fifth sentence: Patient succeeds in Steps 1, 2, and 3 and requires a backup for one specific question in Step 4 but answers all associative questions.	2	2	2	2
Scores	9/10	9/10	8/10	11/15
Total	37/45 (82%)			

TABLE 31-5

Quick Reference Hierarchy Guide Melodic Intonation Therapy Levels I to IV

LEVEL I

Single Step

C (HT) hums melody twice.

C and A (U) hum melody twice. C fades.

Score and progression: No score. Proceed to next melody.

LEVEL II

Step 1

C (HT) hums melody → intones sentence.

C signals A.

C and A (HT) (U) intone sentence.

Score and progression:

Acceptable—1 point. Proceed to Step 2, same sentence.

Unacceptable—Discontinue progress for sentence.

Step 2

C (HT) hums melody → intones same sentence.

C signals A.

C and A (HT) (U) intone sentence. C fades.

Score and progression:

Acceptable—1 point. Proceed to Step 3, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 3

C (HT) intones same sentence → C signals A.

C and A as A intones sentence. C intones sentence. C intones cue if necessary.

Score and progression:

Acceptable without cue—2 points. Proceed to Step 4, same sentence.

Acceptable with cue—1 point. Proceed to Step 4, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 4

C intones “What did you say?” → C signals A.

A repeats intoned sentence. C intones cue if necessary.

Score and progression:

Acceptable without cue—2 points.

Acceptable with cue—1 point.

Proceed to Step 1 for next sentence.

LEVEL III

Step 1

C (HT) intones sentence → C signals A.

C and A (HT) (U) intone sentence. C fades.

Score and progression:

Acceptable—1 point. Proceed to Step 2, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 2

C intones same sentence → C signals A to wait.

C signals A after 1 or 2 seconds.

A (HT) repeats intoned sentence.

(B) to Step 1 if A fails → retrieval of Step 2.

Score and progression:

Acceptable without (B)—2 points. Proceed to Step 3, same sentence.

Acceptable after (B)—1 point. Proceed to Step 3, same sentence.

Unacceptable after (B)—Discontinue progression for sentence.

TABLE 31-5

Quick Reference Hierarchy Guide Melodic Intonation Therapy Levels I to IV (continued)

Step 3

C intones a question → C signals A.

A gives an appropriate answer, intoned or spoken.

(B) to Step 2 if A fails → retrieval of Step 3.

Score and progression:

Acceptable after (B)—2 points.

Acceptable after (B)—1 point.

Proceed to Step 1 for next sentence.

LEVEL IV

Step 1

C (HT) intones sentence → C signals A to wait.

C (HT) presents sentence twice in sprechgesang.

C signals A.

C and A (HT) (U) sprechgesang of sentence.

(B) to C (HT) presentation in sprechgesang if aphasic fails.

Retrial of C and A (HT) (U) sprechgesang.

Score and progression:

Acceptable sprechgesang—2 points. Proceed to Step 2, same sentence.

Acceptable after (B)—1 point. Proceed to Step 2, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 2

C (HT) presents same sentence in sprechgesang → C signals A to wait.

C signals A after 2 or 3 seconds.

A (HT) repeats sentence in sprechgesang.

(B) to Step 1 if A fails → retrieval of Step 2.

Score and progression:

Acceptable without (B)—2 points. Proceed to Step 3, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 3

No hand tapping.

C presents same sentence twice in normal speech prosody.

C signals A to wait 2 or 3 seconds → then signals to repeat.

A repeats sentence in normal speech prosody.

(B) to C presentation in normal speech prosody if A fails.

Retrial of A repetition.

Score and progression:

Acceptable without (B)—2 points. Proceed to Step 4, same sentence.

Acceptable after (B)—1 point. Proceed to Step 4, same sentence.

Unacceptable—Discontinue progression for sentence.

Step 4

C Question about substantive content, same sentence.

A Any appropriate response.

(B) to Step 3 if response is unacceptable → retrieval of Step 4.

C Questions about associative information.

A Any appropriate responses.

Score and progression:

2 points without (B), substantive content, 1 point after (B).

3 bonus points, one or more responses to associative questions.

Proceed to next sentence.

Key: A = patient with aphasia; C = clinician; (HT) = hand tapping by clinician with patient; (B) = backup; (U) = unison.

possible to transfer to other language intervention strategies easily after completion of the hierarchy, as discussed earlier.

Progression from One Level to the Next One

Progression from Level II to Level III, from Level III to Level IV, or from Level IV to post-MIT therapy should occur after sufficient evidence shows that the patient has developed a stable proficiency. Our hypothesis that increased participation of the right hemisphere occurs in MIT implies that a somewhat prolonged process is involved. Whether the clinician who uses MIT agrees with our hypothesis is less essential than whether he or she progresses slowly, to ensure that improvement from this method is maintained. Actually, the rate of progress made by the good candidate will be slow.

Suggested Means of Controlling Rate of Progression

We recommend that moving from one level to the next higher one should occur only after a mean score of 90% or better for 10 consecutive therapy sessions has been achieved. When we consider the usual fluctuation of performance in those with aphasia from day to day, this often may involve some approach-retreat before the 90% mean is achieved.

Participation of the Family During and After Clinical MIT

Much emphasis is placed on members of the person with aphasia's family participating in the process of attempted rehabilitation of his or her language. Participation of the family during the early period, however, when the focus is entirely on intonation and accuracy of intonation patterns, is viewed with reservations unless supervision is provided by the clinician. The family should be encouraged to assist in selection of useful phrases used frequently by themselves and the patient premorbidly. It is important that these lists be extensive to provide great variety of word orders. Experience with this selective process makes it possible for the patient and his or her family to offer information and vocabulary based on observations and experience in their daily activities.

The role of the family to encourage *sprechgesang* as a means of word-retrieval efficiency for the patient in the home and among selected friends is strongly recommended for words and phrases that have a high frequency of use in the household.

SUMMARY

In summary, six major elements of MIT are covered in this chapter:

1. A discussion of certain principles of language therapy for aphasia and associated phonologic disorders that have influenced the design of the MIT strategy.
2. A discussion of the candidacy that contrasts the language profiles of good and poor candidates for this type of language intervention.
3. A description of the technique of intoning and plotting intonation patterns.
4. A detailed instruction of administration of the MIT hierarchy.
5. A discussion of post-MIT strategies.
6. A discussion of participation by family members during clinical intervention and after its completion.

FUTURE TRENDS

The family of the person with aphasia who is receiving, or has received, MIT should be systematically involved as a support team. Future development of MIT should include the development of published guidelines that the family may use. Their support is particularly essential when the patient is receiving less than one therapy session each day with the clinician.

Further collection of data regarding candidacy is essential as a means of providing further evidence of the efficacy of MIT. The contributions of careful language examination and scientific studies are of equal importance.

Chapter 32

Computer Applications in Aphasia Treatment

Richard C. Katz

OBJECTIVES

The objects of this chapter are:

1. To familiarize reader with the various applications of computers and related technology in the rehabilitation of adults with aphasia.
 2. To discuss the strengths and limitations of computerized aphasia treatment.
 3. To describe classic and recent research literature demonstrating the efficacy of computerized aphasia treatment.
 4. To evaluate the effectiveness and appropriateness of treatment software for patients with aphasia.
 5. To incorporate computers and related technology when appropriate into the diagnostic and treatment process for people with aphasia.
-

DEFINITIONS

“Computerized aphasia treatment” refers to the systematic use of computers and software to improve communication skills in people with aphasia. The roles that computers play in aphasia treatment can be described as three discontinuous categories.

The first, computer-only treatment (COT) software, is designed to allow a patient, as part of a clinician-provided treatment program, to practice alone at the computer, without the simultaneous (“online”) supervision or direct assistance of the clinician or others (e.g., spouse or speech-pathology assistant). The clinician later reviews patient performance (“off-line”) by examining task performance scores saved on disk by the program for later review, by directly observing performance using the software during a subsequent treatment session, or by measuring generalization to related, non-computer activities or tests. Operation of the program should be familiar and intuitive for patients,

particularly those who cannot read extensive instructions or other text. In addition, clinicians and programmers cannot anticipate every possible cue or strategy that may be helpful to every patient, resulting in simplistic or nonexistent intervention components. Consequently, COT software usually consists of convergent tasks with simple, obvious goals (e.g., drills) and supplementary tasks designed to reinforce or help generalize recently learned skills.

The second, computer-assisted treatment (CAT) software, is presented on a computer by a clinician working at the same time (“side-by-side”) with the patient. The role of the computer is limited to elements of basic task structure, such as presenting stimuli, storing responses, and summarizing performance, whereas the clinician provides special instruction, intervention, additional cueing, and other information to modify the activity to accommodate the patient’s needs in the same way as during tradition, clinician-provided treatment. This symbiotic relation between clinician and computer permits considerable flexibility, thus compensating for the limitations inherent in the COT approach. In addition to treatment programs written specifically for use with clinicians, other software, such as COT, word processing, or video game programs, can be used in this manner as long as the clinician provides the patient with the additional information needed to perform the task. Fink, Brecher, Schwartz, and Robey (2002) compared the benefits of the same computerized treatment for naming disorders under two conditions, partial independence (similar to COT) and full clinician guidance (similar to CAT), and found that training-specific learning for adults with chronic aphasia was demonstrated under both conditions.

The third, alternative and augmentative communication (AAC), usually, in aphasia treatment, refers to small computers functioning as sophisticated “electronic pointing boards.” Unlike the devices used by patients with severe dysarthria or other speech problems, patients with aphasia cannot simply type the words they want to say. The AAC devices designed for speakers with aphasia may incorporate digitized speech, text, pictures, and animation. Some allow both communication partners to use the device to exchange messages during conversations.

The organization and semantic content of the AAC devices frequently can be modified for each patient's particular needs and abilities. In addition to providing an alternative mode of communication, some researchers attribute improved performance on standardized tests and in "natural language" (e.g., speaking and listening) to treatment involving AAC devices (Aftonomos, Steele, & Wertz, 1997).

A BRIEF HISTORY OF COMPUTERS

A mechanical computer was first built by an English mathematician almost 200 years ago (Babbage, 1822), but the technology for building electronic devices recognizable to us as computers did not exist until the 20th century. Another English mathematician, Alan Turing (1936), described a device similar to a typewriter that used a "contingency table" (criteria and algorithms) to perform complex calculations that, until then, had been completed only by specially trained personnel. The concept of a machine capable of complex decision making without human intervention was revolutionary (Turing, 1950). In the 1950s, computers were large, electronic calculating machines that filled rooms with switches, vacuum tubes, and mechanical relays and that read rolls of punch tape and, later, reels of electronic tape. Only banks, large corporations, and civilian and military governmental agencies could afford to purchase and operate these machines. Over the years, however, computers grew smaller, more reliable, and less expensive. "Microcomputers" were first sold in the mid to late 1970s to hobbyists and other technology enthusiasts who programmed the machines to perform specialized tasks, such as controlling all the lights in a house or measuring rainfall. As computers began to show up in offices and homes, software developers saw a market for functional and entertaining programs for the general public: games, word processing, spreadsheet, data base, graphics, communications (modem), financial planning, will writing, and so on. Today's multimedia desktop, laptop, and palm-size personal computers that access information from the World Wide Web are only the latest stage in this evolution. Looking back on the recent rapid growth—or, some might say, intrusion—of technology, it is understandable why many expect an imminent breakthrough that will abruptly change our lives for the better, a promise that the computer industry's sales force has made since the mid-1950s. People with aphasia and their families may be particularly vulnerable to the unsubstantiated promises made by an avid computer industry intent on increasing sales. While the world rushes forward to embrace technology, those of us engaged in rehabilitation should step cautiously and apply accepted standards to determine the value of computer applications for each patient with aphasia.

LIMITATIONS OF COMPUTERIZED TREATMENT SOFTWARE

A speech-language pathologist, educated in communication theory and sufficiently experienced in both the clinic and real-life, can generate an infinite number of novel and relevant treatment stimuli and recognize, evaluate, and modify treatment activities in response to previously unacknowledged associations and unanticipated responses. In contrast, computer-provided treatment is based on a finite set of rules that are stated explicitly to specify actions likely to occur at particular points during a future treatment session. Limitations in modalities (e.g., computers cannot understand speech or writing very well) ensure that computerized treatment will be a subset of clinician-provided treatment and supplemental to treatment provided by properly trained clinicians.

Computers cannot be all things to everyone. Bolter (1984) described four general properties of computers and computer programming that can be used to illustrate the limitations inherent in the application of computers to aphasia treatment: (1) discrete, (2) conventional, (3) finite, and (4) isolated.

Discrete

Because computers acknowledge and manipulate discrete (i.e., digital) units, qualitative description and decisions are difficult to make. Events must first be separated into distinct, unconnected elements before they can be acted on by a computer. Face-to-face communication is a complex act described as our "oldest and highest bandwidth technology" (Rheingold, 1991, p. 216). Many elements of language and communication are not well delineated or even universally recognized. In summarizing research concerning perception of the meaning of words versus the message's affect (i.e., the emotional content) for listeners during face-to-face communication, Mehrabian (1968) estimated that 55% of a message's affect is communicated via facial cues, 38% vocally, but only 7% by the actual words. Although individual language tasks can be programmed, applying computer technology appropriately to aphasia rehabilitation requires an appreciation of the intricacies and interdependence of elements within verbal (i.e., language) and nonverbal (e.g., kinesics and proxemics) channels of communication (Egolf & Chester, 1973; Katz, LaPointe & Markel, 1978, 2005; Katz, LaPointe, Markel, & Silkes, 2005).

Conventional

Computers apply predetermined rules to symbols that have no effect on the rules. Regardless of the value of the symbols or the outcome of the program, the rules never

change. Although a consensus exists for some fundamental guidelines of aphasia treatment, all the rules are not known, however, and those that are accepted may not be right under all conditions (Rosenbek, 1979). Computer-only treatment does not follow the clinical cycle of (a) administer treatment, (b) measure performance, (c) modify treatment, and (d) re-administer treatment and, therefore, is not adequately responsive to the dynamics of patient performance.

Finite

The rules and symbols that control computer-provided treatment are limited to those that are defined within the program. Except for the most sophisticated (i.e., “artificial intelligence”) programs (see, e.g., Guyard, Masson, & Quiniou, 1990), unforeseen problems and associations do not result in the creation of new rules and symbols. Therapy presents the opposite case. Not all therapeutically relevant behaviors are identified, and those that have often vary in importance between patients and situations. Computer-provided learning commonly defers decisions to software designers and programmers who are not physically present during the session but who must plan in advance how to handle the intervention and code these steps into a computer program (c.f., Odor, 1988).

Isolated

Problems and their solutions presented by computers exist within the computer’s own parameters, apart from the real world. Problems are stated in a way such that symbols can be manipulated to solve the problem by following an algorithm—that is, a finite series of steps described with adequate detail to guide the program to respond to input, answer questions, or solve problems. This lack of “world knowledge” is, perhaps, the most significant impedance to comprehensive computer-provided treatment. Language tasks as presented by computers essentially differ from the meaningful, pragmatic setting in which communication occurs among people. Computers, therefore, only consider problems in which all the variables and rules are known ahead of time and can be solved in a step-by-step procedure with a finite number of steps, much like a game of chess. Learning to solve linguistic riddles on a computer program may lead to better scores on conventional aphasia tests; however, improving communication is quite another matter.

Treatment is recognized as a multi-level, interactive behavioral exchange. Not all therapeutically relevant behaviors have been identified; many that have (e.g., functionality) are influenced by internal (e.g., idiopathic) and external (e.g., environmental) factors and cannot be controlled effectively by a computer. In addition, whereas many basic parameters of therapy and fundamental skills of clinicians have

been identified (Goldberg, 1997), all the rules are not known, and those on which we agree may not be correct (Rosenbek, 1979). For example, use of linguistic models to construct software to diagnose and treat aphasia is appealing (see, e.g., Guyard et al., 1990) and, ultimately, can teach us much about language (see, e.g., Fenstad, 1988) and aphasia (see, e.g., Wallich, 1991). Some researchers (see, e.g., Katz, 1986, 1990; Kotten, 1989), however, believe that the pathologic language behavior of people with aphasia also is influenced by a variety of other factors, including cognition (e.g., attention, vigilance, memory, and resource allocation), cybernetics (e.g., slow rise time, noise buildup, and intermittent imperception), behavioral factors (e.g., discriminatory stimuli, chaining, and extinction), pragmatics (e.g., functionality and social status), and emotion (e.g., interest, relevance, novelty, and enjoyment). No single therapeutic approach currently encompasses all known intervening variables.

If a program were written that could completely represent clinician-provided treatment, the software would be massive and exceed the capacity of modern personal computers. By reducing the scope of the problem to a size that is manageable for the computer, treatment software has been squeezed and shaped to imitate cognitive and language therapy in small, trivial, and predominantly symbolic activities. Rather than emphasize state-of-the-art aphasia treatment, the resultant computerized activity highlights the technical limitations of the computer medium. Odor (1988) referred to this problem when he wrote that computer intervention defers decisions to programmers who are not physically present during the session, but must gather and send information only through the computer medium, plan in advance how to handle the learning interaction, and then encode these steps into a computer program. Consequently, the scope of treatment software is limited, because computer programs are not powerful enough to represent every potentially relevant nuance of interaction during therapy. Odor concluded that computer-assisted instruction often is based on convergent rather than divergent theories of learning. Most computer treatment studies reported in the aphasia research literature describe convergent activities, particularly drills, in which specific responses are learned. Dean (1987) stated that the inability to incorporate divergent strategies in computer programs severely limits their value and application to treatment of patients with aphasia, particularly those with chronic aphasia, for whom such treatment appears promising (Chapey, Rigrodsky, & Morrison, 1976). Divergent treatment software is becoming commercially available, such as Language Activities of Daily Living (Learning Systems), but as of this writing, no data exist to support efficacy. The adaptation of divergent therapy to computer-provided treatment continues to remain a challenge for contemporary software developers.

TREATMENT

The earliest applications of computers to aphasia rehabilitation owe much to behavior modification and the development of instrumental learning devices or “teaching machines” (Skinner, 1958). Some of these devices were prototypes and experimental (see, e.g., Keith & Darley, 1967), whereas others were commercially available and widely used, such as the Language Master (Keenan, 1967) and the Programmed Assistance to Learning filmstrip projector (Pfau, 1974). Following the introduction of small mainframe computers (“minicomputers”), reports began to appear in professional journals describing attempts by researchers and clinicians to use computers to meet the needs of patients with aphasia. For example, Vaughn (1980) incorporated small, microprocessor-driven auditory, visual, and writing devices and minicomputers (e.g., the PDP-11) to provide treatment to outpatients over the telephone (telecommunication). By the time that personal computers (then called “microcomputers”) were introduced in the mid to late 1970s, sufficient interest had grown among clinicians and researcher to develop treatment protocols for specific patients and types of problems (see, e.g., Schwartz, 1984).

Speed, accuracy, reliability, and ease of use are valued characteristics wherever personal computers are used, but the power of computers in rehabilitation is not simply the result of faster microprocessors or larger storage devices. Schuell, Jenkins, and Jiménez-Pabón (1964) stated that principles of aphasia treatment should be used throughout our increasing repertoire of clinical techniques. The role of computers will evolve as the technology improves. In many areas, computers have the potential to become significant tools for treating aphasia.

Supplementary Treatment

Supplementary treatment in the form of workbooks and other structured activities has always been a useful option for clinicians (Brubaker, 1996; Dressler, 1991; Eisenson, 1973). Patients can work longer and more often on a variety of activities designed to stabilize, maintain, or generalize newly acquired skills. Contemporary commercial treatment and educational software extend controlled, treatment-related language and cognitive activities beyond the confines of the treatment session if they are presented in a structured setting that incorporates important therapeutic principles and factors, such as control of stimulus characteristics and response requirements and recording of session performance for later review. Programs can vary along a continuum according to structure and content, ranging from simple, repetitive drills to interactive tasks that not only evaluate individual responses but also measure overall performance and adjust the type and degree of intervention provided (see, e.g., Katz & Wertz, 1997).

Treatment Efficacy and Prognosis

Measuring the effects of intervention on aphasia is an essential part of any treatment regimen. Speech-language pathologists assess the influences of various linguistic, psychological, and physical variables on communication and task performance to evaluate the effectiveness of a treatment approach or activity (Darley, 1972). Computers present treatment activities in a standard manner and routinely store performance data for later descriptive and statistical analysis. Additionally, computers can help clinicians to develop local and national prognostic data bases to predict with confidence that, for example, a 55-year-old adult with Broca’s aphasia who 1-year post-onset is at the 50th percentile on the Porch Index of Communicative Ability (Porch, 1981), or PICA, will require between 125 and 150 trials to learn to write or print 10 functionally relevant words at the third-grade level (LaPointe, 1977). This benchmark of prognostic resolution would serve as an invaluable clinical yardstick against which the success of treatment could be measured (see, e.g., Matthews & LaPointe, 1981, 1983).

The widely used health care assessment tool, the SF-36 Health Survey, is available for downloading from the Internet (<http://www.sf-36.com>). Like the print version of the SF-36, this version can be used for assessing effects from clinical trials, monitoring outcomes in clinical practice, and screening medical patients for mental health referral. It provides measures of physical functioning, bodily pain, general health, vitality, social functioning, emotional role functioning, mental health, and reported health transition. Translations of the SF-36 are being tested in more than 40 countries as part of the International Quality of Life Assessment Project. The face validity of this tool is impressive for clinicians and researchers interested in investigating quality of health care across health disciplines, especially as it relates to the construct of quality of life. The SF-36 software that provides administration, scoring, and data export for research support is available for Windows.

Generalization

“Prepare for rather than pray for generalization” (Rosenbek, LaPointe & Wertz, 1989, p. 138). Ultimately, the value of aphasia treatment is measured by the degree to which skills acquired in treatment are observed in real-life situations. It is imperative that the clinician actively train generalization. Computer-provided treatment is an environment very different from real-life communication. Generalization can be aided by the computer, which can administer some aspects of treatment without the familiar presence and constant conscious (and unconscious) control of the clinician. On fulfilling criteria for a computer task, a similar task should be presented without the computer—for example, writing instead of typing, or performing the actual functional activity rather than a computer simulation. Rosenbek and colleagues (1989)

recommended a series of clinical activities to increase the likelihood of generalization. Several of the recommendations appear well suited for the computer:

1. Expose each patient to numerous repetitions.
2. Train a large number of items in a given category.
3. Extend treatment outside of the clinic.
4. Organize treatment to maximize independence so that patients learn to use treated responses when they want to rather than when told to by the clinician.

Programs like MultiCue (Van de Sandt-Koenderman, 1994) and Visual Confrontation Naming (Parrot Software) help to teach the patient a strategy to stimulate or compensate for word-finding problems by selecting among possible cues. MultiCue offers several different strategies simultaneously, whereas Visual Confrontation Naming provides cues that are audible (i.e., first sound) and visual (e.g., first letter, description, and multiple-choice list containing the word). The CD-ROM version has more than 500 target words with pictures that aid in generalization of self-cueing strategies. Ideally, patients should develop and practice their own self-cueing strategies that have been shown to be effective in treatment.

Independence and Emotional Factors

To foster independence, minimize dependency and depression, and help patients to develop insight regarding their communication problems, patients should be able to use treatment software with minimal assistance from others. The required computer skills include turning on the computer system; selecting the treatment program from a removable disk, hard drive, or the Internet; and following the protocol for each particular program. Patients themselves can then determine when and how often they participate in supplementary language activities. This is consistent with Wertz's (1981) statement that we should allow patients to maintain as much independence as possible and that a long-term goal of aphasia treatment is to have patients become their own best therapists. The insight that patients have regarding *their* problems and *their* strengths can be used instead of ignored, and in this way, patients can take a more active role in their recovery.

Factors such as motivation, dependency, and quality of life are concerns that may become increasingly important to people with aphasia and their families as recovery slows and the degree of disability and its subsequent effect on life become more apparent. Under conditions of perceived helplessness and hopelessness, people frequently become depressed (Seligman, 1975) and have greater difficulty coping with and adapting to changes and problems (Coelho, Hamburg & Adams, 1974). Bengston (1973), Langer and Rodin (1976), Schulz (1976), and others have shown that giving some options and responsibilities to persons in otherwise

dependent situations (e.g., the institutionalized elderly) can have a strong, positive effect on their satisfaction and physical well-being. Decision making and expression of personal preferences by each patient should be a basic part of any treatment program. Computerized activities can address this aspect of treatment by providing patients with aphasia a degree of control over the content and frequency of treatment.

Administrative Functions

Currently, computers are assisting clinicians in the performance of administrative and clinical duties, and in all likelihood, they will soon to do even more (Hallowell & Katz, 1999). Morrison (1998a) describes an active role for computers and related technology in the evaluation of many factors essential to the delivery of services and quality of care. Large-scale systems are expensive to set up and maintain, so it is essential to plan carefully and consult with information technology specialists who are experienced in health care before attempting to integrate technology and clinical and support staff (Morrison, 1998b). On a smaller scale, many clinicians use computers to gather, organize, and report case history information (Silverman, 1997). As is the case for many other professions, general purpose programs have useful applications for clinicians working with patients—for example, report and letter writing (word processing programs); organizing, recording, and recalling information (database programs); and organizing, calculating, and projecting values (spreadsheet programs). Innovations include the use of voice recognition in report writing to increase the speed of generating reports (Tonkovich, Horowitz, Kawahigashi, Krainen, & Kronick, 1991) and the use of authoring systems to customize data base entry and retrieval. One of the most comprehensive systems is Computerized Patient Records System (Kolodner, 1997), which enables clinicians using PCs in every medical center in the Department of Veterans Affairs (the "VA") to access patient records not only within their own medical centers but also from others. This ability saves time and greatly simplifies the process of retrieving and updating patient records, especially for patients who are treated at different facilities across the country. The VA officials have developed a system that many believe could be the low-cost foundation of a nationwide electronic health record system.

Commercially available software provide another path to incorporating technology into administrative activities. Chart Links (Chart Links) is a commercially available system that is based on electronic patient medical records. It creates a record for each patient and tracks reports of each patient encounter, lab report, team report, medical diagnosis, recommended treatment, and treatment schedule. Workflow applications allow charting, sorting, organizing, filing, report writing, and automated review of patient information. Chart Links is based on Lotus Notes, which allows

advantageous communication and security features. Therapist Helper (Therapist Helper) is another clinical practice management software developed to facilitate patient and insurance billing transactions and accounting as well as report writing.

Recreational Activities

Commercial recreational programs (e.g., arcade and adventure games) have long found a limited but useful role in treatment (Lynch, 1983). Enderby (1987) discussed the possibility of computers in this role providing a path toward social and intellectual stimulation for patients with aphasia. Many educational and treatment programs use familiar game formats to minimize learning time and heighten enjoyment (e.g., Laureate Learning Systems). Recreation therapy, a valuable service for many patients, is outside of our scope of practice, but speech-language clinicians can incorporate computer game activities, educational software programs, and even the Internet to help promote intellectual stimulation and social interaction in a novel and entertaining manner for patients with aphasia.

MODALITY CONSIDERATIONS

Conversation (i.e., talking and listening), whether face-to-face or via cell phones, is our primary mode of communication. Management of auditory and verbal skills therefore is central to the concept of aphasia rehabilitation (see, e.g., Schuell et al., 1964). Listening and talking are the communicative behaviors used to classify most types of aphasia (Goodglass & Kaplan, 1983; Kertesz, 1982) and are the focus of most therapy for aphasia. Listening and talking, more than other language modalities, affect the likelihood of a person with aphasia's successful reintegration into the community—the final demonstration of the success of therapy. For most patients, and for their families, friends, and physicians, the *perception* of recovery and treatment success is driven by improvement in listening and talking.

Contemporary treatment software offers little assistance to clinicians treating the speaking and listening problems that occur during conversation for patients with aphasia. Speech recognition is limited and unreliable for multiple speakers (as would be the situation found in the treatment rooms of any clinic) and for speakers who produce variable errors, such as apraxia of speech and phonemic paraphasia. High-quality digital speech is common on today's multimedia computer systems, but programs that merely repeat object names or offer nonlinguistic visual cues are of limited value to patients with auditory comprehension deficits. Listening drills are promising, but the potential to developing automated, complex listening task that address specific patterns of auditory problems has not yet been realized.

The major contribution of computers to aphasia treatment currently appears to be in the areas of reading and writing. Computers are basically visuomotor, graphic-oriented machines. Information from the user normally is entered by typing on a keyboard; the output of the computer is displayed on the monitor screen and read by the user. This makes the computer well suited for presenting reading tasks and, through typing, writing tasks. Reading and writing skills appear to be an appropriate focus of computerized aphasia treatment for several reasons. Most patients with aphasia have problems reading (Rosenbek et al., 1989) and writing (Geschwind, 1973). Reading requires minimal response from the patient. Programs for treating reading can run on standard personal computers, without expensive modification or specialized peripheral devices. Typing on the keyboard can be used to address many aspects central to writing (Selinger, Prescott, & Katz, 1987), with the obvious exception of the mechanics of handwriting. Also, reading and writing as communicative acts usually are done alone; having greater interpersonal distance, they are in many ways less direct and responsive than speaking and listening. As such, reading and writing are appropriate communication (as opposed to therapeutic) activities for people with aphasia to practice on computers. Computerized reading and writing treatment tasks can free up valuable treatment time so that face-to-face, individual therapy can emphasize complex elements of auditory comprehension and verbal output skills that computers do not address. The computer can provide valuable reading and writing activities (see, e.g., Scott and Byng, 1989), but clinicians also should provide additional non-computerized reading and writing treatment that is individualized to each patient's particular need beyond the capacity of computer software.

STRUCTURE OF TREATMENT ACTIVITIES

Many elements are common to the structure of all treatment activities regardless of the underlying principles or mode of delivery, and although some are obvious, none are trivial. An understanding of these task components is useful for describing, developing, and evaluating treatment activities for the computer.

All tasks have a goal, which usually is an intermediate step toward a major or long-term treatment goal. To understand the goal of the task, the patient should recognize both the objective of the task (what is being required) and the underlying purpose of the task (why the task is being required). Equally important, the patient should be aware from the beginning of the steps within the task that advance toward the goal. The clinician should provide the patient with instructions so that the patient knows from the beginning what is expected. The stimuli used and the desired responses should be consistent with the purpose of the task. In many

instances, responses should be described and quantified using a multi-dimensional scoring system (LaPointe, 1977; Porch, 1981) to identify and measure the occurrence of salient behaviors within the task (accuracy being only one). Care should be taken that the patient is not burdened with additional, unnecessary response requirements that could confound performance, such as requiring a typing response (i.e., word retrieval, spelling ability, and motor skills) instead of a simple two key (yes/no) response on a comprehension task. Responses should be as simple as possible to reflect accurately the performance of the target behavior. General feedback (Stoicheff, 1960) to encourage the patient and specific feedback to describe the most recent response should be readily provided. The clinician should provide an intervention (strategy or cue) to improve performance as needed. Teaching specific responses may be the goal of some tasks (e.g., associate printed names of family members to their pictures); a more valuable goal commonly is to develop a task to help the patient learn a strategy (i.e., self-cue or compensatory) to improve communication during actual, functional situations (e.g., point to name on card when referring to particular family member). Criteria for termination of the task should be specified to provide a target against which the patient can measure progress. Responses and performance scores should be stored for later review and analysis. The patient's performance and the intervention can be evaluated using various techniques (LaPointe, 1977; Matthews & LaPointe, 1981, 1983, McReynolds & Kearns, 1983, Prescott & McNeil, 1973). Finally, the intervention may be modified or the activity discontinued, as indicated.

MODELS FOR COMPUTER REHABILITATION

In contrast to the considerable attention afforded the arrival of new treatment programs, software developers rarely provide thorough descriptions of the treatment models influencing software evolution. As described by Wolfe (1987), early reports of computerized aphasia treatment (see, e.g., Katz & Nagy, 1982, 1983, 1984, 1985; Mills, 1982) provided no explicit models of rehabilitation from which the software could be evaluated. Recent studies have reversed the trend (see, e.g., Katz & Wertz, 1997; Loverso, Prescott, Selinger, Wheeler, & Smith, 1985; Scott & Byng, 1989). Bracy (1986) was among the first to explicitly incorporate the work of Luria (1973, 1980) in the development of rehabilitation software. Having an explicit model facilitates the systematic development of software and provides a basis for clinicians selecting software for their patients. Three general models of rehabilitation provide clinicians with the structure to develop and evaluate software. Although they are not mutually exclusive, the models offer a basis from which the role of computers in aphasia rehabilitation can be directed and examined.

Brain-Behavior Relationships

Bracy (1986) described four theories accounting for the recovery of cognitive functions, but the theory that function recovers through the retraining process is the most closely allied to the modern concept of rehabilitation. Luria (1963, 1973) believed the return of skills involved a reorganization of brain functions so that new methods existed of performing behaviors previously executed through the damaged structures ("intersystemic reorganization"). One function of computerized treatment therefore is to provide the patient with the direction and opportunity to retrain skills through the reorganization.

Behavior Modification

Behavior modification (operant conditioning and instrumental learning) describes the process of either teaching a new behavior or eliminating an established one through the systematic application of consequences (Goldberg, 1997). The principles of behavior modification are thoroughly woven into the fabric of human behavior—simply put, people tend to do things that result in rewards and avoid behaviors that result in punishment (Skinner, 1948). [According to Skinner (1957), these principles even guide the way in which we communicate and use language.] The frequency of occurrence, duration (e.g., exposure time), and other parameters (e.g., size, color, and loudness) of elements central to behavior modification (e.g., stimulus characteristics and reinforcement schedules) can be monitored and controlled with a computer. Many computer programs control some aspect of stimulus characteristics and provide reinforcement to patients in the form of corrective and general feedback.

Educational Models

Lepper (1985) contrasted three approaches to learning with direct application to treatment software: (1) individualized drill and practice, (2) educational games, and (3) simulations. Drill and practice capitalize on the computer's advantages in providing immediate feedback, sustained attention, data analysis, and highly individualized instruction. Educational games stimulate a person's interest through game-like activities. Educational simulations, also called microworlds, involve the patient in a series of problems in an imaginary environment. The contingencies between actions and outcome should lead the patient to an understanding of basic principles relevant to real-world environments. These programs assume that active, inductive, "discovery-based" learning is better for learning general skills compared with direct, didactic approaches, which seem to be more effective when learning highly specified information. The three programs that make up the Language Activities of Daily Living (Laureate

Learning Systems) are examples of computer software that represent microworlds in which the patient is free to explore the total simulated environment rather than respond to specific stimuli.

TYPES OF COMPUTERIZED TREATMENT TASKS

Four major types of treatment activities are appropriate for presentation on the computer: (1) stimulation, (2) drill and practice, (3) simulations, and (4) tutorials. This list is not exhaustive, and types are not mutually exclusive. One treatment activity may have several purposes and demonstrate characteristics of more than one type—for example, stimulation and drill and practice (see, e.g., Seron, Deloche, Moulard, & Rouselle, 1980).

Stimulation

As described by Schuell and colleagues (1964), stimulation activities offer the patient numerous opportunities to respond quickly and, usually, correctly over a relatively long period of time for the purpose of maintaining and stabilizing the underlying processes or skills rather than simply learning a new set of responses. The process therefore is the focus of the task. Stimuli are not selected primarily for informational content (e.g., interest and relevance) but, rather, for salient stimulus characteristics (e.g., length, number of critical elements, complexity, and presentation rate). Computer programs can easily be designed that contain a large database of stimuli and control these variables as a function of the patient's response accuracy. Overall accuracy and other salient response characteristics (e.g., latency) usually are displayed at the end of the task. An early example of a computer stimulation task is the auditory comprehension task described by Mills (1982).

Drill and Practice

The goal of drill and practice exercises is to teach specific information so that the patient is able to—or appears able to—function more independently. Stimuli are selected for a particular patient and goal, so an authoring or editing mode is needed to modify stimuli and target responses. A limited number of stimuli are presented and are replaced when criterion is reached. Because response accuracy is the focus of the task, the program should present an intervention or cues to help shape the patient's response toward the target response. Drill and practice exercises therefore are convergent tasks, because the accurate response must match the target response exactly. Results are displayed or stored on disk and show the effectiveness of the intervention. Examples of drill and practice programs are described by Katz and Nagy

(1984); Katz, Wertz, Davidoff, Schubitowski, and Devitt (1989); Katz and Wertz (1997); and Seron and colleagues (1980).

Simulations

Simulations (i.e., microworlds) are programs that present the patient with a structured environment in which a problem or problems are presented and possible solutions are offered. Simulations may be simple, such as presenting a series of paragraphs describing stages of a problem and listing possible solutions. Complex programs more closely simulate a real-life situation by using pictures and sound. The term “virtual reality” (Rheingold, 1991) describes a totally simulated environment created through the interaction of a computer and a human along both verbal and nonverbal channels. Simulations have been used in fields such as chemistry, geology, meteorology, and astrophysics to test conditions that are impossible to experience or to train people in situations that otherwise would be too dangerous to experience firsthand. Simulations provide the opportunity to design divergent treatment tasks that could address real-life problem-solving strategies more fully than those addressed by more traditional, convergent computer tasks—for example, by including several alternative but equally correct solutions to a problem, such as during Promoting Aphasics Communicative Effectiveness, or PACE, therapy (Davis & Wilcox, 1985). The question of whether computer simulations can improve generalization of newly acquired behavior to real-life settings as well as or better than traditional methods remains to be tested.

Tutorials

Some authors (see, e.g., Eisenson, 1973) have suggested that patients with aphasia are best served by modification of their communication environment. In that respect, tutorials offer valuable information regarding communication and quality of life to the family, friends, and others who influence the patient's world. At the most fundamental level, the computer tutorial could present information commonly found in patient information pamphlets in an interactive format, with additional modules provided when needed or requested. This type of self-paced, informational program can be appropriately realized in a hypertext format, such as found on the World Wide Web, where a family member can navigate through text, pictures, animation, and sound describing relevant aspects of aphasia and communication. The tutorial program could incorporate features of an expert system, in which detailed information is provided in response to a patient/family profile, and function as a source of information for family members in the future when new problems and questions arise.

CANDIDACY FOR THERAPY

Most patients with aphasia can benefit from the thoughtful application of appropriate treatment software used in a supplementary role. Prognostic indicators common to patients with aphasia in general will apply, such as etiology and site of lesion, age, time post-onset, educational level, and so on (Eisenson, 1973). Cognitive factors, like those described for patients suffering right hemisphere damage (Myers, 1999) or bilateral brain damage (Goldstein, 1942, 1948), also should be considered. Many factors influence which patients benefit most from computerized aphasia treatment, but the most critical factors are severity, modality, sensory and physical impairments, independence, and self-monitoring. Severely impaired patients may be limited to simple treatment drills, providing little real value or generalization, whereas the meta-communication needs of mildly impaired patients may not be served by complex, problem-oriented software. These patients may benefit from more direct, clinician-provided treatment. Patients with problems involving reading, writing, and to some extent, listening can practice and maintain skills and compensatory strategies learned from the clinician by using various computer programs. Hemianopsia, visual neglect, or simply changes in visual acuity can interfere with the patient's ability to view material on the computer display, whereas right hemiparesis can prevent a patient from easily using the computer mouse, typing on the keyboard, or even sitting comfortably in front of a computer for an extended period of time (Petheram, 1988). Many patients look forward to working with their clinicians, who they see as supportive and sympathetic—feelings that patients do not get from working with a computer. Others may not have sufficient initiative or discipline to maintain a treatment program without the continual watchful eye of the clinician. Perhaps most critically, patients who are unable to monitor their own performance (e.g., detect errors after feedback or modify subsequent responses) will gain little or no value from working independently on a computer.

EFFICACY OF APHASIA TREATMENT SOFTWARE

Treatment efficacy considers whether outcomes are improved as a result of a specific intervention (McGlynn, 1996). According to Rosenbek (1995), efficacy is improvement resulting from treatment applied in a rigidly controlled design when treatment and no-treatment conditions are compared. Wolfe (1987) found that early reports of computerized aphasia treatment did not provide explicit models of rehabilitation from which the software could be evaluated. In an extensive review of the literature, Robinson (1990) reported that the efficacy of computerized treatment for aphasia as well as other cognitive disorders had not been demonstrated. The research studies reviewed suffered from

inappropriate experimental designs, insufficient statistical analyses, and other deficiencies. Since Robinson's critique, a number of publications have described the effect of particular computerized interventions (see, e.g., Crerar, Ellis, & Dean, 1996; Katz & Wertz, 1992, 1997; Loverso, Prescott, & Selinger, 1992), whereas others have surveyed trends reported in the research literature (Cicerone et al., 2000; Wertz & Katz, 2004).

According to Loverso (1987), most computer advocates focus on "appealing" features of computers, such as cost-effectiveness and operational efficiency, but the real issue that demands attention from clinicians is treatment effectiveness. In other words, treatment activities must be effective before they can be efficient. Ineffective treatment programs would be damaging to the overall quality of treatment provided to patients with aphasia. If computerized treatment is to continue to develop and improve, it should undergo the same scientific scrutiny and systematic modification as all other aspects of treatment do.

Software, however, cannot reproduce every process, variable, and nuance that occur during treatment, so computerized treatment in this sense will never be as efficacious as clinician-provided treatment. One way clinicians can increase the likelihood that software is efficacious is to develop and test their own treatment programs. Mills (1988) accurately suggested that clinicians with only limited programming skills tend to produce programs with only limited therapeutic value. It is equally important that programmers have more than a superficial understanding of treatment principles if treatment software is not to be limited in its effectiveness.

A range of support for the clinical application of computers exists in aphasiology. Dean (1987) wrote that existing computer treatment programs "are not firmly grounded in a theoretical rationale for remediation" (p. 267), thus limiting their potential. To Katz (1984, 1986) as well as Loverso, Prescott, Selinger, and Riley (1988), most contemporary treatment software consisted of drills with no explicitly stated intervention goals; their use should be conservative and practical. Other authors (see, e.g., Bracy, 1983; Lucas, 1977; Skilbeck, 1984) advocated the computer rather than the clinician as the primary treatment medium, and a few (see, e.g., Rushakoff, 1984) described the development of clinician-independent, autonomous computerized aphasia treatment programs. Early literature reviews resulted in conflicting opinions of the efficacy of computers (see, e.g., Katz, 1987; Robinson, 1990). Robinson (1990), issued a strong statement, arguing that research evidence was simply not available to support the use of computers for most language and cognitive problems. Robinson claimed that many researchers obscured the basic issue of whether computerized treatment is effective by asking what works with whom under what conditions, as Darley (1972) suggested. He concluded that computers are prematurely promoted in clinical work and that their routine clinical use may be causing

patients more harm than good. A decade and half later, Wertz and Katz (2004) evaluate examples of reports concerning the computerized treatment for aphasia outcomes in the research literature by applying precise definitions of the treatment outcome research terminology, placing the examples within the context of the five-phase treatment outcomes research model (Robey, 1998; Robey & Shultz, 1998), applying a level-of-evidence scale to rate the evidence provided by the selected examples (American Academy of Neurology Therapeutics and Technology Assessment Subcommittee, 1994), and speculating where we are and where we may need to go to demonstrate the influence of computer-provided treatment on improvement in aphasia.

No substitute exists for carefully controlled, randomized studies, the documentation of which has become the scientific foundation of aphasiology. Research reported over the last 15 years has incorporated increasingly sophisticated designs and greater numbers of subjects to assess the efficacy of computerized aphasia treatment (Wertz & Katz, 2004), ranging from simple Phase I and II studies, A-B-A designs, and comparisons of pre- and post-treatment testing (Katz & Nagy, 1982, 1983, 1984, 1985; Mills, 1982) to large, randomly assigned single-subject studies (Loverso et al., 1992) and Phase III clinical trials incorporating randomly assigned treatment and no-treatment groups (Katz & Wertz, 1992, 1997). Efficacy of computerized aphasia treatment is being addressed one study at a time.

Auditory Comprehension

Few studies have investigated the effects of computerized treatment drills on auditory comprehension problems. Until recently, high-quality digitized speech was costly and difficult to include in the computer systems found in most clinics. Also, agreement on treatment approaches was limited by the varied, complex, and transient nature of auditory comprehension problems. Mills (1982) first used computer-controlled digitized speech to provide one-, two-, and three-part auditory “pointing” commands in a simple drill to a patient with chronic aphasia. Intervention was limited to repetitions of the auditory stimulus. Improvement was noted on pre- and post-treatment testing and on PICA (Porch, 1981) and Token Test (De Renzi & Vignolo, 1962) scores. The influence of other factors (e.g., placebo effect) should not be discounted, because no withdrawal or multiple-baseline, single-subject research strategies were used. Even so, the study is a good first step toward adapting auditory comprehension activities to the computer.

Verbal Output

Researchers apply technology to dysnomia in different ways. Colby and colleagues made extensive use of computers and speech synthesizers in attempts to increase verbalization and

communication in autistic and other “non-speaking” children (see, e.g., Colby & Kraemer, 1975; Colby & Smith, 1973). Later, Colby, Christinaz, Parkison, Graham, and Karpf (1981) built and programmed a small, portable micro-computer carried by a subject with dysnomia on a sling and shoulder-strap combination, thus allowing use of the device in actual communicative situations. When the subject experienced word-finding problems (Brown & Cullinan, 1981), she pushed keys in response to prompts from the computer. On a small liquid crystal display (LCD) screen, the computer printed a series of questions designed to help the individual with dysnomia identify the forgotten word—for example, “Do you remember the first letter of the word?”, “...the last letter?”, “...any other letters?”, and “...any other words that go with the forgotten word?” The subject’s answers were applied according to an algorithm outlined in the program, and a list of possible words was produced and displayed across the computer screen, beginning with the most “probable” words. When the patient recognized the forgotten word, she pressed a button, and the word was produced via synthesized speech. [Most patients with dysnomia usually can recognize the correct word and say it after a visual or auditory model (see, e.g., Benson, 1975).] The authors reported that the subject was cued successfully by the portable computer in real-life situations that were functional and communicatively stressful. Although their computer may be viewed as strictly an AAC device, Christinaz (personal communication) reported that the cueing algorithm subsequently generalized to non-computer settings. Patients reported after several weeks of using the computer that they no longer required it, instead asking themselves the same series of questions previously displayed by the computer. Christinaz reasoned that the subjects had “internalized the algorithm” and now cued themselves without the need of external prompts. The frequency and success of this observation was not reported, but the implication of Christinaz’s statement is certainly relevant and potentially significant. As more powerful portable computers are used as compensatory devices, acquisition and generalization of functional communication behaviors may occur if these or similar devices modeled self-cueing strategies for patients during actual communicative situations.

Van de Sandt-Koenderman (1994) described a computer program, Multicue, that is designed to help patients with dysnomia identify and select self-cueing and compensatory strategies for word-finding problems. A picture is presented in the left upper quarter of the computer screen, and the patient’s goal is to type the appropriate name. If the patient does not know the name (or cannot type it), various cues can be selected (e.g., word meaning, word form, and sentence completion) to help the patient retrieve the word. The goal of the program is to allow the patient to evaluate and practice several word-finding strategies, ultimately changing the process of word-finding for the patient. The

effectiveness of Multicue in a controlled study has not been reported.

Naming continues to be the most frequent aspect of verbal output studied by researchers developing aphasia treatment software. Fink and colleagues (2002) compared outcomes of the same computerized treatment ("hierarchical phonologic cueing") for naming disorders under two conditions, "partial independence" (similar to COT) and "full clinician guidance" (similar to CAT), and found that training-specific learning was demonstrated under both conditions. Laganaro, Di Pietro, & Schnider (2003) reported that "computerized treatment of anomia" resulted in item-specific improvement for four subjects with chronic aphasia but only three of seven subjects with acute aphasia. Adrian, Gonzalez, & Buiza (2003) described the Computer-Assisted Anomia Rehabilitation Program that used semantic, phonologic, written, and semantic/phonologic cueing to facilitate naming in a speaker with aphasia. They reported that 30 days after administration of the 12-day treatment program, performance of the practiced words improved 17% (from 53% to 70%), and the performance of untrained words doubled (from 32.5% to 65.8%), suggesting the patient's internalization of the strategies provided during treatment. All researchers recognize the necessity of further testing their software using additional subjects and more sophisticated experimental designs.

Reading Comprehension

Early work by Katz and Nagy (1982, 1983, 1984, 1985) demonstrated various functions that computers could provide when treating reading problems in patients with aphasia, although interpretation of the results must be tempered because of small sample sizes and limited research designs. Katz and Nagy (1982) described a program designed to test reading and provide reading stimulation for patients with aphasia. Five subjects with aphasia ran the computer programs two to four times per week for 8 to 12 weeks. Although several subjects demonstrated improved accuracy, decreased response latency, and increased number of attempted items on some computer tasks, changes in pre- and post-treatment test performance were minimal. The following year, Katz and Nagy (1983) reported a drill and practice computer program for improving word recognition in patients with chronic aphasia. The program was designed to accomplish a task that is difficult to undertake for a clinician and used the advantages of a computer. The program presented 65 words that occur frequently in text and varied the rate of exposure as a function of accuracy of response. The goal of the program was to help increase and stabilize the subject's sight vocabulary, but no changes were observed on pre- and post-treatment measures for the five subjects with chronic aphasia. Later, Katz and Nagy (1985) described a self-modifying drill and practice computerized reading

program for severely impaired adults with aphasia. The objective of the study was to improve functional reading, and a program was developed to teach subjects to read single words without intensive clinician involvement. The program also generated, through a printer, homework (writing activities) that corresponded to the subject's performance. Four of the five subjects demonstrated pre- to post-treatment changes on the treatment items that ranged from 16% to 54%.

Scott and Byng (1989) tested the effectiveness of a computer program designed to improve comprehension of homophones (similar-sounding words) for a 24-year-old subject who suffered traumatic head injury and underwent subsequent left temporal lobe surgery. Eight months after the accident, the subject continued to demonstrate aphasic symptoms as well as surface dyslexia and surface dysgraphia. Reading was slow and labored; she was able to understand printed words by sounding them out, presenting particular problems with homophones. The computer program, based on an information processing model, was designed to focus on this particular aspect of the subject's reading problem. The subject demonstrated steady improvement on the 136-item treatment program, which was run 29 times over a 10-week period. The subject improved in recognition and comprehension of treated ($p < 0.001$) and untreated ($p < 0.002$) homophones used in sentences. Improvement also was demonstrated on recognition of isolated homophones that were treated ($p < 0.05$) and on defining isolated treated ($p < 0.03$) and untreated homophones ($p < 0.02$). Recognition of isolated untreated homophones and spelling of irregular words showed no improvement.

Katz and Wertz (1997) conducted a longitudinal group study to investigate the effects of computerized language activities and computer stimulation on language test scores for adults with chronic aphasia. Fifty-five subjects with chronic aphasia who were no longer receiving speech-language therapy were randomly assigned to one of three conditions: (a) 78 hours of Computer Reading Treatment, (b) 78 hours of Computer Stimulation ("non-language" activities), or (c) No Treatment. The Computer Reading Treatment software consisted of 29 activities, each containing eight levels of difficulty, totaling 232 different tasks. Treatment tasks required visual-matching and reading comprehension skills, displayed only text (no pictures), and used a standard, match-to-sample format with two to five multiple choices. Treatment software automatically adjusted task difficulty in response to subject performance by incorporating traditional treatment procedures, such as hierarchically arranged tasks and measurement of performance on baseline and generalization stimulus sets, in conjunction with complex branching algorithms. Software used in the Computer Stimulation condition was a combination of cognitive rehabilitation software and computer games that used movement, shape, and/or color to focus on reaction time, attention span,

memory, and other skills that did not overtly require language or other communication abilities. Subjects in the two computer conditions worked on the computer for 3 hours per week for 26 weeks. Clinician interaction during the two computer conditions was minimal. Subjects from all three conditions were tested using the PICA and Western Aphasia Battery, or WAB, at baseline, 3 months, and 6 months. Significant improvement over the 26 weeks occurred on five language measures for the Computer Reading Treatment group, on one language measure for the Computer Stimulation group, and on none of the language measures for the No Treatment group. The computer reading treatment group displayed significantly more improvement on the PICA Overall and Verbal modality percentiles and on the WAB Aphasia Quotient and Repetition subtest compared with the other two groups. The results suggest that (1) computerized reading treatment can be administered with minimal assistance from a clinician, (2) improvement on the computerized reading treatment tasks generalized to non-computer language performance, (3) improvement resulted from the language content of the software and not stimulation provided by a computer, and (4) the computerized reading treatment we provided to patients with chronic aphasia was efficacious.

Writing: Typing and Spelling Words

Many reading comprehension activities are easily transferred to the computer. Writing activities, however, are less easily adapted. The most obvious problem is the inability of the common computer to evaluate handwriting and printing. The computerized writing treatment programs described in the literature substitute typing for writing during the intervention. In a comparison of writing and typing abilities of subjects with aphasia, Selinger, Prescott, & Katz (1987) examined seven subjects with left hemisphere damage to assess differences between PICA graphic scores on subtests A through E using standardized PICA graphics responses and PICA responses typed on a computer. No differences were found between scores on the PICA subtests as generated with a pencil and paper and PICA responses typed on a computer. These results suggest that the graphic language abilities of brain-damaged adults are equally represented by the two output systems.

Several investigators have incorporated complex branching algorithms in computerized writing programs to provide multilevel intervention. Seron and colleagues (1980) described a minicomputer/clinician combination that helped patients with aphasia learn to type words to dictation. The clinician said the target word and the subject typed a response on the computer keyboard. (The clinician had to know in advance the order of the stimuli programmed in the computer.) Intervention consisted of three levels of feedback: (1) the number of letters in the target word, (2) whether the letter typed was in

the word, and (3) when the correct letter was typed, regardless of whether that letter was in the correct position. The five subjects completed the program in 7 to 30 sessions. Pre- and post-treatment tests required the subjects to write a generalization set of single words to dictation. A decrease ($p < 0.05$) in the number of misspelled words and in the total number of errors made on the post-treatment test suggested that the computer program had improved spelling of words written by hand. Four of the five subjects maintained improved performance on a second post-treatment test administered 6 weeks later.

Katz and Nagy (1984) used complex branching steps to evaluate responses and provide patients with specific feedback in a computerized typing/handwriting confrontation/spelling task. A stimulus was randomly selected by the program, and a drawing representing the stimulus was displayed on the computer screen. The subject responded by typing on the keyboard. Feedback consisted of auditory sounds and text printed on the screen. Single and multiple cues from a hierarchy of six cues were selected by the program in response to the number of errors made for each of 10 stimuli. A seven-point multi-dimensional scoring system was used to describe performance and track the effectiveness of the various cues. Additional feedback included repetition of the successful and most recently failed cues. At the end of the computer session, pencil and paper copying assignments automatically generated via the computer printer were completed by the subject. Pre- and post-writing tests revealed improved spelling of the target words for seven of the eight subjects with aphasia ($p < 0.01$).

Glisky, Schlacter, and Tuvig (1986) reported the ability of four memory-impaired subjects without aphasia to type words in response to definitions displayed on the computer screen. Cues included displaying the number of letters in the word and displaying the first and subsequent letters in the word, one or all at a time, as needed. Cues continued until either the patient typed the word correctly or the program displayed the entire word. All patients improved in the ability to type the target words without cues. Patients maintained their gains after a 6-week period of no treatment and demonstrated generalization to another typing task, although generalization to writing was not measured.

Katz and colleagues (1989) developed and tested a computer program designed to improve written confrontation naming of animals for nine subjects with minimal assistance from a clinician. The treatment program required subjects to type the names of 10 animals in response to pictures displayed on the computer monitor. If the name was typed correctly, feedback was provided, and another picture was displayed. If an error was made, hierarchically arranged cues were presented, and response requirements were modified. Five of the nine subjects achieved criterion for success within six treatment sessions, and the performance of all nine subjects improved an average of 40% on the computer

task ($p < 0.0001$). In addition, improvement was measured on non-computerized written naming tasks, such as written confrontation naming of the treatment stimuli and written word fluency for animal names ($p < 0.001$). The PICA Writing modality score improved by +4.1 percentile points ($p < 0.05$). Improvement did not extend to PICA Overall and Reading scores. Because the goal of the program was to teach subjects the 10 names, improvement did not—and was not expected to—generalize to written word fluency for an unrelated category. The lack of change in these latter language activities for these 10 subjects with chronic aphasia contrasts with their improved performance on treated words.

Deloche, Dordain, and Kremin (1993) developed software to treat oral and written modality differences in confrontation naming for two subjects with aphasia, a surface dysgraphic and a conduction aphasic. The intervention focused on written naming from the keyboard. Both subjects maintained improvements 1 year following therapy. Mortley, Enderby, and Petheram (2001) used the computer as “a tool to facilitate repetitive practice” and to “encourage the independent use” of the treatment strategy for an adult who, despite his chronic dysgraphia, was able to spell target words orally. Computer practice was part of a more comprehensive regime, including a specially designed word processing program to help with carryover and use of a dictionary to support the spelling strategy. The patient was able to move from non-functional tasks to more functional activities as a result of the treatment.

Augmentative Communication Device

Published reports from Gardner and Gardner (1969), Premack (1970), and others involved in animal communication described success teaching non-human primates (e.g., chimps and apes) the use of nonverbal, language-like symbolic communication systems. These reports stimulated efforts to teach visually based, alternative communication systems to people with severe aphasia (see, e.g., Gardner, Zurif, Berry, & Baker, 1976). Developing the concept further, Steele, Weinrich, Kleczewska, Wertz, and Carlson (1987); Weinrich and colleagues (1989); and Steele, Weinrich, Wertz, Kleczewska, and Carlson (1989) developed and tested a graphically oriented, computer-based alternate communication system called the Computer-Aided Visual Communication, or C-VIC, system for adults with chronic global aphasia. The C-VIC is an interactive pointing board that runs on a Macintosh computer and uses a picture-card design, or metaphor. Subjects use the mouse to select one of several pictures, called icons, each of which represents a general category. The selected icon then “opens up” to reveal pictures of the items within the selected category. After selecting the desired item, the picture is added to a sequence of other selected pictures; this “string” of pictures

represents the message. The message can be read via the sequence of icons, words printed below the sequence, or in some cases, heard through digitized speech. Much attention is given to the selection of icons. Weinrich and colleagues (1989) reported that concrete icons were learned and generalized faster than abstract icons, but that neither type of icon generalized well to new situations. The empirical evidence to support the efficacy of C-VIC was collected in a series of single-case studies (Steele et al., 1987; Weinrich et al., 1989, 1993). Steele and colleagues (1987) noted that, although globally impaired subjects with aphasia using C-VIC improve on expressive and receptive tasks, communication through more traditional modes of communication remains unchanged. Weinrich, McCall, Weber, Thomas, and Thornburg (1995), however, trained two subjects with Broca’s aphasia in the production of locative prepositional phrases and Subject-Verb-Object (S-V-O) sentences on C-VIC and reported that their verbal ability improved considerably. In subsequent reports (see, e.g., McCall, Shelton, Weinrich, & Cox, 2000), Weinrich and colleagues continued to develop and test C-VIC as a potential therapeutic approach to improve the communication and natural language of adults with aphasia.

A commercial version of C-VIC, called Lingraphica, incorporates animation and digitized speech on a Macintosh Powerbook computer. Lingraphica is an integrated, computerized communication system that combines spoken words, printed words, pictures (icons), and text processing. Patients use a mouse device to select one of several icons, each of which represents a general category. The selected icon then “opens up” to reveal pictures of the items within the selected category. After selecting the desired item, the picture is added to a sequence of other selected pictures; this “string” of pictures represents the message, which can be read via the sequence of icons and words printed below the sequence or can be heard through digitized speech. Aftonomos and colleagues (1997) used Lingraphica with 20 subjects and reported improvement in multiple modalities, including verbal, for most subjects. Clearly, further single-subject and group research using standardized measurements is needed to test the effectiveness of new computer technology adapted to the communicative needs of patients with aphasia. The treatment approach referred to in Aftonomos and colleagues (1997) formed the basis of multimodal treatment for aphasia administered by speech-language pathologists using Lingraphica at Lingraphi Care clinics.

Other researchers have taken different approaches to the application of AAC to aphasia. Van de Sandt-Koenderman (2004) reviewed the state of the art in AAC applications for aphasia and suggested that lack of motivation, inadequate vocabulary, insufficient training, and limitations in cognition and language abilities are major obstacles to the functional use of assistive technology in the

aphasic population. She points to the relatively frequent appearance of small, portable devices with ready-made messages tailored to specific communicative situations and calls for more research to refine these devices and improve their adaptability to the needs of individual patients. Linebarger, Schwartz, and Kohn (2001) described a computerized intervention that incorporated speech recognition software with software that allowed patients to construct spoken sentences “piecemeal” for later use. They reported that their five patients with agrammatism patients, using one or both programs, showed gains in language after independent home use of the software, and they concluded that this improvement may have resulted from training during therapy followed by practice under “normal” communication settings.

Artificial Intelligence

Reports by Guyard and colleagues (1990) represent the beginnings of new stage in the development of treatment software by integrating artificial intelligence (AI) programming and computer-assisted instruction (CAI) for the rehabilitation of patients with aphasia. Researchers (see, e.g., Barr & Geigenbaum, 1982) described this union between AI and CAI as “Intelligent CAI” (ICAI). In their view, ICAI can expand the scope, responsiveness, and flexibility of software for aphasia therapy so that a computer program would determine the type, sequence, and rate of stimuli presented based on evaluation of the patient’s responses. While valued in education, ICAI has met with limited success in aphasia rehabilitation, primarily because of two factors: the heterogeneity of the aphasic population, and the complexity of aphasia therapy (Katz, 1990).

Simulations

Roth (1992) as well as Gadler and Zechner (1992) have described computer-simulated worlds (NeueWEGE and AUSWEGE, respectively) in which patients, guided by their clinicians, explore a microworld, making decisions, “traveling,” and taking chances without any real physical or interpersonal risks. Topics of tasks are familiar and function to patients (e.g., planning a vacation). To my knowledge, however, no controlled study measuring efficacy has been reported. Crerar and Ellis (1995) described the “Microworld Project,” a computer system based on sound neuropsychological and psycholinguistic theory and designed to treat impairments in sentence processing. Concepts such as agent, action, object, and spatial relations were manipulated to improve sentence comprehension. A series of experiments (Crerar & Ellis, 1995; Crerar, Ellis, & Dean, 1996) demonstrated improvement in subjects with chronic aphasia after a relatively short duration of treatment.

Telemedicine

American Speech-Language-Hearing Association teleseminars and videoconferences as well as the Telerounds series sponsored by the National Center for Communication Disorders are good signs that telecommunications technology is coming of age in our own discipline (Duffy, 1998). This technology permits improved access to health services, especially for remote and underserved populations. The use of telecommunications technology to provide clinical services has numerous potential advantages, but many factors must be carefully evaluated, such as image quality, appropriateness of the fields of view, training requirements, user preferences, cost, and reliability and validity of the diagnostic findings using such technology (Peters & Peters, 1998).

Technology has been used in the past to provide assessment and treatment for patients with communication impairments who live in remote locations. Tele-Communicology (Vaughn, 1980; Vaughn et al., 1987) incorporated small, microprocessor-driven auditory, visual, and writing devices placed in the homes of patients and remote computers to provide assessment and treatment over the telephone. Wertz, Dronkers, Knight, Shenaut, and Deal (1987) compared the effectiveness of closed-circuit television, computer-controlled video laserdisc, and traditional face-to-face interaction for providing appraisal and treatment of patients with aphasia in remote settings. Subjects in all three treatment conditions demonstrated clinically significant improvement as indexed by scores on the PICA (Porch, 1981). No significant differences among the three conditions were observed. The results suggest that television and video laserdisc transmitted over telephone lines could be employed to provide services for patients who live where services do not exist. Brodin and Magnusson (1994) reported numerous studies conducted in Sweden demonstrating the feasibility of treatment provided over telephone lines for patients with aphasia in rural settings.

Duffy, Werven, and Aronson (1997) summarized results of telemedicine evaluations of speech and language disorders in patients of a small, rural hospital and large, multi-disciplinary medical practices. They concluded that telemedicine evaluations can be reliable, beneficial, and acceptable to patients with a variety of acquired speech and language disorders, both in rural settings and within large, multi-disciplinary medical settings. To date, no explicit technical or clinical national standards or guidelines exist for the use of telecommunications to deliver services in the field of speech-language pathology. Although Medicare does provide coverage for some telehealth services (c.f., Goldberg, 1997), no explicit provision involves coverage for speech-language pathology services at this time.

Comparison of Traditional and Computer Mediums

Comparing the effect of similar treatment activities provided by two different mediums should improve understanding about the influence of the medium and the relative effectiveness of the treatment. Many researchers are attempting to simulate accepted testing and treatment protocols on the computer. Some researchers think that, because of their speed, reliability, and relative autonomy, computers are ideally suited to administer tests to patients with aphasia, who can then work at their own pace and without embarrassment or fear of humiliation (e.g., Enderby, 1987). Odell, Collins, Dirkx, and Kelso (1985) developed two computerized versions of the Raven Colored Progressive Matrices (Raven, 1975). The program used high-resolution graphics and a touch screen input device to administer and analyze test performance quickly and accurately, with minimal supervision from a clinician. The authors compared the two computerized versions of the Raven matrices with a traditional, clinician-controlled, paper booklet administration of the test. The performances of 16 subjects with aphasia were essentially equivalent under all three conditions, leading the authors to conclude that the computer testing conditions did not present greater visual or cognitive demands on the subjects.

Wolfe, Davidoff, and Katz (1987) compared the real-object and computer simulation performances of adults without brain damage and adults with aphasia on another nonverbal problem-solving task, "The Towers of Hanoi" puzzle, originally administered to subjects with aphasia by Prescott, Loverso, and Selinger (1984). The performances of 19 subjects with aphasia and 19 subjects without brain damage were compared using two different methods of presentation: two-dimensional color computer simulation of the puzzle versus the manipulation of the actual wooden model. Subjects without brain damage performed equally well under both conditions. As in the study by Odell and colleagues (1985), subjects with aphasia demonstrated similar performance on the task under both conditions. These same subjects, however, required more time to complete the puzzle in the computer condition than when manipulating the actual wooden model. The results suggest that, although the computer medium did not affect the accuracy of performance for the subjects with aphasia, task completion took longer and was less efficient under the computer condition.

The effectiveness of closed-circuit television, computer-controlled video laserdisc, and traditional face-to-face interaction for providing appraisal and treatment to patients with aphasia in remote settings as measured by Wertz and colleagues (1987) was described earlier. Results suggested no significant differences among the three conditions in the diagnoses assigned to subjects; additionally, subjects in all

three treatment conditions demonstrated clinically significant change (between 12 and 17 percentile points on the PICA). No significant differences in improvement among the three treatment groups were observed, indicating that patients with aphasia could benefit from treatment provided in any of the three conditions.

An excellent example of the process of demonstrating efficacy in a computerized treatment program involves 14 years of published research by Loverso and colleagues, who have documented a series of data-based reports describing the development and testing of a model-driven, clinician-provided treatment approach—the "verb as core"—from its origins as a "clinician-delivered therapy" (Loverso, Selinger, & Prescott, 1979; Loverso, Prescott, & Selinger, 1988) to its encoding and refinement as a computer/clinician-assisted program (Loverso et al., 1985, 1988, 1992).

Loverso and colleagues (1979, 1988) and Selinger, Prescott, Loverso, and Fuller (1987) initially developed and tested a treatment protocol for patients with aphasia in which verbs were presented as starting points and paired with different "wh-" question words to provide cues to elicit sentences in an actor-action-object framework. Thirty verbs were used at each of six modules. The hierarchy was divided into two major levels, each consisting of an initial module and two submodules that provided additional cueing for subjects unable to achieve 60% or better accuracy on the initial module. Level I presented stimulus verbs and the question words "who" or "what" to elicit an actor-action sentence. Level II elicited actor-action-object sentences by presenting stimulus verbs and the question words "who" or "what" for the actor and the question words "how," "when," "where," and "why" for the object. Subjects responded verbally and graphically and were scheduled for treatment three to five times per week. During each session, 30 stimulus verbs were presented for generation of sentences. Statistically significant improvement ($p < 0.05$) was demonstrated on the PICA following 3.5 months of treatment for each of the two subjects with aphasia.

Later, Loverso and colleagues (1985) compared the effects of the same treatment approach when treatment was provided by a clinician versus when it was provided by a computer and speech synthesizer assisted by a clinician. The subject with aphasia responded in the clinician-only condition by speaking and writing and in the clinician-computer condition by speaking and typing. Stimulus presentation and feedback in the clinician-computer condition normally was provided only by the computer. The clinician intervened only if the patient's typed response was correct but the spoken response was in error. The subject improved on the task under both conditions but took longer to reach criteria under the computer-clinician condition. Based on the subject's improvement, both on the treatment task and on

“clinically meaningful” changes during successive administrations of the PICA ($p < 0.01$), the authors concluded that their listening, reading, and typing activities under the clinician–computer condition had a positive influence on the patient’s language performance. They suggested that, although still in the early stages of development, aphasia treatment administered by computers is practical and has the capacity for success. Loverso and colleagues (1988) replicated the study by Loverso and colleagues (1985) with five subjects having fluent and five subjects having confluent aphasia for the purpose of examining whether treatment provided under the computer–clinician condition was as effective as a clinician alone when treating various types and severities of aphasia using their cueing–verb-treatment technique. The 10 subjects required 28% more sessions ($p < 0.05$) to reach criteria under the computer–clinician condition than under the clinician-only condition. Subjects with fluent aphasia required 24% more sessions, and subjects with nonfluent aphasia required 33% more sessions, under the computer–clinician conditions than under the clinician-only condition. Of the 10 subjects, eight showed significant improvement ($p < 0.05$) on the PICA Overall percentile measure, on the Verbal modality measure, and on the Graphic modality measure. All subjects maintained gains after a maintenance phase of 1 month post-treatment or longer. Similar results were reported following a replication of the study using 20 subjects (Loverso et al., 1992).

EXAMPLES OF COMMERCIALY AVAILABLE SOFTWARE

Auditory Comprehension

Although developed for primarily for children, three programs under the title Language Activities of Daily Living (Laureate Learning Systems)—My House, My Town, and to a lesser extent, My School—are good examples of software that can be used to provide stimulation treatment for adults with aphasia. For example, in My House, rooms within a house can be viewed, along with many items typically found in the rooms. For example, the bedroom contains a bed, end table, lamp, bureau, closet, clothes, and so on. A natural-sounding, digitized voice identifies the target item by name or function (pre-elected by the clinician). After the patient uses the mouse (or touch screen, if available) to designate an item, the program indicates accuracy visually and/or auditorially. Text (name or function) also can be displayed, as selected by the clinician. The program provides repetitions when requested by the patient and options for repetitions and nonlinguistic (visual) cues following incorrect responses to help the patient complete the item successfully. Items are drawn with color and charm.

Verbal Output

Technology has been more readily adapted to motor speech problems than to the complex and less completely understood language formulation problems of adults with aphasia; however, some recent programs show promise. Visual Confrontation Naming (Parrot) helps to teach the patient a strategy to stimulate or compensate for word-finding problems by selecting among possible cues. Cues may be audible (i.e., first sound) or visual (e.g., first letter, description, or multiple-choice list containing the word). Ideally, patients should develop self-cueing strategies using the most successful cue. The CD-ROM version has more than 500 target words with pictures. Verbal Picture Naming Plus (Parrot) recognizes spoken words by using sophisticated speech recognition technology. The patient is prompted to name a picture displayed by the computer. The computer then evaluates the verbal response and, if that response is incorrect, prompts the patient to repeat the word after it is verbally presented. The task requirements for patients are not unusual, but clinicians may wish to determine for themselves whether the voice recognition software is sufficiently accurate for the needs of each patient. Also, be aware that speech recognition software designed for some versions of Windows (e.g., Windows 95/98) may not work for others (e.g., Windows NT, Window Vista).

Aphasia Tutor 0: Sights ‘n Sounds (Bungalow) is a word repetition task that displays a word or picture while presenting the word using digitized speech. The patient’s repetition is recorded, and both the computer model and the patient’s response are played back for comparison. The software provides more than 400 words, and clinicians can add their own words (in the “Professional version”).

Reading Comprehension

Treatment of reading problems using computers appears to be particularly appropriate when considering the nature of patients, activities, interventions, and computers. Most people with aphasia—even mild, residual aphasia—report problems understanding long or complex text. Because reading is a task that we typically engage in alone, it is socially appropriate to practice alone. Reading requires minimal responses by the patient, thus simplifying software development. These programs can run on minimally configured, less expensive systems.

Reading Comprehension Adults (Parrot) presents single-page short stories written to be of interest to adults. Aphasia Tutor (Bungalow) is a series of programs that provide reading exercises to improve reading comprehension, allowing progression from letters to words to sentences to paragraphs. It also includes a module allowing “practical reading” of items, such as newspapers, product labels, and

bills. For patients who drive or hope to drive again, Traffic Sign Tutor (Bungalow) may complement functional reading as well as symbolic comprehension goals. This program allows interactive practice with traffic sign recognition and response to written hypothetical driving scenarios.

Writing: Typing and Spelling

Computers also are an appropriate medium for treating writing disorders, a common and persistent problem in patients with aphasia. Like reading, writing tasks usually are done alone. It is unexpected for computers to improve the mechanics of writing, but they can provide tasks that are designed to improve other components of written language, such as spelling and grammar. Word processing software, such as Word (Microsoft), offers many features that could assist mildly impaired patients, such as spelling check, grammar check, thesaurus, templates, and the "Assistant," which automatically provides guidance when writing letters or performing other common functions.

Brubaker on Disk: Database of Customized Language and Cognitive Exercises (Parrot) contains more than 1,500 exercises that can be arranged and printed to create personalized activities or workbooks for patients to complete either during treatment sessions or as homework. The clinician uses a mouse to select among different language and cognitive tasks, difficulty levels, response types, print size, and type face. The program uses these choices to select exercises from a large data base. The clinician then reviews on screen the selected exercises and prints what he or she wants to include in a personalized workbook.

Cognitive Problems

Treatment efficacy for computerized cognitive retraining is less clearly documented than that for speech and language treatment (Robinson, 1990), but researchers are striving to better assess efficacy. Two multi-level computerized cognitive treatment programs that are shared among professionals in neuropsychology and speech-language pathology are Captain's Log (BrainTrain) and PSSCogReHab (Psychological). Captain's Log includes 33 separate computer programs that focus on visuomotor, conceptual, and numeric skills as well as on attention. It allows tracking of performance across several sessions and includes reaction time measures and analyses of error responses. PSSCogReHab (Psychological) includes a set of eight software packages with treatment activities focused on attention, executive skills, visuospatial and memory skills, and problem solving. Many other programs are designed to help treat specific problems. For example, Conditional Statements (Parrot) presents, either visually or auditorally, a hierarchy of conditional statements. Responses are indicated by pointing and dragging icons on-screen with the mouse. Clinicians also may build

their software libraries by subscribing to the *Journal of Cognitive Rehabilitation* (Psychological). Each monthly issue includes a 3.5-inch disk that contains Soft Tools, a treatment program (frequently, a "game") designed for the PC to focus on a different cognitive problem, such as memory or visual spatial skills.

Additionally, many devices are designed to help patients with cognitive impairments cope with complex daily activities. Electronic scheduling and reminding devices as well as computerized calendars (c.f., Herrmann, Yoder, Wells, & Raybeck, 1996) are increasingly affordable for integration into cognitive rehabilitation programs. PocketCoach (Ablelink Technologies) is a portable voice recorder designed to help patients with cognitive problems complete complex, real-life tasks. Using his or her own voice, the clinician records a series of instructions or steps into the device. The patient then plays back the steps, one at a time, until the task is completed.

Alternative and Augmentative Communication Devices

Lingraphica as a compensatory device was described earlier. Steele and colleagues recently have redirected their efforts; as LingraphiCARE America, they have begun to establish a network of specialized "Language Care Centers" for treatment of adults with aphasia by combining the use of Lingraphica technology with standardized clinical treatment strategies and a growing patient data base containing demographics and outcome measures. Although preliminary outcome data have been reported (Aftonomos et al., 1997), further single-subject and group research using standardized measurements is needed.

Another example of an AAC device is the DynaVox 2c, a lightweight (approximately 6 pounds) system designed for children and adults. The device uses a color display and text-to-speech conversion. It has built-in infrared environment control capabilities that permit the user to easily transmit files between the DynaVox and a desktop PC. Infrared capability also permits control of televisions, VCRs, and other appliances, thus providing more independence for the user. DynaVox software uses symbol and word prediction capability and a searchable "concept tagged" vocabulary list, enabling faster programming and automatically generated "pages" or screens of associated pictures and words.

FUTURE TRENDS

The computer can become a very powerful clinical tool by incorporating what we know about aphasia, treatment, and technology. Multimedia PCs are now common, providing better platforms for treatment software focusing on problems of auditory comprehension and verbal output. Improved speech recognition, a goal for the entire computer industry, can result in an entirely new generation of

treatment programs and AAC devices. Replacing traditional, static, still images with dynamic digital video segments in treatment software increases interest and relevance for many patients. Affordable digital still and video cameras increase the ease with which software can be individualized for each patient's needs and interests. Palm-size PCs will influence the development of AAC devices and computers in rehabilitation in the same manner that laptop computers did just a few years ago. Eisenson (1973) suggested that clinicians consider changes the environment of patients with aphasia to maximize their communicative potential. Technology is helping us do that.

The most influential element, however, is not technological but, instead, clinical. In all computerized aphasia treatment studies cited in this chapter, clinicians selected and tested the patients, designed the treatment plans, designed and modified the treatment tasks, trained the patients to use the computers, and measured treatment efficacy. Computers, programmers, publishers, or researchers are not responsible for treatment effectiveness; clinicians are. Because treatment cannot be effectively "prescribed" like medicine, software should be viewed as supplementary treatment, with the clinician providing critical intervention as indicated by performance and other considerations. The role of computers and treatment software, like that of all tools, should extend the abilities of the clinician, allowing clinicians to intervene when skills, experience, and flexibility are required. Rather than emphasize what computers can or cannot do better than clinicians, our focus should be on an intelligent division of labor between computers and clinicians—a combination that can do more than either one alone. The real danger comes from a failure to appreciate the scope and depth of clinical work. An autonomous, robotic therapist, representing the knowledge and experience of a competent aphasia clinician, is a fantasy dreamed up by people who focus too much on the *costs* of care and not enough on the *efficacy* of care. Until we can describe to others precisely how to treat specific problems in individual patients, it is unreasonable, unethical, and a misrepresentation of the complexity of therapy for aphasia to assume that, at this time, a machine can perform the functions of a clinician.

The true value of computers in the rehabilitation of patients with aphasia continues to be studied. Just like the question of efficacy itself in aphasia rehabilitation (Darley, 1972; Fitz-Gibbon, 1986; Howard, 1986) the effectiveness of computer use in aphasia treatment cannot be answered with a simple "yes" or "no." More work is needed. Treatment software may always be an imperfect reflection of clinician-provided therapy, but by improving the software, clinicians and programmers will learn more about how and why treatment works. In the best tradition of scientific and rehabilitative efforts, aphasiologists can work together to shape this tool of technology for the development of their professions and the benefit of all patients.

KEY POINTS

1. What is believed about aphasia and treatment should be reflected in treatment software and not diminished by the limitations of computers.
2. Four properties of computers and computer programming that illustrate the limitations inherent in the application of computers to aphasia treatment are discrete (quantity rather than quality), conventional (pre-applied, unchanging rules), finite (cannot anticipate every possibility), and isolated (artificial rather than real world).
3. Major areas in which computers have the potential to become significant tools for treating patients with aphasia include providing supplemental treatment, measuring efficacy, making prognoses, helping generalization, fostering independence and a more active role in treatment, providing recreational activities, and performing administrative functions.
4. Contemporary multi-media computers are ideal for providing auditory stimulation, reading treatment, and to a lesser extent, writing treatment (through typing).
5. Speech recognition software has improved in recent years but is still inadequate for most clinical applications in aphasia because of poor ability to understand multiple, different speakers as well as speakers with variable phonologic errors (as in aphasic paraphasias and apraxia of speech).
6. Clinicians should assess the following components of any treatment software considered for use by patients with aphasia: goal, instructions, stimulus characteristics, response requirements, scoring system, general feedback, specific ("corrective") feedback, type and degree of intervention, criteria for termination, and scores stored for later analysis.
7. Treatment software, like all treatment activities, should be based on a treatment model or models. Three basic models are brain-behavior relationships, behavior modification, and educational models.
8. Four basic types of treatment software are stimulation, drill and practice, simulation, and tutorial.
9. Treatment efficacy refers to whether outcomes are improved as a result of a specific intervention.
10. A large body of research published in peer-reviewed journals demonstrates the effectiveness of aphasia treatment—and of computerized aphasia treatment—for various populations of people with aphasia.
11. The value of aphasia treatment is measured by the degree to which skills acquired during treatment are observed in real-life situations. Generalization can be aided by the computer, which can administer some aspects of treatment without the familiar presence

and constant conscious (and unconscious) control of the clinician.

12. Success of treatment for adults with chronic aphasia depends more on their acceptance of their residual disabilities and their social re-integration than on periodic but minimal gains in language tasks. Technology can assist patients with aphasia in these goals by helping them gain new language skills, by modifying and helping them gain control of their environment, and by providing them with options to improve their communication and quality of life.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Review treatment software in your clinic. Evaluate the programs as though they were clinician-provided treatment activities. How do they measure up to the treatment you provide your patients?
2. Critically review treatment software described in commercial catalogs. Are expectations stated or implied that seem a little too good to be true? Do the tasks seem to be worthwhile as treatment activities or supplementary activities?
3. Under what circumstances could a person with aphasia improve talking, listening, reading, and/or writing by using an AAC device?
4. What are some of the major limitations of computer-provided treatment? How can you, as a clinician, overcome these limitations with your patients?
5. What would you like to see computers do in aphasia treatment? Describe a program that helps a clinician to improve a patient's reading comprehension.
6. Design a computer program based on a favorite or familiar treatment activity. Incorporate options that allow the clinician to modify task requirements for patients with different types or severities of aphasia.

APPENDIX 32.1

Clinical Examples

Example 1: Auditory Comprehension

MODALITY:	Listening
DESIGN:	Stimulation
GOALS:	To maintain accuracy, self-monitoring, and attention as response time decreases
TASK:	Using digitized speech, the computer states the name (or function) of an item in a complex scene containing several functionally related items displayed on the monitor. The patient selects the correct item with the mouse.
SOFTWARE:	Language Activities of Daily Living: My House (Laureate Learning Systems)
PROCEDURE:	The clinician selects a response time (e.g., 10 seconds) that permits the patient to respond to all items with 100% accuracy. Response time is reduced for subsequent trials until the patient begins to make errors.
INTERVENTION:	Keep response time at the level when errors first occurred. Reduce the number of items to two, and identify those two items for the patient before beginning (e.g., “The computer is going to ask you to point to only this one or that one.”). When 100% accurate for three consecutive trials, increase number of items to three, four, and so on until all items are presented.
SCORING:	1 point per correctly selected item

Example 2: Writing/Printing Personal ID Information

MODALITY:	Writing (typing)
DESIGN:	Drill and practice
GOAL:	To improve the ability to write or print personal information for a chronic, severely impaired, predominantly nonverbal patient with aphasia using a typing drill
TASK:	Type name, address, and telephone number in response to a diminishing set of cues
SOFTWARE:	Word processor
PROCEDURE:	The clinician creates a series of word processing documents with diminishing cues (e.g., Document 1 has the intact model for simple copying, Document 2 has every third letter or number missing, Document 3 has every other word missing, and so on.) The diminishing cues can take any form thought useful by the clinician. From either the word processing program or from within a Windows (or Macintosh) folder, the patient selects the document containing the level of cueing needed to successfully type the personal information. The patient can save the file, or the “autosave” option can be invoked, for later review of performance by the clinician. To aid in generalization, the documents are printed, and the patient practices writing (printing) at home directly on the same pages.
INTERVENTION:	The clinician dictates error items to the patient. If errors persist, the clinician provides models or other cues as needed.
SCORING:	Number of correctly spelled words, legible words, etc.

Therapy for Associated Neuropathologies of Speech- and Language- Related Functions

Chapter 33

Communication Disorders Associated with Traumatic Brain Injury

Mark Ylvisaker, Shirley F. Szekeres, and
Timothy Feeney

OBJECTIVES

The reader will be able to:

1. Describe epidemiologic trends related to traumatic brain injury (TBI).
 2. Describe central themes in the pathophysiology of TBI, including both primary injuries (e.g., diffuse axonal injury and focal damage related to irregular surfaces on the floor of the skull) and secondary injuries (e.g., associated with elevated pressure, swelling, bleeding, neurotransmitter surges, and others).
 3. Describe risk factors for TBI and the relation between preinjury factors and long-term outcome.
 4. Describe central tendencies in long-term outcome from the perspectives of communication, cognition, executive functions, and behavior.
 5. Describe central themes in rehabilitation and ongoing support for individuals with chronic cognitive, communication, and behavioral impairment after TBI.
 6. Offer several rationales for a context-sensitive, everyday, routine-based approach to intervention.
 7. Describe procedures associated with ongoing, context-sensitive, collaborative hypothesis testing assessment, and give a rationale for this approach to assessment for planning intervention.
 8. Create functional, individualized rehabilitation plans in the domains of executive functions/self-regulation, cognition, social communication, and behavior.
 9. Describe executive function routines, and give illustrations for individuals at varied stages of recovery.
 10. Give reasons for avoiding process-specific cognitive exercises.
 11. Create functional cognitive rehabilitation and support plans.
 12. Implement self-coaching procedures for individuals with social communication problems.
 13. Distinguish between antecedent-focused and consequence-focused behavior management, and offer a rationale for antecedent-focused approaches for individuals with TBI.
 14. Create functional intervention plans designed to teach positive communication alternatives to negative behavior.
 15. Offer several rationales for collaborating with everyday people, and describe effective ways to create such collaborative relationships.
-

In this chapter, we offer a functional and highly context-sensitive perspective on assessment and intervention for individuals with chronic cognitive and behavioral impairments, which underlie the most common and most debilitating communication-related disabilities after traumatic brain injury (TBI; i.e., damage to the brain caused by external forces acting on the skull). The perspective is based on (1) our combined 85 years of clinical experience in the field, (2) current theory and research in cognitive neuroscience, (3) a considerable body of efficacy research in related disability fields, and (4) a growing body of efficacy literature in TBI rehabilitation. The importance of the approach to cognitive rehabilitation described in this chapter is underscored by pessimistic reviews concerning the effectiveness of restorative, decontextualized cognitive and executive function exercises, possibly combined with neuropharmacologic management.

The length of this chapter is dictated by our attempt to address many critical themes associated with an increasingly important disability group for specialists in cognitive, behavioral, and communication disorders. Because readers tend to use this textbook as an ongoing resource, we have included a large number of tables, figures, and appendices

designed to organize and summarize large quantities of information for easy access. The chapter is divided into eight sections:

1. Epidemiology
2. Pathophysiology
3. Disability associated with TBI, including frequently used measures of disability, considerations associated with prediction of outcome, stages of improvement, and commonly occurring communication consequences of TBI
4. Framework for everyday, routine-based intervention, including theoretical, neuropsychological, and economic rationales
5. Functional assessment for planning intervention
6. Intervention for self-regulatory impairments: cognitive and executive function disorders associated with TBI
7. Intervention for self-regulatory impairments: social-communication and behavioral disorders associated with TBI
8. Collaboration among professional clinicians, the person with disability, and the everyday people in that person's life.

Throughout the chapter, we highlight the role of the self-regulatory/executive system because of its vulnerability after frontal lobe injury and its significance in relation to successful outcome in the domains of rehabilitation discussed in this chapter. In other publications, we have developed these themes in greater detail than is possible here (see, e.g., Feeney & Ylvisaker, 1995, 1997; Szekeres, Ylvisaker, & Cohen, 1987; Ylvisaker, 2003, 2006; Ylvisaker & Feeney, 1996, 1998a, 1998b, 2000a, 2000b; Ylvisaker, Feeney, & Feeney, 1999; Ylvisaker, Feeney, & Szekeres, 1998; Ylvisaker, Szekeres, & Feeney, 1998; Ylvisaker, Szekeres, & Haarbauer-Krupa, 1998).

EPIDEMIOLOGY OF TBI

Incidence and Prevalence

According to the Centers for Disease Control and Prevention (CDC; 2001), at least 1.5 million TBIs occur in the United States annually, resulting in approximately 50,000 deaths and 235,000 hospitalizations. Of the 1.5 million injured people, 80,000 are expected to experience persisting disability, yielding a prevalence estimate of 5.3 million Americans living with TBI-related disability. These estimates are lower than previously reported (Kraus, 1993), possibly representing a positive trend in highway safety and increasingly restrictive criteria for hospital admission. Because of the relative youth of most individuals with TBI, prevalence-to-incidence ratios are much higher than those for neurogenic disorders associated with aging. Approximately 80% of those hospitalized with TBI have mild injuries, with an expectation of excellent recovery in

most, but not all, cases (80%–90% excellent recovery) (Kraus & Nourjah, 1988; Ruff, 2005). Many more cases of mild injury are uncounted, either because those affected do not seek medical attention or because the brain injury is masked by more pressing medical concerns (e.g., high spinal cord injury). Direct medical costs (acute hospitalization and rehabilitation) have been estimated at \$48.3 billion per year, not including the enormous financial and psychological costs associated with ongoing support and reduced employability (AHCPR, 1999).

Risk Factors

The incidence of TBI is highest among young people, with 15- to 24-year-old males being most vulnerable. Secondary peaks have been identified in people older than 65 years and in children 5 years or younger (CDC, 1997; Kraus, Rock, & Hemyari, 1990). With the introduction of TBI as an educational disability category in the revised Individuals with Disability Education Act (IDEA: Federal Register, 1991), children have received increasing attention in the clinical and education literatures. In contrast, elderly individuals, who also are at risk both for TBI and for relatively severe consequences of the injury, continue to be under-represented in the literature (Goldstein & Levin, 1995; Payne, 1999).

Several risk factors in addition to age have been identified. Historically, males have been said to have twice the rate of TBI as females, with this ratio being even higher (3:1 or 4:1) for the highest risk group of older adolescents and young adults (Kraus, 1993). More recent CDC estimates place the male-to-female ratio at closer to 1.5:1. Clinicians often characterize the highest risk group as including adolescent and young adult males from lower socioeconomic groups, whose preinjury lives may have been characterized by some degree of risk-taking behavior, poor academic and vocational achievement, and greater-than-average use of alcohol and recreational drugs. Supporting this stereotype, incidence studies have suggested that TBI appears to be especially common in lower socioeconomic groups, among people with less than a high school education, and among those with a history of poor academic performance (Fife, Faich, Hollinshead, & Boynton, 1986; Haas, Cope, & Hall, 1987; Sosin, Snizek, & Thurman, 1996). Alcohol often is a contributing factor in the occurrence of TBI, strongly associated with both motor vehicle-related injuries and with falls in both young adults and the elderly (Hartshorne, Harruff, & Alvord, 1997; Kraus, 1993; Santora, Schinco, & Trooskin, 1994; U.S. Department of Transportation, 1995). Previous TBI increases the risk of subsequent TBI by threefold (Annegers, Grabow, Kurland, & Laws, 1980; Gerberich, Priest, Boen, Staub, & Maxwell, 1983). Previous TBI also may increase the negative consequences of subsequent TBI (Collins et al., 1999; Gronwall & Wrightson, 1975).

Not all epidemiologic reports, however, are consistent with the stereotype. For example, in two Australian studies, Tate (1998) failed to find a high rate of pretrauma social maladjustment in her cohort and, more surprisingly, did find that such maladjustment, when present, appeared not to have a pronounced effect on outcome. In contrast to Tate, our experience with several hundred young adults referred for neurobehavioral support as a result of behavior-related community reintegration problems suggests that preinjury factors play a significant role in outcome, with preinjury developmental and adjustment problems often exacerbated by the injury (Ylvisaker & Feeney, 2000a).

With respect to the cause of injury, transportation-related events account for approximately 50% of TBI cases (CDC, 1997), followed by falls (slightly more than 20% of the total, but much higher in young children and the elderly), assaults (approximately 20%), and finally, sports-related injuries and other causes. Tragically, abuse is a major factor in infants and the elderly. Consideration of the causes of TBI reveals that this is a largely preventable epidemic. With concerted efforts to improve automobile safety, reduce alcohol-impaired driving, enhance safety measures in sports, and eliminate child and elder abuse, the epidemiology of TBI could be dramatically changed.

PATHOPHYSIOLOGY OF TBI

The term “traumatic brain injury” refers to damage to the brain caused by external forces. Traumatic brain injuries can be open, involving penetration of the dural covering of the brain, or closed. Penetrating missile injuries, in which focal damage is related to the site of penetration and trajectory of the missile, are more strongly associated with aphasia than is closed head injury (CHI) (Newcomb, 1969). Generally, CHI refers to brain injuries in which the primary mechanism of damage is a blunt blow to the head or rapid changes of skull motion, both of which are associated with acceleration/deceleration forces acting on the brain (Levin, Benton, & Grossman, 1982). In special education discussions of students with brain injury, acquired brain injury often is used to identify an even broader pathophysiologic category, including stroke, tumor, anoxia, toxic encephalopathy, meningitis, encephalitis, and other causes of noncongenital brain impairment. Federal education law, PL 101-476 (Individuals with Disabilities Education Act, 1990; amended 1997), defined TBI in relation to external causes, but some state departments of education use TBI as a synonym for acquired brain injury.

Primary Impact Damage

Primary and secondary injuries associated with TBI are summarized in Figures 33-1 and 33-2 (information taken from Alexander, 1987; Katz, 1992; Pang, 1985; Povlishock & Katz, 2005; Young, 1999). Contact of a moving skull with

a stationary surface may cause skull distortion and fracture and, traditionally, is thought to be responsible for coup (site of contact) and contrecoup (opposite side) brain contusion and cavitation injury (Fig. 33-3). Neurobehavioral deficits associated with lesions that vary with the site of impact cannot explain central tendencies within the population as a whole. Rather, damage associated with differential tissue movements within the skull, both brain—skull and brain—brain movements created by inertial forces (especially rotational inertia), often plays the greatest role in determining outcome and best explains population commonalities. This type of injury is possible even in the absence of a blow to the head if the skull is accelerated and/or decelerated rapidly (e.g., shaken baby syndrome) (Gennarelli et al., 1982).

In severe CHI, brain—skull differential movement in the area of bony prominences within the skull can cause surface contusion and laceration as well as deeper shearing of axons (diffuse axonal injury) and blood vessels (subdural and intracerebral hematoma) (Povlishock & Katz, 2005). Regardless of site of impact in high-speed CHI, focal contusion as well as axon shearing often are concentrated within anterior and inferior frontal and temporal lobe structures bilaterally because of their adjacency to sharp, irregular surfaces inside the skull (Alexander, 1987; Courville, 1937; Katz, 1992) (Figs. 33-4 and 33-5). Damage to these areas explains many of the commonly observed behavioral symptoms that negatively affect communication after CHI, including (a) depressed executive control over cognitive and communicative functions (prefrontal damage), (b) impaired social perception and social reactivity (prefrontal and frontolimbic damage, particularly right hemisphere), and (c) generally reduced behavioral self-regulation (prefrontal, frontolimbic, and anterior temporal lobe damage). Diffuse neuronal shearing also often is concentrated in subcortical white matter, brain stem, and corpus callosum, contributing to initial coma and subsequent arousal/attentional deficits as well as slowed mental processing (Adams, Graham, Murray, & Scott, 1982). Over the weeks and months after severe TBI, diffuse axonal injury can continue to contribute to degeneration at nerve terminals. Characteristic stages of recovery are related to diffuse rather than focal injuries (Povlishock & Katz, 2005). The relative infrequency of specific aphasic syndromes in CHI is, in part, a consequence of the smooth interior surface of the skull adjacent to the traditional perisylvian language centers in the brain.

Secondary Damage

Secondary damage in TBI is associated with slowly developing hemorrhages and localized or widespread swelling and edema, both of which contribute to increased intracranial pressure, which can be acutely life-threatening and contribute to morbidity in those who survive. In addition,

Figure 33-1. Mechanisms of immediate injury in closed and open traumatic brain injuries.

Figure 33-2. Pathologic events that often follow severe traumatic brain injury and contribute to impairment.

Figure 33-3. Representation of coup injury (i.e., contusion and cavitation at the site of impact) and contrecoup injury (i.e., contusion and cavitation at the opposite side of the brain). (Adapted with permission from Walker & the North Carolina State Board of Education, 1997; with permission.)

hypoxic-ischemic injury and pathologic neurotransmitter surges (specifically glutamate), both of which are common secondary consequences of severe TBI, often pick out specific vulnerable structures, notably the hippocampus bilaterally, thereby contributing to memory and new learning problems after the injury (Katz, 1992). This is an especially

ominous consequence for young people who face substantial new learning challenges in school and on the job. Tragically, the vast majority of individuals with TBI are children, adolescents, and young adults. Post-traumatic seizures, including both early onset (within the first week) and late onset (appearing after the first week), also can complicate recovery and become a major concern if epilepsy persists.

DISABILITY FOLLOWING TBI

Predictable inconsistencies are found in the published descriptions of disability following TBI. Because of the extended period of neurologic improvement, the time post-injury at which consequences of the injury are assessed influences the description of central tendencies in the population.

Figure 33-4. Diffuse axonal injury: twisting, tearing, and breaking of axons associated with primary impact damage in traumatic brain injury.

Figure 33-5. Contusions after traumatic brain injury, based on 40 consecutive cases, clearly depict the tendency for maximum pathology in the orbitofrontal and temporal regions. (Reprinted from Courville, 1937; with permission.)

Variation in the severity mix from study to study also adds to variation in this outcome picture. Furthermore, as increasingly valid language and cognitive assessments have become available (e.g., sensitive analysis of extended discourse versus aphasia batteries developed for a different clinical population) (Coehlo, Ylvisaker, & Turkstra, 2005), increasing numbers of individuals with TBI have been shown to have language and more general cognitive processing and self-regulatory difficulties. Finally, because of the variable associations among impairment, activity/participation, and context, different outcome profiles inevitably emerge depending on which domain is assessed.

The World Health Organization International Classification of Functioning

Throughout the chapter, we use the World Health Organization (WHO) framework of body structure and function (previously impairment), activity/participation (previously disability and handicap), and environmental context (WHO, 2001). Disorders of body structure and function include the underlying physiological or psychological (“in the head”) impairments traditionally measured by office-bound test batteries (e.g., slowed processing, memory impairment, loss of organizing schemata, disruption of phonologic or grammatical systems, and hemiplegia). Disorders at the level of activity and participation, which may or may not be directly associated with the underlying impairment, refer to reduced ability to successfully perform activities that are important in the individual’s life (e.g., difficulty maintaining a conversation, problems comprehending school textbooks, difficulty remaining focused and organized at work, and impulsive or aggressive interaction under stress). This level also includes the individual’s potential educational, vocational, and social losses as a result of the disability, including loss of work, educational opportunity, friends, living situation, avocational pursuits, social status, community mobility, and the like. Context or environmental factors include potential barriers or facilitators in the physical and social environments. For example, ramps are a positive environmental factor for people with physical disability. Well-oriented and trained communication partners, on-the-job supports, and understanding work supervisors are examples of positive context factors for individuals with cognitive and communication disability.

Many of the changes in rehabilitation over the past two decades have been associated with an increasing emphasis on functional activities and participation (Level 2 of the WHO classification system) and context/environmental supports for social, educational, vocational, and avocational participation (Level 3), in contrast to the primary focus on the underlying impairment, as with traditional rehabilitation. Clearly, the relationships among the three levels are complex and relative to individuals and their contexts in life. For example,

the same underlying impairment can result in dramatically different types and degrees of activity and participation limitations in different individuals with varying activity and environmental demands, compensatory strategies, emotional adjustment, and social/educational/vocational supports. Furthermore, as we argue later in this chapter, intervention that begins with a focus on context supports, and then emerging into an activity/participation-oriented focus on compensatory strategies, can ultimately result in reduced impairment as the individual practices supported compensatory procedures until they become habitual and automatic aspects of information processing.

Measures of Injury and Disability Severity

Several rating scales have enjoyed increasing popularity as measures of initial severity of injury, ongoing improvement, and chronic disability. These scales are not intended for use in planning interventions with specific individuals; sensitive, individualized assessments are needed for that purpose. Furthermore, rating scales rarely are sufficient to measure the effectiveness of intervention in individual cases. For that purpose, no substitute exists for objective documentation of progress toward or achievement of individualized functional objectives directly related to important personal life goals.

General rating scales, however, have become part of the lingua franca of medical rehabilitation, are useful in capturing severity of injury and disability in general terms, and often are used in epidemiologic and program evaluation studies. Table 33–1 includes descriptions of commonly used scales. Many other functional scales have been developed, attesting to the shortcomings of impairment-oriented tests for measuring functional disability after TBI. These include the Patient Competency Rating Scale (Prigatano & Altman, 1990), Mayo-Portland Adaptability Inventory (Malec & Thompson, 1994), Neurobehavioral Functioning Inventory (Kreutzer, Marwitz, Seel, & Serio, 1996), Supervision Rating Scale (Boake, 1996), and BIRCO-39 Scales (Powell, Beckers, & Greenwood, 1998).

Prediction of Outcome

Many studies suggest a general “dose–response” relation between injury severity and long-term outcome (Katz & Alexander, 1994). Most studies correlating injury severity and outcome after TBI, however, use broad severity categories (e.g., four or five grades of severity, based on Glasgow Coma Scale score, duration of coma, or duration of post-traumatic amnesia, possibly combined with focal neurologic signs) and broad outcome categories (e.g., the five grades of outcome defined by the Glasgow Outcome Scale). Although useful for epidemiologic purposes, these studies must be interpreted cautiously by rehabilitation clinicians. First, correlation studies will always contain individuals who deviate

TABLE 33-1

Assessments Commonly Used to Measure Injury Severity and Associated Disability

Assessment Procedure	Description
Glasgow Coma Scale (GCS) (Teasdale & Jennett, 1974)	A three-category (eye opening, motor response, and verbal response), 15-point scale commonly used to measure the initial severity of TBI. Scores of 8 or lower within the first several hours after injury typically are classified as severe injuries, scores of 11 or 12 as moderate, and scores of 13–15 as mild.
Duration of Coma	Generally based on time from injury to eye opening and resumption of normal sleep–wake cycles. Measured in minutes or hours for mild to moderate injuries and in days, weeks, or months for severe injuries. Sometimes used more informally to refer to the period of significantly altered consciousness.
Duration of Post-Traumatic Amnesia	Based on time from injury to resumption of orientation and integration of day-to-day memories. Very hard to establish with precision in severe cases.
Galveston Orientation and Amnesia Test (GOAT) (Levin, O'Donnell, & Grossman, 1979)	A 10-question test of orientation to person, place, and time and of memory for recent, postinjury events as well as for most recent preinjury events.
Glasgow Outcome Scale (Jennett & Bond, 1975)	A five-category global outcome scale: death, persistent vegetative state, severe disability (conscious but disabled and dependent), moderate disability (disabled but independent), and good recovery (relatively normal life but possibly with ongoing minor impairment).
Rancho Los Amigos Levels of Cognitive Functioning (Hagen, 1981)	An eight-level scale of cognitive recovery based on observation of responsiveness, purposeful activity, orientation, memory, self-regulation, spontaneity, and independence. Levels: no response, generalized response, localized response, confused-agitated, confused-nonagitated, confused-appropriate, automatic-appropriate, and purposeful-appropriate.
Disability Rating Scale (Rappaport, Hall, Hopkins, Belleza, & Cope, 1982)	A rating scale developed to track improvement of people with TBI from coma to community. Includes subscales for impairment (similar to GCS), disability (cognitive ability for feeding, toileting, and grooming), and handicap (level of community functioning, and employability).
Functional Assessment Measure (FIM+FAM) (Hall, 1992)	A rating scale that adds 12 domains for disability rating to the 12 domains of the older Functional Independence Measure (FIM). The additional items, added specifically for individuals with brain injury, include swallowing, reading, writing, orientation, attention, safety judgment, emotional status, and adjustment to limitations.
Community Integration Questionnaire (Willer, Ottenbacher, & Coad, 1994)	A 15-item questionnaire designed to assess home and social integration and productivity in the following domains: household activities, shopping, errands, and leisure activities.
American Speech-Language-Hearing Association FACS	A rating scale designed to assess functional communication with greater precision than is possible with most general disability rating tools.
Communication Effectiveness Survey (Beukelman, 1998)	A survey designed to assess functional communication in natural contexts.
LaTrobe Communication Questionnaire (Douglas, O'Flaherty, & Snow, 2000)	A 30-item questionnaire divided into six communication domains: conversational tone, effectiveness, flow, engagement, partner sensitivity, and attention/focus. Self and “close other” forms are available.

Key: TBI = traumatic brain injury.

sharply from the general population relationships (Ponsford, Olver, Current, & Ng, 1995), and these exceptional individuals and their families often are those with whom clinicians interact in their everyday clinical practice. Second, within broad severity of injury and outcome categories is substantial individual variation, rendering specific predictions hazardous and leaving room for optimism regarding the potential effectiveness of intervention efforts. For example, two individuals in the good outcome category can be extremely different with respect to (a) their level of success measured in relation to preinjury success, (b) the effort required to maintain that level of functioning, (c) the level of supports they require and the associated caregiver burden, and (d) their subjective level of satisfaction and adjustment to life after the injury. Because of these sources of variability, intervention that fails to change a person's outcome category may, nevertheless, be very effective for the individual and caregivers alike.

Patterns and Stages of “Recovery”

In the heading, the word *recovery* is in quotation marks because it is a frequent source of miscommunication. In ordinary language, “to recover” is to return to normal. In contrast, rehabilitation professionals typically use the word to refer to gradual improvement, without intending to suggest that improvement will continue until a full recovery is achieved. Indeed, full recovery is rare following TBI with coma of a few days or more. Therefore, *improvement* may be a better choice of words to communicate what professionals often intend with *recovery* (Kay & Lezak, 1990).

Most individuals with severe TBI experience a large number of distinct stages or levels of cognitive and self-regulatory functioning over the course of their spontaneous neurologic improvement and rehabilitation. In many cases, improvement is characterized by a stairstep pattern rather than a smooth recovery curve, as commonly is observed following ischemic stroke (Brookshire, 1997). Furthermore, spontaneous neurologic improvement may continue for many months and, in some cases, even years (at decreasing rates of improvement) after severe TBI.

The popular Rancho Los Amigos Hospital Levels of Cognitive Functioning (see Table 33–1) organizes cognitive and behavioral recovery into eight relatively distinct levels. An understanding of typical levels of improvement helps treatment staff, family members, and individuals with TBI to place in perspective behaviors that would otherwise be distressing (e.g., agitation associated with Level IV) and to organize their rehabilitative efforts effectively. For purposes of discussing broadly different focuses of assessment and intervention—and, importantly, different levels and types of support provided to the patient by rehabilitation staff and families—we have collapsed the eight Rancho Los Amigos levels into three broadly distinct stages of recovery (Szekeres, Ylvisaker, & Holland, 1985) that also can be understood in

terms of the amount and types of support needed by the individual to function. Any discussion of stages, however, must be sensitive to the varied patterns and rates of improvement experienced by specific individuals and to the many small changes in functioning, required supports, and appropriate expectations that are more properly represented as a continuum rather than a series of qualitatively different stages.

Early Stage: Intensive Cognitive Supports

This stage begins with the first generalized responses to environmental stimuli and ends with stimulus-specific responses (e.g., visual tracking or localizing to sound), recognition of some common objects through appropriate use of the object (if motorically capable), and comprehension of some simple commands in context. From a cognitive perspective, this stage often is called the sensory or coma stimulation stage of rehabilitation, a controversial and hotly debated field of intervention. Zasler, Kreutzer, and Taylor (1991) presented a useful review of these themes and a conservative approach to coma management. From the perspective of performance of everyday activities (e.g., self-care), individuals at this stage require intensive levels of support.

Middle Stage: Moderate Cognitive Supports

This stage begins with heightened alertness and increased activity combined with some degree of confusion and disorientation, which may include agitated behavior unrelated to environmental provocation. This stage ends with a reduction in confusion, which is manifested by adequate orientation and behavior that generally is goal directed in a familiar environment. Most individuals experience gradual improvement in focused attention and episodic (autobiographical) memory, but memory impairment may remain a residual deficit. Behavior, including social communication, may continue to be impulsive; lack of initiation is an alternative possibility. Most individuals have difficulty with organizing complex tasks, including discourse tasks, and with planning how to achieve their goals.

During this stage, individuals require moderate, but systematically decreasing, levels of support to succeed at everyday tasks. The rehabilitation (or home) environment as well as group and individual therapy sessions are simplified, structured, focused, and rich in external compensatory supports so as to reduce confusion, facilitate improved and increasingly independent performance of functional activities (including relevant social, educational, and vocational activities), and promote adaptive behavior and a progressively increasing ability to process information and communicate effectively.

Late Stage: Minimal and Variable Cognitive Supports

This stage begins with an adequate, though perhaps superficial and fragile, orientation to important aspects of life, and

it ends with the individual's ultimate level of neurologic improvement, which may or may not include cognitive and communicative impairments that are functionally disabling. Environmental supports are gradually withdrawn to help individuals become maximally independent and learn how to compensate for and adjust to their residual deficits. This stage also is the stage of refinement of skills, with a focus on effective information processing and social communication in real-world settings and with real-life demands (e.g., school, work, and social life). No specific upper limit exists to learning, compensation, and adjustment that can be facilitated by creative clinicians and, thereby, substantially improve real-world success.

Sequence of Service Settings

Severe TBI typically is associated with many service settings and sets of service providers. Emergency medical services routinely are administered at the site of the injury and during transport to a trauma center. Emergency room care largely is devoted to managing life-threatening increases in intracranial pressure as well as treating other injuries (e.g., orthopaedic injuries and internal organ injuries) that frequently accompany TBI. Following initial stabilization, patients are transferred to the intensive care unit for ongoing management of critical intracranial dynamics. Stabilization of intracranial pressure often is followed by transfer to the hospital's neurologic care floor and the beginning of early rehabilitation. Speech-language pathologists may be members of the early rehabilitation team, often focusing their efforts on resumption of oral feeding, development of simple communication systems, and family education and support.

In the event of slow recovery, patients may be transferred to a rehabilitation unit or free-standing rehabilitation hospital for intensive acute rehabilitation. When cognitive, behavioral, physical, and general medical needs reach a level at which the person can be cared for in a less restrictive setting, the individual is discharged to home—and, often, ongoing outpatient or community support services—or to a community reintegration post-acute rehabilitation facility. Individuals with ongoing intense medical needs (e.g., respirator-dependent patients) or severe and unchanging cognitive impairment (e.g., persistent unresponsiveness) may be discharged to a long-term care nursing facility, with the possibility of resuming aggressive rehabilitation if signs of neurologic improvement are noted.

Individuals with concussion (i.e., traumatically induced alteration in mental status not necessarily resulting in loss of consciousness) or mild TBI (i.e., brief loss of consciousness or initial Glasgow Coma Scale score of 13–15) may be examined in a physician's office, observed in a hospital emergency room, admitted briefly, or not come to the attention of medical professionals at all. In most cases (approximately

80%–90%), mild TBI is associated with excellent recovery within a few days to a few weeks (Ruff, 2005). Persistent, serious disability is possible, however, requiring professional support and possible work or school accommodations. Individuals with a history of previous concussion or other neurologic vulnerability (e.g., learning disabilities or neurologic impairment associated with aging) are at increased risk for persistent symptoms (Collins et al., 1999; Gronwall & Wrightson, 1975; Rimel, Giordani, Barth, Boll, & Jane, 1981).

Long-Term Communication-Related Outcome

Earlier, we stated that the relation between injury severity and outcome is, at best, very general. Many factors interact to determine a person's ultimate level of impairment; ability to perform activities of daily living; ability to maintain desired levels of participation in social, educational, vocational, and avocational pursuits; level of personal satisfaction with life after the injury; and level of support required from everyday people in the environment. In addition to the injury itself, these factors include preinjury and postinjury variables summarized in Figures 33–6 and 33–7.

Given preinjury variability (Fig. 33–6) and the variety of pathophysiologic mechanisms in TBI (Figs. 33–1 and 33–2), some of which are related to site of impact, it is understandable that no consistent outcome profiles exist with respect to communication. Constellations of communication-related strengths and weaknesses potentially associated with TBI are extremely varied, depending on the nature, location, and severity of the injury as well as on the characteristics of the individual who is injured and post-trauma supports. Indeed, many professionals consider TBI to be, at best, misleading as a disability category, because it actually is an etiologic category, identifying a potential cause of varied disabilities and not the disability itself. In this respect, TBI is comparable to stroke or perinatal asphyxia, neurologic events that may or may not produce varied disabilities. Therefore, clinicians should expect not only great diversity within this group but also possible overlap between TBI and other categories of adult neurogenic communication disorder, such as aphasia, dementia, and the so-called right hemisphere syndrome.

As indicated in Figures 33–6 and 33–7, heterogeneity within the population is increased by diversity in pre-traumatic intelligence, educational and vocational levels, age, personality, and coping styles as well as by variation in post-traumatic environments, support systems, and emotional and behavioral reactions of the individual. Despite many commonalities among survivors of severe TBI (described below), these considerations underscore the importance of customizing assessment procedures as well as intervention goals and methods for this diverse clinical population.

Figure 33-6. Factors that often are present before traumatic brain injury and that may contribute to outcome.

Figure 33–7. Factors that occur after traumatic brain injury and that contribute to outcome.

Infrequency of Aphasia

Although symptoms of aphasia often are present early in recovery and, in some cases, specific language impairment does persist, aphasia, as defined in terms of the classical syndromes, is relatively uncommon after TBI in adults (Heilman, Safran, & Geschwind, 1971; Sarno, 1980, 1984; Sarno, Buonaguro, & Levita, 1986) and children (Chapman, 1997; Ylvisaker, 1993). Anomia, which can be associated with a wide variety of brain lesions, often is reported to be the primary residual aphasic symptom in the absence of general cognitive disruption (Heilman et al., 1971; Levin, Grossman, Sarwar, & Meyers, 1981; Sarno, 1980, 1984; Thomsen, 1975). Generalized and persistent expressive and receptive language impairment usually is associated with widespread diffuse injury that also produces global cognitive deficits (Levin et al., 1981). If aphasia is present, clinicians should apply the assessment and intervention frameworks presented elsewhere in this text.

Non-Aphasic Communication Disorders: Executive Functions, Cognition, Behavior, and Communication

Communication challenges following TBI most often are “non-aphasic” in nature; that is, they co-exist with intelligible speech, reasonably fluent and grammatical expressive language, and comprehension adequate to support everyday interaction. Depending on the severity of injury, stage of recovery, and particular focus of research, the characteristic communication profiles following TBI have been variously referred to as “the language of confusion” (early in recovery) (Halpern, Darley, & Brown, 1973), “non-aphasic language disturbances” (Prigatano, 1986; Prigatano, Roueche, & Fordyce, 1985), “cognitive-language disturbances” (Hagen, 1981), and “subclinical aphasia” (Sarno, 1980, 1984). Sarno (1984) found that, although a distinct minority of a consecutive series of 69 severely injured individuals admitted to an inpatient rehabilitation facility could be diagnosed with aphasia, all of the patients were found to have some combination of language deficits that were not apparent in everyday interaction. These included impaired confrontation naming, word fluency, and comprehension of complex oral commands. Sarno did not evaluate their interactive competence with increasing cognitive and social demands, social competence, or behavioral self-regulation—factors that clinicians, teachers, family members, and recent investigators often identify as major contributors to communication breakdowns after TBI.

The overlapping collections of communication deficits highlighted by these investigators have been grouped by the American Speech-Language-Hearing Association (ASHA) under the heading “cognitive-communication impairment” (ASHA, 1988) and are all associated with frontolimbic damage, the most common damage in CHI. These impairments are included in Table 33–2, which also includes lists of impairments under three additional headings: executive sys-

tem, cognitive, and psychosocial/behavioral impairments. In important respects, these four lists are descriptions of the consequences of the same underlying impairments, using four distinct professional frameworks. The extent of overlap in deficit domains underscores the importance of professionals from different clinical fields collaborating in their approach to assessment and intervention.

Communication Disorders Associated with Executive Function/Self-Regulatory Impairment

The same executive function/self-regulatory (EF/SR) skills underlie emotional/social/behavioral self-regulation (e.g., controlling affective states, inhibiting impulses, deferring gratification, communicating respectfully, and benefitting from feedback) (Vohs & Ciarocco, 2004) and cognitive-vocational-academic self-regulation (e.g., planning a work task, reading strategically, studying efficiently, and taking responsibility for vocational and academic success) (Meichenbaum & Biemiller, 1998) and, thus, should be viewed within one consistent intervention framework (Ylvisaker, Jacobs, & Feeney, 2003). Consistent with our previous work on the subject, we have chosen a functional definition of the construct, based on an analysis of prerequisites for successful performance of any difficult task (Ylvisaker & Feeney, 1998a; Ylvisaker, Szekeres, & Haarbauer-Krupa, 1998). These include: (1) some degree of awareness of one's strengths and weaknesses (thereby enabling a judgment of task difficulty) and (2) an ability to set reasonable goals, (3) organize plans to achieve the goals, (3) initiate goal-directed behavior, (4) inhibit impulses that interfere with goal achievement, (5) monitor behavior and (6) evaluate it in relation to the goals, (7) benefit from feedback, (8) flexibly select and modify strategies in response to performance feedback, and (9) flexibly perceive situations from a variety of possible perspectives. Each of these components falls on a continuum of performance and develops gradually during childhood, in dynamic interaction both with each other and with related domains of cognitive and social development (Flavell, Miller, & Miller, 2002). Because the term “self-regulation” is better understood by those who are unfamiliar with neuropsychological discussions of the topic, and because that term brings to the table a large literature in related fields of psychology, we have chosen to combine the terms to form the general construct, EF/SR.

The growing literature on self-regulation has close theoretic ties with psychological theory construction regarding the self and clinical ties with fields such as substance abuse, eating disorders, health problems, crime, motivation, procrastination, and the like (Baumeister & Vohs, 2004). Self-regulation and self-determination also have come to be used as the central terms within theory construction and research related to intrinsic motivation (Ryan & Deci, 2002). The literature on executive functions has close theoretic ties with neuropsychological investigations and clinical ties with

TABLE 33-2**Vulnerable Frontolimbic Structures and Frequently Associated Impairments****Frontolimbic Injury and Executive System Impairment**

- Reduced awareness of personal strengths and weaknesses
- Difficulty setting realistic goals
- Difficulty planning and organizing behavior to achieve the goals
- Impaired ability to initiate action needed to achieve the goals
- Difficulty inhibiting behavior incompatible with achieving the goals
- Difficulty self-monitoring and self-evaluating
- Difficulty thinking and acting strategically and solving real-world problems in a flexible and efficient manner
- General inflexibility and concreteness in thinking, talking, and acting

Frontolimbic Injury and Cognitive-Communication Impairment

- Disorganized, poorly controlled discourse or paucity of discourse (spoken and written)
- Inefficient comprehension of language related to increasing amounts of information to be processed (spoken or written) and to rate of speech imprecise language and word retrieval problems
- Difficulty understanding and expressing abstract and indirect language
- Difficulty reading social cues, interpreting speaker intent, and flexibly adjusting interactive styles to meet situational demands in varied social contexts
- Awkward or inappropriate communication in stressful social contexts
- Impaired verbal learning

Frontolimbic Injury and Cognitive Impairment

- Reduced internal control over all cognitive functions (e.g., attentional, perceptual, memory, organizational, and reasoning processes)
- Impaired working memory
- Impaired declarative and explicit memory (encoding and retrieval)
- Disorganized behavior related to impaired organizing schemes (managerial knowledge frames, such as scripts, themes, schemas, and mental models)
- Impaired reasoning
- Concrete thinking
- Difficulty generalizing

Frontolimbic Injury and Psychosocial/Behavioral Impairment

- Disinhibited, socially inappropriate, and possibly aggressive behavior
- Impaired initiation or paucity of behavior
- Inefficient learning from consequences
- Perseverative behavior
- Impaired social perception and interpretation

Adapted from Ylvisaker, Feeney, & Feeney, 1999; with permission.

rehabilitation for individuals who have frank neurologic impairment (Burgess & Robertson, 2002; Cicerone, 2005; Shallice & Burgess, 1991; Ylvisaker, Szekeres, & Feeney, 1998). In educational psychology and special education, the term “meta-cognition” has, historically, been used to refer to “executive self-regulatory” control over cognitive processes in the context of learning and academic performance (Flavell, Miller, & Miller, 2002); today, however, “self-determined learning” is increasingly used to describe these approaches (Martin et al., 2003; Meichenbaum & Beimiller, 1998). Finally, the term “self-determination” commonly is used to

cover much the same ground in discussions of developmental disabilities (Wehmeyer, Agran, & Hughes, 1998). We have attempted to mine all these fields in formulating a theoretically informed but practice-based approach to serving children and adolescents with EF/SR impairment.

Pathophysiological Bases: Frontolimbic Injury

It has long been known that prefrontal or frontolimbic structures are most vulnerable in CHI (Adams, Graham, Scott, Parker, & Doyle, 1980; Levin, Goldstein, Williams, &

Eisenberg, 1991; Mendelsohn et al., 1992; Mesulam, 2002; Povlishock & Katz, 2005; Varney & Menefee, 1993). Although it certainly is possible to escape frontolimbic injury in TBI, its frequency and profound impact on communicative effectiveness combine to give it—and its general neurobehavioral correlate, EF/SR dysfunction—an important heuristic role in organizing intervention planning (Ylvisaker, 1992). In recent years, investigators have increasingly differentiated varied frontal and limbic functions and have loosened, to some degree, the connection between frontal lobe functions and executive functions (Stuss, 1999a, 1999b). The most common communication-related themes after TBI, however, continue to be associated with frontolimbic injury.

Indeed, all the symptoms listed in Table 33–2 are associated with damage to the frontal lobes, limbic structures, and/or the critical axonal connections between prefrontal and limbic structures (Alexander, Benson, & Stuss, 1989; Povlishock & Katz, 2005; Stuss & Benson, 1986). For example, both right and left hemisphere prefrontal structures are associated with self-regulation (e.g., initiation, inhibition, and direction) of behavior, including communication behavior; with organization of language into coherent discourse; and with control over attentional and memory processes to make them useful in daily life. Both left and right hemisphere orbital frontal damage have been associated with personality changes, including disinhibition, volatility, and verbal “dysdecorum” (Alexander et al., 1989). Right frontal lobe damage has been associated with more specific pragmatic deficits, such as (1) decreased ability to produce appropriate para-linguistic accompaniments to speech, including gesture and facial expression as well as prosody in speech; (2) decreased ability to comprehend prosodic features in the speech of others and to interpret indirect pragmatic intents, including humor, sarcasm, metaphor, and other indirect meanings (McDonald, 2005); and (3) inattention to context, including social context, resulting in socially inappropriate behavior (Alexander et al., 1989; Shammi & Stuss, 1999; Stuss & Alexander, 1999).

Damage to the hippocampus and surrounding limbic tissue is associated with impaired declarative and explicit memory—roughly, memory for facts rather than procedures, combined with a subjective sense that one possesses the memory (Schacter, 1996; Squire, 1992). Because of the extreme vulnerability of the hippocampus to postinjury anoxia, new learning problems are very common after TBI, despite potentially good recovery of pretraumatically acquired and effectively stored knowledge and skills. Damage to other limbic structures and frontolimbic connections contribute to the transient or persistent difficulty with emotional and behavioral self-regulation commonly seen after TBI (Izard, 1992; Ledoux, 1991, 1996).

Discourse Impairment

Discourse impairment (i.e., difficulty organizing language over more than one utterance for production or comprehension)

probably has received more attention than other communication-related deficits in the recent TBI research literature (Coelho et al., 2005). Both adults and children with TBI have been found to be impaired relative to controls on many measures of interactive (conversational) and noninteractive (monologic) discourse (Biddle, McCabe, & Bliss, 1996; Chapman, 1997; Chapman, Levin, Matejka, Harward, & Kufera, 1995; Chapmen et al., 1992, 1997; Coelho, Liles, & Duffy, 1991; Dennis, 1991, 1992; Dennis & Barnes, 1990; Dennis, Barnes, Donnelly, Wilkinson, & Humphreys, 1996; Dennis & Lovett, 1990; Ehrlich, 1988; Groher, 1990; Hagen, 1981; Hartley, 1995; Hartley & Jenson, 1991; Liles, Coelho, Duffy, & Zalagens, 1989; McDonald, 1992a, 1992b, 1993; McDonald & Pearce, 1998; Mentis & Prutting, 1991; Pearce, McDonald, & Coltheart, 1998; Sarno et al., 1986; Togher, Hand, & Code, 1997; Turkstra & Holland, 1998; Ylvisaker, 1992, 1993).

Discourse impairment in the presence of adequate vocabulary, grammar, and motor speech ability often can be understood as a language consequence of more general cognitive disruption—that is, the loss or inaccessibility of the knowledge structures needed to organize thought units across multiple utterances (sometimes referred to as ideational apraxia). Alternatively, discourse impairment may be a consequence of failure to select and implement the appropriate organizing schemas when they are needed (sometimes referred to as frontal apraxia), or to maintain directed attention to the organizing scheme in a conversation or monolog, and monitor success of the communication. The latter phenomenon sometimes is referred to as impairment of the supervisory attentional system, which is the component of the executive system responsible for controlling behavior-regulating schemas in nonroutine contexts (Shallice, 1982). In most cases, discourse impairment after TBI represents a failure of executive control over cognitive and linguistic organizing processes rather than a linguistic impairment *per se* (Schwartz, 1995; Schwartz, Mayer, FitzpatrickDeSalme, & Montgomery, 1993). Alexander (2002) refers to the disorder as impaired action planning in the verbal domain.

In the intervention section of this chapter, we focus on organizational functioning in part because of its important relation to these common discourse impairments. According to many cognitive theories, the same cognitive macrostructures or managerial knowledge units (e.g., scripts, themes, schemas, plans, and mental models) that guide organized thinking, remembering, reasoning, and acting also guide organized talking, writing, and comprehension of lengthy discourse. According to one leading neuropsychological theory, such managerial knowledge units are stored in prefrontal parts of the cortex, explaining the frequency of organizational impairment in TBI (Grafman, 1995; Grafman, Sirigu, Sepctor, & Hendler, 1993), particularly with left hemisphere dorsolateral prefrontal involvement. Thus, discourse is one of the critical points of intersection between language and

cognition, mandating an informed cognitive focus during intervention and collaboration among professionals who address the cognitive dimensions of behavior.

Communication Disability Related to Memory/Retrieval Impairment

Memory deficits are among the most commonly reported problems after TBI. Encoding of new information into memory often is impaired, either as a result of damage to the vulnerable hippocampal system responsible for consolidating new declarative memories (Giap, Jong, Ricker, Cullen, & Zafonte, 2000) or of damage to the frontal lobes (especially left hemisphere), resulting in poorly focused attention and/or shallow, nonstrategic organization and elaboration of information during its initial processing (Anderson, Damasio, Tranel, & Damasio, 1988; Brazzeli, Colombo, DellaSala, & Spinnler, 1994; Cabeza & Nyberg, 1997; Gluck & Myers, 1995; Schacter, 1996; Squire, Knowlton, & Musen, 1993). Encoding new memories for facts and events (declarative memory) often is more severely impaired than encoding for procedures (procedural memory); similarly, memories stored with some awareness of the memory (explicit memory) often are more vulnerable than those stored without such awareness (implicit memory) (Ewert, Levin, Watson, & Kalisky, 1989; Schacter, 1996). Procedural and implicit memory often are run together in the TBI literature but, in fact, are neuropsychologically distinct (Salmon & Butters, 1995). Storage over time is less commonly impaired in TBI; once information is adequately processed and encoded, it is unlikely to decay rapidly, as is the case in degenerative diseases, such as Alzheimer's.

Retrieval may be impaired in TBI as a result of posterior damage that reduces the number of retrieval routes in the networks of neural connections that compose the storage system (Buschke & Fuld, 1974). More commonly, however, word and information retrieval is impaired as a result of frontal lobe injury, which can result in nonstrategic searches of memory (Petrides, 1995; Schacter, 1996; Shimamura, 2002) and degraded managerial knowledge units being used to direct those searches (Grafman, 1995, 2002). For example, when looking for car keys, people characteristically focus their search around organized routines of everyday life. Similar organizational schemas are used to guide internal searches of memory, which therefore are rendered ineffective in the presence of degraded schemas. Recent positron-emission tomographic investigations of explicit retrieval of information have isolated important contributions of left lateral prefrontal cortex, right anterior frontopolar cortex, and anterior cingulate gyrus (Buckner et al., 1995; Shimamura, 2002). Retrieval of episodic memories is differentially impaired by right frontal lobe damage, even if encoding of that same information may have made greater use of left frontal lobe systems (Schacter, 1996; Tulving,

Kapur, Craik, Moscovitch, & Houle, 1994). Meta-cognitive skills, particularly the ability to monitor memory searches, are required for effective retrieval and are an aspect of executive functioning that often is impaired in TBI (Hanton, Bartha, & Levin, 2000; Kennedy & Yorkston, 2000).

These memory problems affect communication in a variety of ways. Inefficient information and word retrieval slows interaction and can be socially distracting. Failure to recall information can result in tedious repetition during conversation and embarrassing social breakdowns. Impaired verbal learning has an obvious negative impact on return to school or to a job that requires new learning, possibly resulting in failure that may lead to social withdrawal. Impaired prospective memory without effective compensation creates substantial everyday difficulties as the individual misses appointments or other scheduled activities, forgets medication, and the like.

Communication Disability Associated with Psychosocial and Behavioral Impairment

Any combination of the deficits listed in Table 33-2 can substantially affect life after TBI. Often, however, it is the communication-related personality and psychosocial changes that most profoundly influence the individual's social, vocational, familial, and academic reintegration. For example, families routinely report that it is easier to adjust to physical disability in a loved one than to personality changes manifested in stressful and unsatisfying communication; employers often highlight communication-related obstacles to maintenance of employment; and teachers frequently identify social and behavioral changes as most problematic in school reentry (Bond, 1990; Brooks, Campsie, Symington, Beattie, Bryden, & McKinley, 1987; Brooks & McKinlay, 1983; Brooks, McKinlay, Symington, Beattie, & Campsie, 1987; Brown, Chadwick, Shaffer, Rutter, & Traub, 1981; Filley, Cranberg, Alexander, & Hart, 1987; Fletcher, Levin, & Butler, 1995; Hall et al., 1994; Jacobs, 1993; Klonoff, Costa, & Snow, 1986; Lezak, 1986, 1987; Livingston & Brooks, 1988; McKinlay, Brooks, Bond, Martinage, & Marshall, 1981; Morton & Wehman, 1995; Perlesz, Kinsella, & Crowe, 2000; Prigatano, 1986; Taylor et al., 2002; Thomsen, 1974, 1984, 1987; Weddell, Oddy, & Jenkins, 1980; Ylvisaker et al., 2001). Social communication and general psychosocial problems were found to be critical predictors of vocational failure and poor quality of adult life in two groups of young adults who were injured as children and followed into adulthood (Cattalani, Lombardi, Brianti, & Mazzuchi, 1998; Nybo & Koskiniemi, 1999).

These social communication problems are common in both children and adults with TBI, and they often are associated with personality changes, including increases in negative behavior and awkward or impulsive social communication

(see the review by Ylvisaker, Jacobs, & Feeney, 2003). Among children and adolescents with severe TBI, estimates of new persisting behavior and psychosocial problems (i.e., those not predating the injury) range from approximately 35% (Max et al., 1997) to a high of 70% (Costeff, Grosswasser, Landmen, & Brenner, 1985). Behavior and social-communication problems also are common among adults with TBI and remain at high levels at long-term follow-up (Baguley, Cooper, & Felmingham, 2006). Preexisting behavior and social interaction problems, which are common among both children (Cattalani et al., 1998) and adults (MacMillan, Hart, Martelli, & Zasler, 2002), add to this already alarming total. The intensity of behavior and psychosocial disorders has been associated in some studies with the severity of injury (Schwartz et al., 2003) and with preinjury problems (MacMillan et al., 2002).

Personality changes frequently highlighted in the TBI literature include irritability, impatience, frequent loss of temper, emotional volatility, egocentrism, impulsiveness, anxiety, depression, loss of social contact, lack of interests, and reduced initiation. Blumer and Benson (1975) summarized the inhibition-related and initiation-related personality changes associated with frontal lobe injury with the labels pseudo-psychopathic and pseudo-depressed personalities, respectively. Mesalun (2002) used the terms “frontal disinhibition syndrome” and “frontal abulic syndrome” to cover much the same territory. For communication specialists, these psychosocial and behavioral themes typically are grouped under the heading “pragmatics of language.”

Aggressive, poorly controlled, or otherwise awkward social behavior has been linked to disruption in a variety of frontal lobe or frontolimbic circuits, which often are injured in TBI (Scheibel & Levin, 1997), but most often to orbitofrontal damage and/or connections between these areas and limbic structures (e.g., the amygdala). Furthermore, damage to prefrontal areas, in association with the amygdala, insula, anterior cingulate gyrus, and basal ganglia (right hemisphere more than left), results in difficulty interpreting the emotional states of others and in “reading” the non-literal aspects of their communication (McDonald, 2005). Difficulty with interpreting sarcasm (and, possibly, other non-literal meanings) and with recognizing vocal expressions of emotions is common in TBI and has a negative impact on social communication (Channon, Pellijeff, & Rule, 2005; Milders, Fuchs, & Crawford, 2003). Brothers (1997) used the term “damaged social editor” to characterize the functional consequences of damage to a circuit that includes the orbitofrontal cortex, amygdala, anterior cingulate gyrus, and temporal poles; the individual has difficulty “editing” social behavior because of impairment in the ability to read social situations and interpret the emotional states of others (i.e., impaired “theory of mind”). Commonly occurring cognitive and executive function impairments (in the domains of attention, memory, organization, planning,

flexible problem solving, self-awareness, and the like) can further reduce social effectiveness directly and also indirectly by contributing to failure and frustration.

Variability in Performance

Teachers, family members, work supervisors, and others often emphasize a frustrating inconsistency in performance when describing people with TBI. An uncharitable but common interpretation of this variability is that the person is unmotivated (i.e., lazy) or excessively moody, perhaps even depressed. Although these characteristics may be present, neuropsychological investigations have found relatively extreme variability in performance to be associated with frontal lobe injury, particularly injury to the right frontal lobes (Stuss, 1999b; Stuss, Pogue, Buckle, & Bondar, 1994). Variability is increased with increasing task demands and with aging. This inconsistency in performance is one of several reasons for caution when interpreting the results of standardized tests with this population (see below).

FRAMEWORK FOR COGNITIVE AND PSYCHOSOCIAL REHABILITATION

Our goal in this section is to explain and offer a rationale for an approach to intervention that deviates in important ways from traditional approaches to medical rehabilitation for individuals with severe TBI. In addition, we offer operational definitions of cognition and executive functions, two of the primary targets of intervention for individuals with TBI. Later in this chapter, we offer procedural detail in four overlapping domains: (1) executive functions/self-regulation, (2) specific aspects of cognition, (3) social communication, and (4) behavioral self-regulation.

Appendix 33-2 contrasts central tendencies in two generally different approaches to communication, behavioral, and cognitive rehabilitation for people with TBI. We have labeled these approaches conventional and functional, with the caveat that any approach to rehabilitation that is successful as measured by real-world indices is functional. Therefore, the appropriateness of these labels depends, in part, on relatively disappointing results of TBI efficacy research conducted within the traditional or conventional paradigm (Carney et al., 1999; Cicerone et al., 2005; Park & Ingles, 2001; Ylvisaker, 2003) and on the accumulation of supporting research conducted within the functional paradigm (Feeney et al., 2001; Park & Ingles, 2001). What we refer to as the conventional approach has a long history in medical speech-language pathology (and other fields), featuring restorative services offered in clinical settings and dominated by massed practice of hierarchically organized, decontextualized training exercises. In this section, we explain the general approach referred to as “functional” in Appendix 33-2.

Positive, Everyday Routine-Based Intervention

Central to the functional approach outlined in Appendix 33–2 is the concept of positive, supported, everyday routines of action and interaction. From a behavioral perspective, a “routine” is a behavior chain in which each link—that is, each discrete behavior—is a discriminative stimulus for the next link and a conditioned reinforcer for the previous link (Halle & Spradlin, 1993). The goal of intervention, from this perspective, is to help people acquire flexible and situationally successful behavior chains (defined by stimulus and response classes) that include observable as well as internal (cognitive and emotional) behaviors as links in the chains—that is, successful routines of everyday life.

From a cognitive perspective, a routine is a concrete structured event complex (Grafman et al., 1993), which, at a more general level, becomes a script, which is an organized internal (mental) representation of a type of event complex that includes the people, places, associated objects, associated language, and their organization. Everyday routines and scripts are those that occur during the course of everyday social, familial, vocational, recreational, and educational life and involve everyday communication partners (ECPs), including family members, friends, work supervisors, and teachers. The organized knowledge that enables one to be oriented and behave successfully in a variety of restaurants, from McDonald’s to fine restaurants, is an example of a fairly general script. From a cognitive perspective, a primary goal of rehabilitation is to help people with TBI acquire and apply appropriate scripts and other general knowledge structures (or Managerial Knowledge Units) (Grafman et al., 1993) to guide successful thinking, remembering, problem solving, decision making, talking, and acting in social context.

We highlight the word “routine” for several reasons. First, routine suggests habit—that is, behavior that does not require effortful deliberation or planning. With frontal lobe injury and associated executive function impairment, habitual behavior often is relatively unaffected, whereas behavior that requires a novel plan for unfamiliar circumstances may be severely impaired (Mesulam, 2002; Stuss & Benson, 1986). Later in this chapter, we suggest that executive functions themselves, including planning, organizing, and problem solving, can become routine with extensive coached practice of executive function routines within everyday action contexts. Second, routine suggests normal activities of life, motivating clinicians to move beyond commercial therapeutic materials, generic therapeutic activities, and exclusively clinical intervention settings and, instead, capitalizing on the activities that are routine for the individual and using ECPs as collaborators in intervention. Countless studies of generalization and maintenance of learned behaviors with many disability groups support the conclusion that adequate performance of targeted skills in a treatment

setting—even after mastery of the skill using personally meaningful activities—is no guarantee for ongoing use of the skill in the routines of everyday life (Detterman & Sternberg, 1993).

Supports (Scaffolding)

Within an everyday, routine-based approach to intervention, the technical term “support” designates a pivotal concept, connected with a Vygotskian approach to cognitive and behavioral intervention (discussed later). To say that routines of action or interaction are positive and supported is to say that people with disability are provided with the supports or “scaffolding” (Wood, Bruner, & Ross, 1976) that they need to be successful. Table 33–3 lists examples of supports commonly used to facilitate success with cognitively demanding tasks (“supported cognition”) (Ylvisaker & Feeney, 1996) and with behaviorally stressful tasks (“supported behavioral self-regulation”) (Ylvisaker, Jacobs & Feeney, 2003). In both cases, supports can be understood using the more familiar model of supported employment, wherein workers with disability are enabled to perform otherwise difficult work tasks because they have the help of a job coach or designated peer, use customized equipment and strategies to compensate for their disability, and/or rely on other environmental supports. Supported employment has enjoyed considerable success among adults with TBI (Curl, Fraser, Cook, & Clemmens, 1996; Wehman, West, Kregel, Sherron, & Kreutzer, 1995; Wehman et al., 1993) and is one of the few areas of TBI rehabilitation found by a government-sponsored, systematic evidence review to have a solid research base (National Institutes of Health, 1999).

Progression of Intervention

Table 33–4 outlines a progression of intervention that is consistent with a context-sensitive, everyday, routine-based approach to cognitive, psychosocial, and communication rehabilitation. First, staff and everyday people (ideally including the person with disability) collaborate to identify what is and is not working in the everyday routines of life.

Second, the same group of collaborators identifies what changes in everyday routines (including context supports) could quickly produce increases in domains of activity and participation and, in the longer run, in reduction of disability (i.e., improved performance of functional activities) and, ultimately, in reduction of the underlying impairment. Systematic hypothesis testing (described in the next section) often is required to identify the source of the manifest problem and, therefore, to identify the most useful and positive changes in everyday routines.

Third, the same stakeholders collaborate to identify the supports needed for positive changes in everyday routines and ways to motivate these changes for the person with disability and for others in the environment. Often, this stage

TABLE 33-3

Antecedent Procedures for Supporting Individuals with Cognitive and Behavioral Impairment

Supported Cognition

1. Ensure do-ability of tasks; eliminate unreasonable demands.
2. Create facilitative work/study environment.
3. Ensure orientation to setting and tasks; use clear, facilitative instructions.
4. Induce positive internal setting events (see section on behavioral intervention) before cognitively demanding tasks:
 - Positive behavioral momentum (see section on behavioral intervention).
 - Choice and control.
 - Rest, relaxation, absence of pain.
5. Establish well-rehearsed routines and scripts.
6. Use advance organizers (e.g., organizationally clear graphic organizers) for complex tasks.
7. Use appropriate cognitive prosthetics as needed (e.g., memory aids, electronic pager/reminder systems, organization aids, and attention aids).
8. Use collaboration to complete difficult tasks (e.g., cooperative work/learning groups; buddy system).
9. Ensure that communication partners use elaborative and collaborative conversational competencies (see later in this chapter).
10. Ensure that communication partners use supportive cognitive scripts (see later in this chapter).
11. Desensitize the individual to events and tasks that cause anxiety.
12. Help the individual to manage cognitive antecedents.

Supported Behavioral Self-Regulation

1. Eliminate unreasonable provocation, including unreasonable demands.
2. Ensure orientation to setting and task.
3. Ensure do-ability of tasks.
4. Induce positive internal setting events before stressful tasks:
 - Positive behavioral momentum.
 - Choice and control.
 - Rest, relaxation, absence of pain.
5. Teach positive communication alternatives to negative behavior.
6. Establish alternative scripts to negative behavior (e.g., give the individual a positive role that requires responsible behavior).
7. Ensure that the individual has positive, meaningful roles to play and goals to achieve.
8. Desensitize the individual to events that cause anxiety.
9. Help the individual to manage behavioral antecedents (e.g., avoid overly stressful tasks, create scripts for potentially negative interactions, and alert friends and supervisors to how they might help during a stressful experience).

Adapted from Ylvisaker and Feeney, 1998a; with permission.

requires considerable creativity and flexibility. No rehabilitation textbook can prescribe the unique combinations of supports that often are needed in people's real-world contexts or can show how these changes in everyday routine can be motivating for everyone involved.

Fourth, systems of support are implemented so that everyday routines of action and interaction are successful and that important skills, possibly including compensatory skills, can be practiced extensively in real-world contexts.

Finally, levels of support are systematically reduced as the individual becomes more successful at everyday tasks and/or

habituates the use of compensatory procedures; at the same time, contexts of successful action and interaction are systematically increased. Later in this section, we illustrate how the process of modification and reduction of supports applies across the continuum of recovery after severe TBI.

This context-sensitive, everyday, routine-based approach to rehabilitation reverses the traditional "first impairment, then disability (functional activities), then handicap (participation), finally context" hierarchy in rehabilitation. Table 33-5 outlines this reversal. Within traditional rehabilitation, the initial goal generally has been to eliminate or reduce the

TABLE 33-4

Progression of Intervention Within a Functional Everyday Approach to Rehabilitation

Step 1	Identify successful and unsuccessful routines of everyday life: What is working, and what is not working?
Step 2	Identify what changes (including changes in the environment, in the behavior of others, and in the individual's own behavior) hold the potential to transform negative, unsuccessful routines into positive, successful routines and to build repertoires of positive behavior.
Step 3	Identify how those changes in everyday routines can become motivating for the individual and for critical everyday people in that environment.
Step 4	Implement whatever supports are necessary for intensive practice of positive routines in real-world contexts.
Step 5	Systematically withdraw supports and expand contexts as it becomes possible to do so.

From Ylvisaker and colleagues (1999); with permission.

underlying impairment with decontextualized exercises or medical interventions. If these efforts are insufficiently successful, the intervention has tended to shift to attempts to equip the individual with compensatory behaviors to perform functional activities and overcome the ongoing disability. Finally, in the event of insufficiently successful disability-oriented interventions, the focus again shifts, this time to attempts to increase the individual's participation possibilities by focusing on the environmental context: simplifying tasks, modifying the environment, and increasing the support behaviors of others in the environment. This traditional approach often is most efficient in the case of physical restoration—and in other domains as well, if reason exists to believe that decontextualized, restorative, impairment-oriented interventions are effective. Research and clinical experience, however, give little reason for such optimism in the case of individuals with significant chronic cognitive and psychosocial impairment after TBI.

Reversing the traditional hierarchy does not imply abandoning the goal of reducing the individual's underlying impairment. Rather, impairment is potentially reduced as a result of internalizing habits of action and interaction that may have originated as deliberate compensations for chronic impairment. For example, a person who uses a graphic organizer to succeed in complex vocational planning tasks or discourse tasks may internalize the organizer so that it becomes an automatically applied knowledge structure, thereby reducing the original underlying impairment. Several case illustrations have been presented in which impairment reduction was a long-term outcome of intervention that

TABLE 33-5

Two Perspectives on Relations Between Impairment-Oriented, Disability-Oriented, and Handicap-Oriented Interventions for People with Chronic Cognitive, Communication, and Behavioral Impairment after Brain Injury

I. THE TRADITION IN REHABILITATION

First: Attempt to eliminate the individual's underlying impairment with impairment-oriented treatments.

- Medical treatments (e.g., neuropharmacology, surgery)
- Impairment-oriented exercises

Second: Attempt to improve performance of daily activities and increase participation if impairment-oriented treatment is insufficiently successful.

- Practice with compensatory procedures
- Extensive practice of specific functional activities

Third: Attempt to modify the social, vocational, or educational contexts if impairment- and disability-oriented interventions are insufficiently successful.

- Modification of tasks, routines, and the environments in which they take place
- Modification of the support behaviors of other people in the environment
- Modification of the attitudes of important people in the environment

II. AN ALTERNATIVE PERSPECTIVE

First: Increase participation by modifying everyday routines, including the support provided by everyday people in the environment.

Second: Potentially, improve performance of daily activities by including functional compensatory procedures in the individual's everyday routines and ensuring intensive context-sensitive practice in the use of those compensatory procedures.

Third: Potentially reduce the underlying impairment by ensuring that the individual practices compensatory procedures—in increasingly varied contexts—to the point at which they are internalized and become components of his or her automatic cognitive or self-regulatory mechanism.

From Ylvisaker and colleagues (1999); with permission.

began with participation-oriented and context supports for successful performance of everyday activities (Ylvisaker & Feeny, 1998a, 2000a; Ylvisaker et al., 1999).

Rationale for a Context-Sensitive, Everyday, Routine-Based Approach to Executive System, Cognitive, Social, and Behavioral Rehabilitation

Theoretical Support: Developmental Cognitive Psychology

For many years, our work in cognitive, social, and behavioral intervention for children and adults with TBI has been

guided, in part, by the theoretic formulations of the great Russian psychologist Lev Vygotsky. Over the past 30 years, his work has enjoyed a striking renaissance in many applied fields, including educational psychology (see, e.g., Brown, Campione, Weber, & McGilly, 1992; Campione & Brown, 1990), developmental cognitive psychology (see, e.g., Berk, 2001; Flavell et al., 2002), reading instruction (see, e.g., Palinscar & Brown, 1989), early childhood education (see, e.g., Berk & Winsler, 1995; Bodrova & Leong, 1996), special education (see, e.g., Ashman & Conway, 1989; Evans, 1993), child language disorders (see, e.g., Schneider & Watkins, 1996; Westby, 1994), and other professions. In light of Vygotsky's lifelong influence on the work of his colleague, Alexander Luria (Luria, 1979), it is rather surprising that relatively little attention has been paid to Vygotsky's work in adult neurologic rehabilitation (Ylvisaker & Feeney, 1998a).

According to Vygotsky, internal cognitive and self-regulatory functions, beyond those that are instinctive or purely sensorimotor, are derived in childhood (and later) from internalization/appropriation of interaction with others who are more competent within the context of social-communication routines. "Higher mental functions evolve through social interactions with adults; they are gradually internalized as the child becomes more and more proficient and needs less and less cueing and other support from the adult" (Vygotsky, 1981, p. 261). Thus, cognitive processes like remembering, organizing, and problem solving, as well as self-regulatory processes like self-instructing, first exist as supported interpsychological processes—that is, as interaction between a child or other "apprentice-in-thinking" and a more mature thinker. Gradually, the processes are internalized and become internal, or intrapsychological, processes. Within cognitive and psychosocial rehabilitation, clinicians and other ECPs play a role comparable to expert-parents in relation to apprentice-children, with the goal of equipping the client with the cognitive, communication, and self-regulatory skills needed for success in his or her chosen contexts of life.

The apprenticeship metaphor, which often is used to capture the spirit of Vygotsky's theories (Rogoff, 1990), helps in translating a developmental theory into operational terms during adult rehabilitation. Table 33-6 contrasts two different approaches to teaching: the traditional behavioral training model, and a Vygotskian apprenticeship model. The latter underpins interventions described later in this chapter.

Theoretical Support: Cognitive Neuroscience and Neuropsychology

Commonly observed neuropsychological profiles following TBI—and most leading neuroscience theories designed to explain these profiles—can be understood as lending support to an everyday, routine-based approach to rehabilita-

tion. For example, Damasio's frontal lobe injury dilemma can be resolved with supported everyday routines of action and interaction as the basis for learning and successful behavior. Context dependence, highlighted by Mesulam and others as being central to the diverse manifestations of frontal lobe injury, yields an alternative neuropsychological rationale for a context-sensitive, everyday, routine orientation to rehabilitation. Grafman's theory of executive processes as complex representations stored in the prefrontal cortex lends further support for a systematic, routine-based approach to rehabilitation. The limitations of information processing capacity associated with diffuse injury as well as with frontal lobe injury can similarly be addressed with automatized routines of action and interaction in everyday contexts. Finally, increasing evidence supports errorless learning practices with individuals who have severe memory impairments associated with TBI-related damage to the hippocampus. Real-world apprenticeship teaching offers the possibility of rehabilitation interventions that are, at the same time, ecologically valid as well as designed to minimize errors.

A Rehabilitation Dilemma and Its Resolution

Ylvisaker and Feeney (1998a) borrowed from the work of Antonio Damasio in building neuropsychological support for an everyday, routine-based approach to rehabilitation after TBI. In his classic book *Descartes Error*, Damasio (1994) sketched an apparently destructive dilemma associated with frontolimbic injury. To be successful in everyday activities, it appears that one must either (1) make good decisions, based on careful consideration of the information available and memory for past successes and failures (the "high reason" approach), or (2) act on the basis of learned behaviors derived from one's personal history of reinforcement (the operant or "somatic marker" approach). Unfortunately, frontolimbic injury jeopardizes both routes to successful action.

Success via high reason presupposes reasonable planning skill, adequate space in working memory for consideration of many relevant factors, adequate explicit memory for past actions and their consequences, reasonable ability to inhibit impulsive action, and an ability to flexibly transfer learning from one context to another. People with significant frontolimbic injury tend to be impaired in all of these cognitive functions, jeopardizing the high reason approach to successful decision making and action.

Success via learning from consequences presupposes reasonable intactness of the neural circuits that are responsible for connecting two types of memory: memory for the factual aspects of past behavior, and memory for the "somatic markers" or feeling states associated with the consequences of those behaviors. Without such connections in memory (however unconscious they may be), past rewards and

TABLE 33–6**Features of Teaching Tasks: Traditional Training Model Versus Vygotskyan Apprenticeship Model****Traditional Training Model****Context**

- Training takes place outside of a natural setting.
- Performance of the learner is demanded by the trainer.
- Performance is solo, not social.
- Tasks and components of tasks are hierarchically organized.

Task structure

- The trainer requests performance of a specific task.
- The trainer may model performance.
- The learner performs.
- If the performance is adequate, the learner is reinforced.
- If the performance is inadequate, the trainer either:
 - Requests a hierarchically easier task.
 - Reduces the difficulty of the task.
 - Provides needed cues, prompts, shaping procedures.
- When performance is adequate, repeated practice is required to habituate the learned behavior.
- Systematic transfer procedures are then applied.

Vygotskyan Apprenticeship Model**Context**

- Learning (ideally) takes place in a natural setting for the behavior or skill that is to be learned.
- Learning takes place within the context of projects designed to achieve a meaningful goal.
- Performance is not demanded from the learner; rather, the task is completed collaboratively.
- Completion of the task is social, not solo.
- The learner is not expected to fail; the collaborator is available to contribute whatever the learner cannot contribute to successful completion of the task.
- Tasks are not necessarily organized hierarchically; the learner can learn aspects of difficult tasks by participating with a collaborator.

Task structure

- The teacher (facilitator, collaborator) introduces a task and engages the learner in guided observation (not necessarily task specific).
- The teacher engages the learner in collaborative, functional, goal-oriented, project-oriented work.
- The learner contributes what he or she can contribute.
- The teacher coaches (including suggestions, modeling, brainstorming, cues, feedback, and encouragement) and continues to collaborate as the learner accomplishes more components of the task.
- As the learner improves, supports are systematically withdrawn, the task is made more difficult, or both.
- The teacher continues to provide ongoing incidental coaching.
- Transfer is guaranteed because it is part of the context-sensitive teaching process from the outset of the teaching process.

From Ylvisaker and Feeney (1998a); with permission.

punishments lack the power to drive future decision making and behavior. Extensive investigations of adults with frontal lobe injury have convinced Damasio and colleagues that ventromedial prefrontal lesions, which are very common in CHI, weaken the ability to connect these two types of memory, resulting in the common clinical profile of people who respond immediately to rewards and punishments but whose behavior in the long run is inefficiently shaped by the organized arrangement of such consequences (Damasio, 1998; Damasio, Tranel & Damasio, 1990, 1991; Tranel, 2002).

Some clinicians respond to this dilemma by suggesting (a) that consequences must be much more extreme than is commonly necessary or (b) that individuals with significant frontolimbic injury may require a substantial degree of external control indefinitely. In our view, escaping through the horns of this dilemma requires the development of contextually relevant cognitive, communication, and behavioral habits, acquired with the help of antecedent-focused apprenticeship procedures (see Tables 33–3 and 33–6 for operational definitions) rather than relying on consequences to shape behavior, as in traditional training models of intervention and traditional behavior management. In the section on behavioral and psychosocial rehabilitation (below), we return to this theme of relative inefficiency in learning from consequences.

Related to the somatic marker theory is Roll's view, based on extensive research with primates and humans, that the key function of ventral prefrontal cortex, in particular the orbitofrontal cortex, is to distinguish rewarding consequences and to modify behavior in relation to changing contingencies (Rolls, 2002). This explains the observed phenomenon of individuals with frontal lobe injury failing to learn from the consequences of their behavior. Rolls also attempts to bring more general frontal lobe phenomena under this reinforcement-learning umbrella, including difficulty sorting, shifting, and changing direction; perseverating; euphoria; irresponsibility; lack of affect; lack of concern/egocentrism; socially inappropriate and disinhibited behavior; and impaired perception/identification of facial and voice emotion—with associated alteration of emotional processing and increased disinhibition and behavioral problems. The theory of Rolls, like that of Damasio and colleagues, provides a comfortable theoretical home for intervention based on the creation of positive, everyday, context-sensitive routines of action and interaction.

Context Dependence and Frontal Lobe Injury

Mesulam's (2002) review of frontal lobe function and dysfunction highlights, as its central theme, that the frontal lobes enable humans to transcend "the default mode" of inflexible stimulus–response linkages tied to the immediate stimulus environment. From this central theme evolve the

commonly observed deficits associated with frontal lobe injury:

1. Poor working memory (i.e., difficulty expanding consciousness beyond the here and now)
2. Distractibility, perseveration, and disinhibition
3. Difficulty with decision making in novel situations
4. Impaired integration of reason, experience, and emotion
5. Inflexibility, insensitivity to contextual subtleties, failure to appreciate ambiguity, and difficulty with abstract thinking
6. Cognitive egocentrism or difficulty switching perspectives (otherwise known as impaired "theory of mind")

Each of these themes is addressed within an intervention perspective that is context sensitive and attempts to build repertoires of successful behavior, thinking, and self-regulation triggered by environmental stimuli specifically relevant to the individual being served. Mesulam also uses his default mode theory to explain the well-documented ecological invalidity of office-bound assessments. (We will return to this theme in the section on assessment.)

Executive Dysfunction as Impairment of Structured Event Complexes

Grafman's theory of prefrontal function proposes that executive processes really are complex mental representations ("structured event complexes") at greater or lesser levels of generality (Grafman, 2002). Thus, "executive direction" of complex activities, understood neurologically, is activation of a complex knowledge structure that represents that activity. These representations or knowledge structures are strengthened by multiple experiences with activities in the world. Like the previous theories, Grafman's view supports an approach to rehabilitation that attempts to strengthen these complex knowledge structures by creating routines of action and interaction triggered by contextually appropriate environmental stimuli.

Limited Processing Capacity

Individuals with frontal lobe or diffuse neuronal pathology, both of which are common in TBI, often have limited processing resources (Schmitter-Edgecombe, 1996). These limited resources are easily exhausted, particularly in the context of novel, complex, or inadequately rehearsed activities. When additional demands are placed on those resources, activity failures and contextually inappropriate behaviors are likely to occur. Thus, we argue later that everyday activities as well as scripts of self-regulation should be practiced to habituation. Furthermore, this practice should take place within the context of everyday activities so that the environmental triggers are those that the individual will encounter in everyday life. The clinical need to automatize self-regulation

scripts is based on studies (see review by Schmeichel & Baumeister, 2004) showing that self-regulatory resources are depleted with effortful self-regulation.

Procedural Memory, Implicit Memory, and Errorless Learning

The superiority of implicit memory and learning over explicit memory and learning in many individuals with TBI provides additional support for an everyday, routine-based approach to rehabilitation and errorless teaching procedures. As we describe apprenticeship teaching, the teaching/learning process can be conducted either in a trial-and-error manner or in an errorless manner. Individuals with significant memory disorders associated with damage to the hippocampus benefit from errorless teaching procedures (described below). Thus, everyday habits and procedures of action and interaction can be learned without error and triggered by environmental stimuli, assuming that the teaching was adequately sensitive to context.

Empirical Support: Transfer (Generalization) and Maintenance

Decades of experimental studies of generalization and maintenance offer yet another support for a richly context-sensitive, everyday, routine-based approach to intervention. Many investigators in behavioral, cognitive, and educational psychology have amassed large quantities of evidence that yields the following heuristic principle: *Behaviors or skills acquired in a laboratory or training context are unlikely to transfer to functional application contexts and be maintained over time without heroic efforts to facilitate that transfer and maintenance* (Detterman & Sternberg, 1993; Horner, Dunlap, & Koegel, 1988; Martin & Pear, 1996; Morris, 1992; Singley & Anderson, 1989). Recognition of the impact of this principle has led to the development and validation of increasingly context-sensitive interventions in many clinical fields, including vocational rehabilitation (see, e.g., Wehman et al., 1993, 1995), special education (see, e.g., Giangreco, Cloninger, & Iverson, 1993), strategy intervention for students with and without specific disability (see, e.g., Baker, Gersten, & Scanlon, 2002; Pressley, 1995; Sweet & Snow, 2002), behavioral intervention (see, e.g., Carr et al., 1994; Carr, Reeve, & Magito-McLaughlin, 1997; Kennedy, 1994; Koegel, Koegel, & Dunlap, 1997; Reichle & Wacker, 1993), and language and social skills intervention (see, e.g., Fey, 1986; Gresham, Sugai, & Horner, 2001; Koegel & Koegel, 1995; MacDonald, 1989; Walker, Schwarz, Nippold, Irvin, & Noell, 1994; Wiener & Harris, 1998).

In our judgment, the use of decontextualized cognitive retraining exercises (popular during the 1980s for TBI rehabilitation and still used today by some practitioners) is insensitive to this important principle. Isolating components of cognition (e.g., selective attention, working memory, sequential or categorical organization, and deductive rea-

soning) and engaging people in massed learning trials with tasks largely unrelated to functional application tasks falls squarely in the tradition of decontextualized cognitive training that has been found to be relatively ineffective with many disability groups, including mental retardation (Mann, 1979), learning disabilities (Kavale & Mattson, 1983), and TBI (Carney et al., 1999; Cicerone et al., 2005; Park & Ingles, 2001), as well as in people without disability (Singley & Anderson, 1989). More than 100 years ago, William James made the same observation in connection with memory training: “the retention of particular things” but not “general physiological retentiveness,” can be improved with practice (James, 1890, p. 665). The systematically increasing use of everyday contexts for cognitive and behavioral interventions bears testimony to these concerns about transfer (Ylvisaker, 2003; Ylvisaker et al., 2003).

Economic Support: Managed Care and the Demand for Efficient Rehabilitation

A fourth category of support for an everyday, routine-based approach to rehabilitation is provided by the fierce economic realities that have come to play a prominent role in rehabilitation planning. Managed care and cutbacks in federal supports for rehabilitation have dramatically shortened the lengths of inpatient rehabilitation stay and reduced access to outpatient services (AHCPR, 1999; Johnson, 1999). Some funders routinely deny reimbursement for interventions, such as cognitive rehabilitation, that are said to have an inadequate research base. At the same time, funders increasingly demand improved functional outcomes in return for their limited support of rehabilitation (Henri & Hallowell, 1999; Schmidt, 1997).

Meanwhile, the prevalence of TBI-related disability continues to increase because of the population's relative youth at the time of injury. For example, over the past 10 years, the New York State Department of Health Neurobehavioral Resource Project has served more than 1,000 young adults who have a history of TBI and ongoing difficulty with community reintegration, often many years after their injury. This Medicaid waiver community support program was designed specifically for individuals with serious, chronic cognitive and behavioral impairment after TBI. Feeney and colleagues (2001) found that the program not only yielded positive outcomes for the participants but also proved to be cost-effective, yielding substantial savings for the New York State Department of Health. Under these stressful economic circumstances, it is critical for rehabilitation specialists to creatively design ways to accomplish more with less, to achieve positive outcomes with fewer resources. Inviting specialists to intensify their collaboration with everyday people (e.g., family members, direct care staff, job coaches, and others) so that long-term rehabilitation can be provided in large part in the context of the everyday routines of life

TABLE 33-7

Rationale for an Everyday, Routine-Based Approach to Intervention for Individuals with TBI**From the Perspective of Executive Functions**

- A. *Threat to Social Success:* Difficulty making good decisions based on thoughtful consideration of consequences and other relevant factors.
Possible Solution: Provide needed supports in everyday routines, stopping short of a degree of support that creates learned helplessness or oppositional behavior.
- B. *Threat to Social Success:* Reduced inhibition.
Possible Solutions: (1) Create everyday routines that include ample antecedent supports, such as positive setting events and avoidance of identified triggers; (2) help the individual self-manage antecedents.
- C. *Threat to Social Success:* Reduced initiation.
Possible Solution: Create everyday routines that include initiation supports, such as initiation scripts, initiation cues (e.g., alarm watch), and peer support for initiation.

From the Perspective of Cognition

- A. *Threat to Social Success:* Impaired working memory.
Possible Solutions: (1) Practice positive everyday routines so that they come to be elicited by everyday environmental cues, obviating the need for complex thought processes; (2) create prosthetic reminder systems (e.g., pager systems); (3) Create positive metaphors that package several pieces of information into one thought unit.
- B. *Threat to Social Success:* Impaired explicit and strategic memory; difficulty remembering past successes and failures.
Possible Solution: Proceduralize positive context-sensitive routines using implicit versus explicit memory processes, procedural versus declarative memory systems, and involuntary versus strategic or effortful learning tasks.
- C. *Threat to Social Success:* Reduced organizational skills.
Possible Solution: Create positive, everyday routines that include external organizers, possibly including graphic advance organizers.
- D. *Threat to Social Success:* Difficulty transferring newly acquired skills from training to application contexts.
Possible Solution: Facilitate acquisition of social competencies in the context of everyday social interaction.

From the Perspective of Behavior Management

- A. *Threat to Social Success:* Inefficiency in learning from consequences.
Possible Solution: Build repertoires of positive behaviors using antecedent supports versus relying on consequences to shape positive behaviors.
- B. *Threat to Social Success:* Oppositional behavior.
Possible Solutions: (1) As much as possible, work within the individual's world of meaning and personal goals; (2) tie interventions to positive personal metaphors or life narratives.

From Ylvisaker and Feeney (2000a); with permission.

represents a positive response to the crisis of funding for rehabilitation.

Summary

Table 33-7 summarizes ways in which an everyday, routine-based approach to rehabilitation addresses chronic obstacles to social success after TBI. Obstacles are grouped under the headings of executive functions, cognition, and behavior. Some of the solutions are elaborated later in this chapter.

ASSESSMENT FOR PLANNING FUNCTIONAL, CONTEXT-SENSITIVE INTERVENTION

Cognitive and communication assessments may be conducted for several distinct purposes, including (a) diagnosing

a disorder, (b) formulating a prognosis, (c) generating epidemiologic information, (d) preparing for legal testimony, (e) acquiring services or funding, (f) developing an intervention plan, and (g) monitoring the results of intervention. Specific assessment procedures may be valid for some, but not all, purposes of assessment. For example, a standardized aphasia battery may be useful in diagnosing a specific language impairment but offers little help in identifying the associated activity reductions (i.e., degree of difficulty following directions at work), participation limitations, and context facilitators and barriers. Furthermore, the tests may offer little guidance in creating the most fruitful approach to reducing the individual's impairment and increasing activity and participation domains.

Over the past 15 years, several standardized tests have been developed for use with adults who have TBI, including the Scales of Cognitive Ability for Traumatic Brain Injury

(Adamovich & Henderson, 1992); Ross Information Processing Assessment (Ross-Swain, 1996), or RIPA-2; Brief Test of Head Injury (Helm-Estabrooks & Hotz, 1991), or BTHI; Behavior Rating Inventory of Executive Function—Adult Version (Roth, Isquith, & Gioia, 2005); Behavioral Assessment of the Dysexecutive Syndrome (Wilson, Alderman, Burgess, Elmslie, & Evans, 1996); Measure of Cognitive-Linguistic Abilities (Ellmo, Graser, Krchnavek, Hauck, & Calabrese, 1995); Functional Assessment of Verbal Reasoning and Executive Strategies (MacDonald, 2005); Rivermead Behavioral Memory Test (Wilson, Cockburn, Baddeley, 1985); and others. Turkstra, Coehlo, and Ylvisaker (2005) discussed the strengths and limitations of standardized testing for individuals with TBI.

Standardized assessments can serve a variety of useful purposes. In this chapter, however, we restrict our discussion to assessment for purposes of planning, monitoring, and modifying individualized intervention. Functional intervention often is directed at reducing disability by improving compensatory behavior in specific functional contexts of activity or at increasing participation either by modifying the environment or by improving the support behaviors of others. In these cases, standardized, office-bound assessments are not particularly helpful.

In Table 33–8, we present categories of assessments, grouped under the headings of impairment, activity/participation, and context. This scheme for classifying assessment procedures may help clinicians to avoid the common pitfall of attempting to achieve an assessment goal by administering a type of assessment designed for other purposes. Furthermore, static versus dynamic assessments are contrasted. Whereas static assessment often is used for diagnosis, classification, and outcome monitoring, dynamic hypothesis-testing assessment is designed to identify the intervention and support procedures that hold the greatest promise for rehabilitation of the individual.

Functional, Collaborative, Context-Sensitive, Hypothesis-Testing Assessment for Planning Intervention

Elsewhere, we have described and illustrated an experimental approach to assessment that is consistent with the functional, everyday approach to intervention described in this chapter (Ylvisaker & Feeney, 1998a; Ylvisaker & Gioia, 1998). In the case of individuals with complex impairment and disability in the domains addressed in this chapter, assessment for purposes of planning intervention is ongoing, context-sensitive, collaborative, and based on careful tests of hypotheses. This approach to assessment has its historical roots in Vygotsky's dynamic assessment (Vygotsky, 1978), as elaborated by Feuerstein (1979) and, more recently, by many practitioners in educational psychology (see, e.g., Palinscar, Brown, & Campione, 1994), special education, speech-language

TABLE 33–8

Approaches to Communication Assessment for People with Traumatic Brain Injury

Impairment-Oriented Assessment

Purpose:	For diagnosis: to identify underlying neuropsychological, including linguistic and motor, strengths and weaknesses
Static:	Standardized neuropsychological tests and test batteries Standardized aphasia tests and test batteries Standardized motor speech tests
Dynamic:	Process assessment: to identify what intact neuropsychological process explains successful performance and what affected processes explain unsuccessful performance, using systematic hypothesis-testing modification of test items (Kaplan, 1988)

Activity/Participation-Oriented Assessment

Purposes:	For diagnosis: to identify possible effects of neuropsychological impairments on real-world performance of functional activities and associated limitations of social, vocational, and educational participation For treatment planning: to identify everyday activities that require intervention and to identify strategies that may improve performance
Static:	Customized: Observation of performance of functional tasks of everyday life Standardized: Functional scales (e.g., American Speech-Language-Hearing Association FACS, FIM, and DRS)
Dynamic:	Experimentation with strategies and supports that hold the potential to improve performance of daily activities (OCCHTA)

Context-Oriented Assessment

Purposes:	For treatment planning: to identify facilitators and barriers in the environment; to identify environmental modification strategies that may enhance participation; to identify strengths and needs of everyday communication partners (e.g., family members, friends, job supervisors, and teachers) relative to their ability to serve as supports for the individual with ongoing disability; and to identify changes in the behavior of communication partners that may enhance successful participation
Static:	Standardized: Quality-of-life inventories Customized: Observation of and interviews regarding level of participation and level of success in social, familial, academic, and vocational pursuits and roles
Dynamic:	Context-sensitive experimentation with environmental supports and with potentially helpful changes in the support behaviors of others (OCCHTA)

pathology, and other fields. Behavioral psychologists have a long history of assessment by means of experimental analysis of variables that potentially influence behavior (Iwata, Vollmer, & Zarcone, 1990; Kern, Childs, Dunlap, Clarke, & Falk, 1994). Our goal in this section is restricted to presenting a brief rationale for this type of assessment and an outline of the steps of functional, hypothesis-testing assessment (Ylvisaker et al., 1999).

Rationale

Why Ongoing?

Following severe TBI, individuals can continue spontaneous neurologic recovery for months and, in some cases, years. This by itself mandates ongoing assessment. In addition, changes in environmental and task demands, in the individual's ability levels and psychoreactive responses, and in the skill levels of everyday people in the environment all contribute to ongoing unpredictability in evolving outcome, inviting ongoing assessment to ensure that services and supports are maximally effective.

Why Context Sensitive?

The ecological validity of office-bound, standardized tests of cognitive and communication functioning for individuals with TBI (or, more specifically, frontal lobe injury) has been challenged by the results of many neuropsychological studies (Anderson, Damasio, Tranel, & Damasio, 2000; Benton, 1991; Burgess, Alderman, Evans, Emslie, & Wilson, 1998; Cr  peau, Scherzer, Belleville, & Desmarais, 1997; Dennis, 1991; Dywan & Segalowitz, 1996; Eslinger & Damasio, 1985; LeBlanc, Hayden, & Paulman, 2000; Rath, Simon, Langenbahn, Sherr, & Diller, 2000; Stuss & Benson, 1986; Stuss & Buckle, 1992; Tranel, 2002; Turkstra et al., 2005; Varney & Menefee, 1993). Some individuals with impairment of executive function perform better on standardized tests than one would expect based on real-world performance, because the tests are externally structured and impose few demands in the areas of goal setting, task identification, initiation, self-monitoring, or real-world strategic thinking. Others perform surprisingly poorly on standardized tests, because the tasks are novel and the familiar stimulus cues of everyday life are not present to support performance. In either case, tests must be supplemented by effective use of real-world contexts in functional assessment.

Why Collaborative?

Collaboration increases the number of observations that can be made, the number of real-world contexts that can be explored, and the number of functional experiments that can be performed. In addition, when many people collaborate in assessment, the likelihood that these same people will collaborate in implementing the intervention plan resulting

from the assessment is increased. Participation in collaborative assessment also is an ideal way for everyday people to learn about the realities associated with the disability. Finally, asking professional colleagues, aides, family members, and others to become collaborators in assessment is a profound statement of respect and, therefore, contributes to team building.

Why Tests of Hypotheses?

Many capacities, processes, and skills are involved in most human behavior. Therefore, if a person has trouble with a task, there typically are scores of potential explanations for that difficulty. Similarly, when a person succeeds, that success may be a product of varied strategies (Kaplan, 1988). If specialists in rehabilitation do not know why people succeed when they succeed or what underlying impairment explains failure when they fail, these specialists are not in a position to create a meaningful, appropriately targeted intervention program. Therefore, alternative hypotheses must be tested.

Assessment Process

Ylvisaker and Feeney (1998a) illustrated the processes of collaborative, context-sensitive hypothesis-testing assessment. In each case, the process included collaborative identification of the problem, collaborative formulation, selection and testing of hypotheses, and collaborative interpretation of the findings in relation to planning interventions and supports.

Collaboratively Identify the Problem

In some cases, little difficulty exists in identifying the functional problem that calls for intervention. In other cases, however, it is not so easy. For example, the same behavioral issue may be identified by one person as defiance, by another as withdrawal, and by still others as lack of initiation or laziness. In these cases, it is critical to agree to a neutral description of the problem behavior before proceeding.

Collaboratively Formulate Hypotheses

Hypotheses may be derived from neurodiagnostic information, neuropsychological or other testing, clinical experience with similar individuals, or real-world interaction with the person whose intervention plan is being developed. Typically, teams of professionals and others have little difficulty in generating possible explanations for the person's behavior or proposing intervention plans. It may not be as easy to label one's favored explanation as a hypothesis and then subject it to testing along with other hypotheses. This is precisely the process, however, that enables teams to move beyond conflict over treatment plans and to identify interventions that have a demonstrable effect.

Collaboratively Select Hypotheses to Test

Some hypotheses may be easier to test than others, and some may have greater face validity than others, more interesting implications for intervention than others, and be embraced by more members of the team than others. Selecting hypotheses to test—and the order in which to test them—requires balancing these considerations. In general, it is important to start with hypotheses that are readily testable, with results that will be recognized and accepted by all members of the team.

Collaboratively Test Hypotheses

In some cases, several hypotheses can be tested within a short period of time and, possibly, within a controlled assessment setting; in other cases, the process extends for weeks and mandates exploration in several real-world settings. In some cases, hypothesis testing is designed to explore the impact of hypothesized variables one at a time; in other cases in which the issue to be explored is serious (e.g., aggressive behavior) and requires immediate attention, it may be desirable to combine hypotheses—that is, to experiment with a multifaceted intervention. If the complex hypothesis is confirmed (i.e., if the intervention is successful), it may not be possible to know which individual hypotheses were confirmed and in what combination, but at least the clinical problem is solved. Feeney and Ylvisaker (1995) presented three single-subject experimental designs that fit this description.

Collaboratively Interpret the Results and Formulate an Intervention Plan

In many cases, the test is, in effect, a trial intervention. If the trial intervention works well, then the treatment plan may follow in a relatively automatic manner. In other cases, the treatment plan may be an elaboration of the initial experiments. When people have chronic disability in the executive system, cognitive, communication, and behavioral domains, intervention often takes the form of supportive modifications of everyday routines—modifications that were identified as positive by means of hypothesis testing (Ylvisaker & Feeney, 1998a).

Context-Sensitive, Experimental Assessment in the Early and Middle Stages of Recovery

Early in neurologic recovery, context-sensitive experimental assessment from the perspective of cognition, communication, and behavior is designed, in part, to identify the conditions under which the individual is maximally alert, externally focused, and responsive to environmental stimuli. Variables that need to be explored include time of day; the sensory environment (e.g., lighting, auditory stimuli, and

tactile responsiveness); responses to positioning, movement (e.g., rocking) and temperature (e.g., warm bath); levels of medication; and differential responses to people and their communication styles. The goal of this systematic exploration is to maximize the amount of time the individual spends at the highest levels of responsiveness, to minimize stimulation associated with pathologic responses or withdrawal, and to encourage basic levels of communication (e.g., reaching for desired objects or pushing undesired objects away). In addition, staff explore ways in which the individual can be supported in participating in activities of everyday life (e.g., self-care, turning on and off lights, and controlling sources of stimulation like tape-recorded music). Once appropriate supports are identified, family members and nursing staff are encouraged to engage the individual frequently in meaningful activities of everyday life, even if the individual appears to give little response at the time.

During the middle stage of recovery, context-sensitive experimental assessment from the perspective of cognition, communication, and behavior largely is designed to identify the environmental and task supports that are needed to perform adaptively on activities of daily living as well as on personally meaningful communication, educational, vocational, recreational, and social tasks. The supports and scaffolding highlighted later in this chapter (Table 33–9) often are the variables manipulated experimentally to identify the nature of the disability and the supports that are useful in increasing participation and improving everyday functional activities (Table 33–9).

Illustration of Context-Sensitive, Collaborative Hypothesis Testing

Sue incurred severe TBI at age 35 in a motor-vehicle crash. In addition to diffuse injury, neurodiagnostic imaging revealed significant left hemisphere frontotemporal damage. Before her injury, Sue was employed as a laborer in a large factory. She had a history of marital conflict, and her two children had been removed from her home as a result of neglect and suspected abuse.

At the time of our involvement, Sue was 47 years old and had been a resident of a nursing home for 12 years. She had been diagnosed with serious cognitive-language impairment (including anomia, circumlocution, and wandering, tangential discourse), disorganized behavior in all domains of life, episodic and semantic memory impairment, reduced anger control, and physically aggressive behavior. With newly available community support funding through a Medicaid waiver program, she was placed in a supported apartment and given a job in a developmental disabilities sheltered workshop. In the social environment of that work setting, Sue's aggression escalated.

Local staff proposed that she be returned to the nursing home until she demonstrated the communication and anger

TABLE 33-9

Illustration of Functional, Content- and Context-Sensitive Executive Function/Cognitive Rehabilitation Through the Continuum of Recovery: Organization, Memory, Language, and Executive Functions

Client: Tom is a 30-year-old, married father of two with a pretrauma avocational and vocational interest in baseball cards. He collected cards and traded them at shows and on the Internet. Residual impairment in the areas of executive functions (e.g., self-awareness, planning, organizing, and self-monitoring), memory, and organization of language were associated with frontolimbic injury.

Long-Term Goal: The client will regulate his behavior adequately to manage his baseball card collection and resume trading with minimal assistance.

Facilitators: Therapists, family members, direct care staff, friends.

Early Stages (Maximal Support)	Middle Stages (Moderate Support)	Late Stages (Relative Independence; Support as Needed)
EF-Cognitive-Language Goals: • Increase alertness and arousal. • Improve external focus. • Increase recognition of objects and people. • Increase engagement in overlearned activities. • Improve basic communication: comprehension of simple, everyday language; expression of basic wants, needs, and reactions.	EF-Cognitive-Language Goals: • Increase duration of attention; ability to shift attention from object to object and activity to activity; ability filter out distractions. • Improve perceptual scanning abilities. • Use organizing schemes, including external organizers, to complete functional tasks. • Use a prosthetic log/memory system to aid orientation, organization, memory, and self-management. • Improve organization of spoken and written discourse, with external supports. • Improve awareness of needs and strategies to compensate for deficits.	EF-Cognitive-Language Goals: • Improve awareness of self as a thinker, learner, communicator, and self-manager. • Increase independent use of strategies to compensate for ongoing cognitive deficits. • Improve organization of discourse with decreasing use of external organizers. • Improve comprehension of vocabulary and extended texts related to vocational and avocational interests. • Improve independent goal setting, planning, initiating, and self-evaluating. • Increase independent creation, implementation, review, and revision of compensatory strategies.
Meaningful Activities/Everyday Routines: • Turn pages of a baseball card album or collector book. • Move cards in and out of album sleeves. • Stack cards as others look at them. • Find particular cards on the page. • Help find all the cards from a team. • On request, hand the cards to visitors to see. • Place cards into rows for viewing. Transfer Activities: • With support, participate in self-care activities and other activities of daily living. • With prompts, activate switches to control electronic devices (e.g., TV or tape recorder).	Meaningful Activities/Everyday Routines: • Organize cards by team or value. • Write names of players on each team. • Show and describe cards to others, including children. • Read/write short narratives or biographical sketches about players; describe players to others (e.g., in group therapy). • Determine value of cards and list prices. • Role play selling cards at a show; determine costs for purchase of various combinations of cards. • Explain features of card trading to peers in group therapy; prepare script in advance with the help of a graphic organizer. Transfer Activities: • Use graphic organizers and written reminders for other tasks (e.g., activities of daily living on the nursing unit, writing letters to family members). • Plan menus, prepare own lunch. • Organize narratives and descriptions of experiences to offer visitors.	Meaningful Activities/Everyday Routines: • Use sales books and the Internet to determine availability and cost of cards. • Purchase and organize new cards in the collection. • Keep financial records. • Read and write articles about baseball card collecting. • Create organized displays for card shows. • Set up a display at a card show. • Interact with visitors at a card show. • Help his children with their collections. Transfer Activities: • Assist other individuals with traumatic brain injury at an earlier stage of recovery or with greater disability. • Work with his children in the use of organizing systems for their homework. • Develop strategies and organizers for other demanding activities (e.g., banking or shopping).

(continued)

Illustration of Functional, Content- and Context-Sensitive Executive Function/Cognitive Rehabilitation Through the Continuum of Recovery: Organization, Memory, Language, and Executive Functions (continued)

- Review family picture albums.
- Look at greeting cards.

Facilitator Expectations and Mediation:

- Facilitator is responsible for modifying the environment and stimulus presentation to fit Tom's response potential.
- Facilitator treats Tom's actions, even if accidental, as meaningful and makes them seem appropriate to the situation (e.g., touching a card is interpreted as a request).
- Facilitator associated simple language with actions (e.g., "Let's see if we can find a Yankee; no, that's a Dodger.").

Scaffolding:

- Facilitator may be required to perform all components of the task, but collaboratively engaging Tom in any way possible (e.g., hand-over-hand joint performance of the task).

Log/Journal/Memory Book:

Facilitators keep a log of Tom's significant experiences and progress. The system is used, in part, to help facilitators identify factors that promote improved cognitive and adaptive functioning and to communicate with one another. Facilitators review the log with Tom with the ultimate goal of improving recall of daily events and establishing a routine of review.

- Play simple card games with children.
- Write letters, thank you cards.
- Use goal-plan-do-review format in all therapies, including physical therapies.

Facilitator Expectations and Mediation:

- Facilitator ensures that the environment is appropriate for efficient information processing.
- Facilitator gradually turns over more components of tasks to Tom.
- Facilitator changes prompts from physical (e.g., hand-over-hand) to verbal (simple instructions) to graphic (e.g., graphic organizers such as price sheets, inventory sheets, discourse guides for narrative and biographical sketches, feature analysis guide for organizing full descriptions and practicing organized word retrieval).
- Facilitator begins all activities with identification of the goal and formulation of a plan (e.g., use of an organizer), monitors progress ("Let's make sure we're getting the job done right."), ends all sessions with review of achievement ("Did you finish? How'd you do?") and usefulness of supports (e.g., "Did this organizer help?"), and helps Tom record important information in a memory book for future reference.
- Facilitator highlights improvements and the value of the supports that are used, helping Tom gain greater insight into his strengths and needs.

Scaffolding:

- In addition to cues and organizers, the facilitator uses verbal mediation to highlight the important aspects of each component of the task, routinely reviews the goal, plan, and progress, models organized thinking, makes connections to related activities.

Log/Journal/Memory Book:

Tom gradually assumes greater responsibility for management of the log/memory book system. He begins to write his own entries, with guidance. The book plays a meaningful role in helping Tom stay oriented, know his schedule, plan activities, remember important events, and keep track of goals and assignments. Photographs of staff, well-organized schedules, and graphic organizers for important tasks are included in the book.

- Continue to use goal-plan-do-review format for major life activities.

Facilitator Expectations and Mediation:

- Tom increasingly assumes responsibility for creating organizing systems to accomplish home and work tasks; facilitator (e.g., therapist, Tom's wife) may simply play a monitoring role.
- Tom assumes responsibility for independent use of memory aids; facilitator engages Tom in brainstorming if systems fail.
- Tom assumes responsibility for independent use of organizing systems (e.g., graphic organizers; prepared scripts) to communicate (speak and write) in an organized manner; facilitator provides feedback.
- Tom assumes primary responsibility for self-management (e.g., sets goals, makes plans, initiates work, evaluates self and products, and chooses strategic compensations); facilitator encourages daily use of executive function routines and brainstorms with Tom about strategies.

Scaffolding:

- Facilitator plays an ongoing role as coach (if necessary), consultant, and source of emotional support. As a consultant, the facilitator helps Tom identify barriers to success (e.g., inattention to scheduled responsibilities, reading comprehension problems, disorganized record keeping, gaps in his knowledge base) and develop customized strategies to overcome them.

Log/Journal/Memory Book:

Tom has primary responsibility for upkeep and use of the book, which may become more like a traditional day planner to organize daily events and facilitate memory. An outline of needs and strategies may continue to be included. An electronic pager system and/or computer memory system may be used.

management skills as well as the positive attitude needed to live and work in the community. Sue's opposing view, which she offered in emotionally strong language, was that she would do fine if she had a meaningful life, including work in a "real" work setting. The staff insisted that she must first demonstrate work and interpersonal skills in a sheltered setting. With considerable encouragement, staff were convinced to treat Sue's proposal as a testable hypothesis. With the approval of her preinjury boss, Sue was placed in her old job with detailed, negotiated plans for asking for help when needed and for anticipating and dealing with frustration. Relevant employees in the factory were oriented to Sue's cognitive and communication deficits and given scripts to negotiate routine, work-related interaction. A job coach was used for less than a month. Four years later, Sue continues to be successful in her nonsupported job and community living—an achievement made possible, in part, by framing alternative recommendations (those of the staff versus that of Sue) as hypotheses to be tested collaboratively and using real-world routines as the context for those tests.

TBI REHABILITATION: EXECUTIVE FUNCTIONS/SELF-REGULATION AS THE UNIFYING THEME

In our discussion of disability associated with TBI, we offered a definition of executive functions, tied it to the more general concept of self-regulation (using the hybrid term "executive functions/self-regulation" [EF/SR]), and stated that we would organize the intervention sections of the chapter around this unifying concept. Most cognitive problems of people with TBI (e.g., poorly controlled attention, weak encoding and retrieval of new information, and impaired planning and organizing), communication problems (e.g., disorganized discourse and impulsive or otherwise unsuccessful social communication), and behavioral problems (e.g., aggression and sexually inappropriate behavior) can be traced to weak executive control over their cognition, communication, and behavior as opposed to problems specific to the domain. This is not universally true, however, and in our discussion below, we do address memory problems that are not a consequence of frontal lobe injury and, therefore, could be seen as independent of the EF/SR system. Yet even in these cases, the most common approach to intervention is compensation for the problem as opposed to restoration of function. Therefore, the EF/SR system again becomes the key to successful rehabilitation.

Following general comments about executive functions/self-regulation, our discussion of intervention is divided into four main sections:

1. EF/SR interventions, including the processes of facilitating compensatory strategies in general and discourse strategies specifically.
2. Cognitive rehabilitation, including a critique of traditional processes-specific cognitive retraining and discussions of memory aids, errorless learning for individuals with severe memory impairment, and the use of virtual reality (VR) in rehabilitation.
3. Social communication intervention, including a critique of traditional social skills and pragmatics training.
4. Behavioral intervention, including a critique of traditional contingency management, a discussion of positive behavior supports, and a special focus on teaching positive communication alternatives to negative behavior.

Executive Functions/Self-Regulation: An Intervention-Relevant Operational Definition

In Appendix 33.1, the executive system is included as a component of cognition. In this limited and "cold" sense of the term (Denckla, 1996), executive functions direct and regulate cognitive processes. Thus, people with frontal lobe injury may perform well on tests of intelligence and may appear to attend, perceive, organize, learn, and reason adequately under highly structured and externally directed conditions but, because of executive system impairment, fail to use their cognitive processes effectively under real-world conditions.

In discussions of TBI and frontal lobe injury, executive functions often are highlighted for separate consideration in their role as planner, initiator, and regulator of all aspects of behavior, not just cognitive processes. Understood most generally, the executive self-regulatory system includes those mental functions involved in formulating goals, planning how to achieve them, carrying out the plans, and revising those plans in response to feedback (Lezak, 1982; Luria, 1966). In this broad sense, the same set of control functions directs all deliberate, nonroutine behavior, including cognitive (e.g., paying attention in the presence of distractions), emotional (e.g., controlling anger), communication (e.g., planning an effective way to express a complex or sensitive thought), social (e.g., inhibiting aggressive behavior when provoked), educational (e.g., using effective reading and writing strategies), and vocational (e.g., planning a day at work to complete a large number of assigned tasks). Earlier in this chapter, we explicitly tied our discussion of EF/SR to important literatures in related fields. Table 33-10 offers a functional operational definition of the executive system, based in part on analysis of the characteristics (beyond intellectual, linguistic, and motor skills) that enable successful people to be successful—that is, to make efficient real-world use the abilities and knowledge that they possess.

In discussions of neuropsychological rehabilitation, executive functions often are characterized as being high on a hierarchy of cognitive functions and, therefore, an inappropriate target for intervention until late in recovery after most aspects of cognition have undergone substantial recovery.

TABLE 33–10

A Functional Operational Definition of the Executive System

1. Awareness of strengths and limitations, and associated understanding of the difficulty level of tasks.
2. Based on this awareness, an ability to:
 - Set reasonable goals.
 - Plan and organize behavior designed to achieve the goals.
 - Initiate behavior toward achieving goals.
 - Inhibit behavior incompatible with achieving those goals.
 - Monitor and evaluate performance in relation to the goals.
 - Benefit from feedback.
 - Flexibly revise plans and strategically solve problems in the event of difficulty or failure.
3. Ability to assume a non-egocentric perspective and “read” others’ mental states.
4. Ability to think abstractly and transfer skills from training to application contexts.

Unfortunately, this hierarchical view is insensitive to developmental studies of both immature primates (Goldman, 1971) and humans (Bjorklund, 1990; Bronson, 2000; Welsh & Pennington, 1988). Recent work in developmental cognitive psychology strongly suggests a developmental course for executive functions characterized by early onset of development (in infancy); slow maturation of functions (continuing through the adolescent years); dynamic interaction with other aspects of cognitive, linguistic, and social development; and modifiability of development with experience and training (Bjorklund, 1990; Bronson, 2000; Tranel, Anderson, & Benton, 1995; Welsh & Pennington, 1988). Indeed, one of the most popular and successful curricula for preschoolers with and without disability, the High Scope Curriculum, organizes preschool activities around a simple, executive function, goal-plan-do-review routine (Schweinhart & Weikart, 1993). Recognizing the profound importance of executive functions for success in life and with these developmental themes as background, we introduce executive functions as a rehabilitation target relatively early in recovery, along with all other aspects of cognition (see Table, 33–9 and 33–11).

Executive Function Intervention Themes**Executive Function/Self-Regulatory Scripts and Development of Autonomy**

Ylvisaker, Szekeres, and Feeney (1998) described a variety of interventions that address specific components of executive functioning. Our goal in this section is to highlight the core of EF/SR intervention by describing routines or scripts of interaction organized in such a way that the individual gradually internalizes the script as automatic, self-regulatory

self-talk. Thus, the theme is facilitation of automatic self-regulation or EF/SR habits via internalized, self-regulatory self-talk (Ylvisaker & Feeney, in press). The section ends with a discussion of empirical evidence.

The general notion that thinking, including self-regulatory self-talk, is internalized speech has a varied and venerable lineage, including classical philosophy (see, e.g., Plato in the *Phaedrus*), classical behavioral psychology (see, e.g., Skinner, 1953), and classical developmental cognitive psychology (see, e.g., Vygotsky, 1934). Often, the operation of these self-regulatory executive functions is assumed to be conscious and deliberate. Indeed, many theorists draw a sharp contrast between self-regulated behavior on the one hand and automatic or habitual behavior on the other. Fitzsimons and Bargh (2004) disputed this dichotomy by summarizing evidence showing that self regulation—that is, “the capacity of individuals to guide themselves . . . toward important goal states” (p. 151)—can be active, dynamic, complex, and *automatic*. Automatic EF/SR behavior in adults is illustrated by the habit or automatically triggered routine of fastening the seat belt when entering an automobile. The clinical need to automatize EF/SR scripts is based on studies (for review, see Schmeichel & Baumeister, 2004) showing that self-regulatory resources are depleted with effortful self-regulation. Individuals with frontal lobe or diffuse neuronal pathology often have limited processing resources even without placing additional demands on those resources with deliberate self-regulation (Schmitter-Edgecombe, 1996).

Consistent with the Vygotskian theme of thinking as self-talk internalized from interaction with more competent members of the culture, Landry and colleagues recently documented a significant association between parents’ interactive style and growth in the preschool child’s executive self-regulatory functions, specifically problem-solving skills (Landry, Miller-Loncar, Smith, & Swank, 2002; Landry, Smith, Swank, Assel, & Vellet, 2001; Landry, Smith, & Swank, 2003). Effective parental scaffolding (including hints, prompts, and other verbal supports) at age 3 predicted high scores on executive function measures at age 6. In educational psychology, teacher “scaffolding” for problem solving (i.e., hints that facilitate success without taking over the problem-solving activity) have been shown to facilitate self-determined learners (Reeve, 2002; Reeve, Bolt, & Cai, 1999). Because many professionals take over the executive, self-regulatory aspects of functioning for individuals with disability, they should be alerted to the importance of engaging their clients in scripted EF/SR routines, providing whatever support may be necessary but stopping short of threatening the development of learned helplessness. Larsen and Prizmic (2004) reviewed the available developmental evidence regarding affect-regulation strategies, including self-talk strategies, that might be encouraged within these everyday routines of interaction.

Table 33–11 includes examples of specific EF/SR scripts as well as the most general goal-obstacle-plan-do-review

TABLE 33–11

Examples of Executive Function/Self-Regulation (EF/SR) Scripts of Interaction Designed to be Used at Appropriate Times in Real-World Contexts with the Goal of Having the Individual Internalize EF/SR Self-Talk

The words can be customized for specific individuals, and delivery should be conversational, non-punitive, and motivating. Questions can be used rather than statements if you are confident that the individual can answer the question.

General EF/SR Script: Goal-Obstacle-Plan-Do-Review

1. This is the goal (what do you want to accomplish, make happen; what will it look like when you're done?).
2. This might be hard because . . . So you need a plan; how about . . .?
3. Do it.
4. Review it: How did it work out? What worked for you? What didn't work? What adjustments need to be made?

Hard/Easy Script

1. This seems to be kind of hard (or easy) for you (or Hard or easy for you?).
2. I think it's hard (easy) because . . . (or Why do you think it's hard/easy?).
3. Because it's hard, you should probably . . . (or What do you think you can do?).
4. There's always something that works.

Ready/Not Ready Script

1. I think you are ready now (or You ready?).
2. You look ready because . . . (or What makes you think you're ready?).
3. Because you're ready, you can . . . (or What do you think you should do?).
4. There's always something that works.

Problem-Solving Script

1. This seems to be a problem.
2. It's a problem because . . . (or Why is this a problem?).
3. Let's see if this works . . . (or What do you want to try to solve the problem?).
4. There's always something that works.

Big Deal/Little Deal Script

1. I think this is a big deal (or not a big deal) (or Is this a big deal?).
2. It's a big (or little) deal because . . . (or Why is it a big deal?).
3. Because it's a big (little) deal, you . . . (or What do you think you should do?).
4. There's always something that works.

Scary/Not Scary (Dangerous/Not Dangerous) Script

1. This is kind of dangerous (or not dangerous) (or Do you think this might be dangerous?).
2. It's dangerous (or not) because . . . (or Why dangerous?).
3. Because it's dangerous, you . . . (or What do you think you should do?).
4. There's always something that works.

What About You Script

1. It's important to know what John thinks/John feels (or What's John's perspective?).
2. It's important because . . . (or Why should you try to get into John's head?).
3. Here's a way to find out (or How can you find out what John's perspective is?).
4. There's always something that works.

Experimental Script

1. You and I have different ideas about how to get this done.
2. We disagree because . . . (or Why do you suppose we disagree?).
3. Let's try it both ways and see what works best.
4. There's always something that works.

script, listed first because it is a simple operational definition of executive self-regulatory functioning that should pervade the facilitation process from preschool through adulthood. As a rule, successful people facing important decisions (a) make choices about what they wish to accomplish, (b) set reasonable goals for themselves (based on their understanding of their strengths and limitations), (c) identify obstacles to achieving the goals, (d) create intelligent plans for achieving the goals (possibly predicting their level of success), (e) act on the plans, and (f) review their performance, profiting from the feedback they receive (what worked and what did not work) (Meichenbaum & Biemiller, 1998). Often, these processes operate in a relatively automatic manner (Bargh & Chartrand, 1999). These same self-regulatory processes can—and should—become routine for people with disability, from preschoolers through adults. Clearly, people with significant impairment of executive function require considerable support from others to engage in these intellectual processes and, ultimately, make them habitual. Precisely such habits, however, are the goal of executive function intervention.

Figure 33–8 presents a guide for addressing the executive components of any task. With relevant modifications (e.g., simplifying the routine for people with substantial impairment), this general schema can be used to incrementally improve everyday routines of self-regulation. To remind individuals with disability and their caregivers to use the routine, we frequently post brightly colored reminders with the words GOAL-OBSTACLE-PLAN-DO-REVIEW and help family members, staff, and the person with TBI to become comfortable with simple, conversational use of the routine.

Scripts similar to those listed in Table 33–11 can be devised for strategy exploration routines, social self-control, and the like. The goal is to associate the scripts with the everyday occurrences for which that self-regulatory thought process would be helpful. With repetition and gradual reduction of supports, these scripts can then be internalized as relatively automatic, self-regulatory thought processes triggered by relevant environmental events. For some individuals, the scripts can be framed as questions (e.g., “Is this a big deal or a little deal?”); for others, questions should be avoided, particularly for those individuals whose anxiety is aroused by questions or who would have difficulty answering the question accurately. In some cases, it is important for clinicians to formulate the script for the individual carefully. In each case, the scripts should be delivered in a supportive, conversational manner using language that the person understands and reacts to positively. Ideally, these scripts are used frequently (while avoiding boredom and nagging) and within everyday action contexts when the person ideally should have use of the script as self-regulatory self-talk. To avoid negative associations with the scripts, the positive versions (e.g., easy, little deal, not a problem, and not scary) should predominate early in the facilitation process.

For many adolescents and young adults, particularly those with experience in sports (strongly valued in many cultures), we have framed this self-regulatory self-talk as self-coaching (Ylvisaker, 2006). Individualized self-regulatory (self-coaching) “plays” can be negotiated with the person and then videotaped during role-playing activities in which the words of the “self-coach” are used by the client, and perhaps, negotiated cueing words can be used by staff or other ECPs. The video also should include a meaningful rationale for the “play,” possibly including relevant information about brains as well as about situations in which the play is important. In other words, the goal is not only to improve self-regulation of behavior and emotions but also to increase understanding of the personal and social worlds—all within the compelling context of personally meaningful sports metaphors. The video can then be repeatedly viewed, much as an athlete views game films, to improve performance by internalizing the self-coaching script.

Commonly used adolescent and young adult “self-coaching plays,” in addition to those core plays listed in Table 33–11, include the following:

1. “Am I sure?” For example, am I sure that John is angry at me; did I interpret his behavior correctly? (Sports: Has the quarterback called the right play for this defense, or should he change the play at the line of scrimmage?)
2. “What exactly am I trying to accomplish?” For example, do I have a major test to study for or an important project at work? (Sports: Who’s the opponent this week?)
3. “What’s the game plan? What do I need to do to win?” For example, what do I need to do to prepare for this test? (Sports: What’s the game plan?)
4. “How’d I do?” For example, did I get a low grade because I didn’t study enough? What will I do the next time? (Sports: Review the game films.)
5. “Call time out! Spike the ball! Get organized!” For example, I feel overwhelmed, but maybe if I just stop and organize my tasks, I’ll get back on track. (Sports: Call time out.)
6. “Let’s think about that.” For example, I feel like smacking him, but maybe I’d better get the facts. (Sports: Should the coach throw the replay flag or not?)

For sports-minded adolescents and young adults, sports metaphors should be used liberally to create positive associations with effortful self-regulation. For those who are not sports minded, a variety of other positive metaphors are available, such as “self-direction” (drama, film), “self-guiding” (hiking), “self-choreographing” (dance), “self-supervising” (business), and “self-conducting” (music).

Evidence for Self-Regulatory/Self-Talk Interventions

Self-talk interventions have been studied with a variety of disability populations, mainly children and adolescents.

Figure 33–8. A guide for explicitly teaching or highlighting the executive components of any task. This form can be simplified to goal-obstacle-plan-do-review for ease of remembering. (Reproduced from Ylvisaker, Szekeres, and Feeney, 1998; with permission.)

Although this book is devoted to interventions for adults, evidence from the adolescent literature is relevant in this chapter, because many of the patients and clients in adult TBI programs are adolescents or young adults. The most thoroughly studied self-talk/self-regulation intervention is cognitive behavior modification (CBM) (Meichenbaum, 1977). Barkley (2004) reviewed the reviews and meta-analyses of CBM applied to adolescents with attention-deficit/hyperactivity disorder (ADHD; understood as an EF disorder) and concluded that, despite documentation of statistically significant improvements, the literature has failed to demonstrate clinically meaningful outcomes. Missing from Barkley's review, however, was a meta-analysis in which the investigators restricted their review to studies in which the intervention was delivered in the setting in which the problems were occurring. Robinson, Smith, Miller, and Brownell (1999) wisely restricted the scope of their meta-analysis to studies implemented in everyday school settings for adolescent students with aggressive behavior associated with ADHD. Twelve studies (with 36 effect size measures) yielded a large mean effect size of 0.64, or a 24-percentile rank increase for the CBM subjects compared to controls.

It is reasonable to interpret this positive meta-analysis—particularly in contrast to earlier pessimistic reviews—as underscoring the importance of a culture in which the interventions are embedded within the routines of everyday life, especially for children and adolescents with EF/SR impairment. Consistent with this interpretation, Berk (2001) pointed out that clinic-based CBM is not consistent with its purported Vygotskian roots. Rather, modeling and coaching for self-regulatory self-talk should be provided within the individual's authentic tasks and settings. The approach described in this chapter is fully consistent with Berk's authoritative advice.

Reid, Trout, & Schartz (2005) completed a meta-analysis of peer-reviewed studies that examined the effectiveness of more specific self-regulation interventions for children with ADHD. The four interventions examined were self-monitoring training, self-monitoring plus reinforcement, self-reinforcement, and self-management (combining self-monitoring, self-rating, and self-evaluating). Each of these interventions can be readily incorporated within the scripts listed in Table 33–11. The 16 studies, which included 51 participants, were mainly single-subject experiments with elementary school students, implemented in their educational setting. Large effect sizes (greater than 0.8) were found for most of the interventions in relation to most of the outcome variables: on-task behavior, socially appropriate behavior, and academic accuracy and productivity. Furthermore, the self-regulation interventions showed a strong additive effect in those cases in which the children were simultaneously treated pharmacologically. Averaging across all interventions and outcomes, the effect sizes were greater than 1.0.

The meta-analysis of Reid and colleagues (2005) regarding executive function interventions for children with

ADHD contrasts sharply with the results of a randomized, controlled clinical trial reported a year earlier by Abikoff and colleagues (Abikoff et al., 2004; Hechtman et al., 2004). These investigators found that none of the behavioral or psychosocial interventions for students with ADHD added to the effect size produced by medication alone. These contradictory findings can, perhaps, be explained by some combination of the following two differences: (1) The behavioral and social interventions in the study by Abikoff and colleagues were decontextualized and, therefore, poorly conceived in relation to what is known about the underlying impairment; and (2) the positive meta-analysis of Reid and colleagues mainly considered single-subject experiments. Single-subject studies tend to use highly individualized and context-sensitive interventions (in contrast to group intervention protocols like those used in the Abikoff et al. study), to select subjects likely to benefit from the intervention, and to terminate the study in the event of likely failure of the intervention.

Graham and Harris (2003) presented results of a meta-analysis of 18 experimental studies that yielded large to very large effect sizes across a variety of outcome measures using their executive function academic curriculum, self-regulated strategy development. This program embeds several self-regulation scripts within its teaching routines. At least two additional studies have evaluated the effectiveness of teaching-learning routines in which the adolescent student is trained to use something like the goal-obstacle-plan-do-review EF/SR routine described in Table 33–11. Martin and colleagues (2003) found that a plan-work-evaluate-adjust routine, delivered in the context of everyday academic lessons, improved the self-regulated learning of intellectually normal students in a residential school for students with severe emotional and behavioral problems.

Wehmeyer, Palmer, Agran, Mithaug, & Martin (2000) evaluated the effectiveness of the Self-Determined Learning Model as applied to 40 adolescents with mild mental retardation, learning disabilities, or emotional/behavioral disturbance. Teaching-learning routines included 12 self-addressed questions that the students used to guide their learning behavior. Again, the goal-obstacle-plan-do-review EF/SR routine described in Figure 33–8 was represented in these questions:

- **Goal** “What do I want to learn?”
- **Obstacle** “What could keep me from taking action?”
- **Plan** “What can I do to make this happen?”
- **Do** “When will I take action?”
- **Review** “Do I now know what I want to know?”

Teacher facilitation of these self-talk questions resulted in goal attainment beyond teacher expectations and improvements on standardized measures of self-determination. No significant differences were found among the three disability groups, suggesting equal effectiveness across disabilities.

The lesson to be derived for clinicians from the variety of overlapping studies is that an underlying intervention theme

can be operationalized in a variety of ways in a variety of settings with a variety of individuals. Therefore, rigid adherence to a specific model is clinically dangerous.

Functional Approaches to Executive Function and Cognitive Processes and Systems through the Continuum of Recovery

In Table 33–9, we present a plan for improving cognitive functioning for a specific individual who improved slowly after TBI and retained residual cognitive impairment. The focus of intervention in this case included organization, memory, language, and general executive functions, although any aspect of cognition could be targeted within this everyday, routine-based framework. The table includes appropriate goals, activities, and daily routines within which the intervention plan was implemented (including transfer activities) as well as a description of the types of mediation and support used at each phase. Project-oriented rehabilitation was used with Tom (Table 33–9) during both the middle and late stages of his cognitive recovery. Ylvisaker, Feeney, and Capo (2007) explore project-oriented interventions and supports in post-acute rehabilitation. We use the term “facilitator” to refer to people who have regular interaction with the person with disability (e.g., family members, direct care staff, therapists, teachers, job coaches, friends, co-workers, and others) and who therefore are in a position to use everyday activities and routines of life to facilitate improved cognitive functioning. Table 33–9 also suggests evolving uses for a log or memory book system over the continuum of recovery.

Clearly, specific activities and routines as well as specific intervention emphases within the broad domain of cognition vary from individual to individual. Our goal in offering the detailed intervention plan in Table 33–9 is to encourage clinicians to similarly apply, in an individualized manner, the intervention framework described earlier to specific individuals, integrating their goals, interests, needs, support systems, and routines of life.

Compensatory Strategies and Strategic Behavior

In the general five-step template for functional, everyday, routine-based intervention (Table 33–4) and also in the description of Tom’s cognitive and executive function intervention (Table 33–9), we highlighted the use of compensatory procedures. Compensatory strategies are procedures—sometimes unconventional—that an individual deliberately uses to achieve goals that cannot be achieved without such special effort. Although the ultimate goal of intervention is habituation (“routinization”) of the procedures so that their use need not consume limited attentional resources, we emphasize the word “deliberate” to distinguish this sense of “strategy” from the general notion of organized behavior, which often is referred to as a strategy, even if not

deliberate, and from instructional or treatment strategies, which are procedures used by therapists and teachers.

Strategies designed to compensate for cognitive deficits may involve the use of external aids (e.g., memory book, printed reminders, maps, task guide, alarm watch, electronic organizer, or pager system). External memory aids are discussed in the section on cognitive rehabilitation. Alternatively, a person might compensate using overt behavior (e.g., requesting clarification or repetition) or covert behavior (e.g., self-reminders, mental rehearsal or elaboration, or structured thinking procedures). Appendix 33–3 includes a large number (by no means exhaustive) of strategic procedures that appropriately selected individuals can use to compensate for selected cognitive and communicative deficits.

Compensatory strategies may be used temporarily in the case of transient impairment. Alternatively, they may be used indefinitely to reduce the functional disability of people with chronic impairment. Compensatory procedures may require effort initially but, with sufficient practice, become a routine component of the individual’s automatic processing system, thereby possibly reducing the underlying impairment. Unfortunately, as discussed in earlier sections, the parts of the brain associated with strategic thinking and behavior (i.e., the frontal lobes) are particularly vulnerable in TBI. Therefore, intervention designed to equip individuals with strategic procedures for overcoming obstacles is, at the same time, extremely important and extremely tricky.

It is tempting to conceive of strategy intervention as being no different from other teaching—that is, the clinician identifies the client’s needs, selects an appropriate strategy, selects appropriate teaching procedures, teaches the strategy, and then monitors and evaluates the outcome. The client’s role is, therefore, to follow the clinician’s lead and acquire the strategic procedure. If strategies are what strategic people do, however, then this model of teaching must be thought of as **antistrategic strategy intervention**, because all the truly strategic, problem-solving behavior is assumed by the clinician. In denying the client the right to participate in the strategic aspects of strategy learning, the clinician might inadvertently contribute to the client’s learned helplessness—that is, passive reliance on others to solve critical problems posed by cognitive and communicative weakness. Furthermore, not only does this model of teaching fail to promote truly strategic behavior, it also has been found to fail the litmus tests of generalization and maintenance when applied to a variety of populations of impaired learners (Flavell, Miller, & Miller, 2002; Meichenbaum & Beimuller, 1998; Pressley, 1995; Pressley & Associates, 1990).

Following Pressley’s advice to structure strategy intervention around a model of a good strategy user (Pressley, Borkowski, & Schneider, 1989), therefore, has clinical wisdom. Such a model serves not only to identify a variety of diverse goals that may be components of this intervention but also helps to separate reasonable from risky candidates

for strategy intervention. Truly strategic people have the following characteristics:

- They have goals to which strategies are relevant.
- They know that their performance needs to be enhanced, that strategies enhance performance, and that they are capable of using strategies.
- They know when, where, and why to use specific strategic procedures.
- They monitor and evaluate the effectiveness of their performance so that being strategic is its own reward.
- They know a number of strategic procedures, can select the procedure most relevant to a particular challenge, and can flexibly modify it as needed or create new procedures.
- They use strategic procedures frequently so that they become relatively automatic and require little effort or planning.
- They have adequate “space” in working memory so that they can think about the task at hand and the strategic procedures at the same time (assuming that the strategies have not become automatic).
- They are not so impulsive that they habitually act before considering a strategic maneuver. (Context-sensitive automatization may overcome this obstacle.)
- They are not so anxious that they neglect strategic behavior because of their focus on fear of failure.
- They have the support of teachers, employers, and family members to use strategies.
- They know enough about the subject at hand that they can meaningfully use strategies to learn more.

Ideal candidates for strategy intervention are individuals who have specific goals; are aware of their needs; have sufficient meta-cognitive maturity to think about thinking, communicating, and other cognitive issues; are disposed to strategic behavior (e.g., like to play games of strategy); have adequate attentional resources; are motivated; have reasonable self-control; and live in supportive environments. College students returning to school after a mild to moderate injury often fall into this category. At the other extreme, individuals who are extremely weak in many of these dimensions may require considerable support to use all but the most simple external aid strategies (e.g., printed schedules or maps). For most people with TBI, strategy intervention includes attempts to improve functioning in a variety of domains (outlined above) that are related to strategic behavior.

Selection of the areas for compensation and of specific strategic procedures must involve active engagement of the client, which frequently includes a tension between his or her natural strategic inclinations and the judgment of the clinician. Brainstorming and experimentation with alternative strategies (Table 33–12) help to resolve this tension. The ultimate test of the appropriateness of the strategy is spontaneous, automatic use and improved performance in natural

settings. Intervention will inevitably fail if clients do not see the usefulness of the strategy relative to their goals or if the strategy does not fit the individual’s overall style of learning, interacting, and coping. For example, it is quixotic at best to expect shy and generally noninteractive individuals to enthusiastically adopt an input control strategy that requires them to request that speakers slow down or clarify and simplify their language. Variables to be reviewed in negotiating the selection of strategies include:

- Whether the procedure is used spontaneously
- Whether its degree of complexity and abstractness fits the client’s cognitive level
- How difficult the procedure is to use relative to its payoff
- Whether it fits the client’s profile of neuropsychological strengths
- Whether it fits the client’s personality
- Whether it specifically addresses obstacles to the individual’s concrete goals

In Table 33–12, we outline intervention procedures that we have found to be useful in working with individuals who have TBI. The three components are very roughly sequential but should not be considered as mutually exclusive or hierarchical. For example, attempts to promote improved awareness of strengths and weaknesses (part of Component I) often continue throughout a client’s entire rehabilitation program. In addition, work on generalization (Component IV) should begin early, before a procedure is habituated in a clinical setting.

In summary, our experience in helping individuals with TBI to become increasingly strategic underscores the importance of the following principles of strategy intervention:

1. Intervention should be embedded in natural, meaningful activities and settings, with strategic procedures specifically related to the client’s goals.
2. The individual should be maximally engaged in experimenting with strategies, using the general goal-obstacle-plan-do-review format, selecting the strategies to use, and monitoring their effectiveness.
3. Intervention should be intensive and long term.
4. Goals should be modest.
5. Other things being equal, simple, low-tech options often are preferable to complicated, high-tech options, and external supports (e.g., graphic organizers for complex tasks or memory books) often are preferable to internal elaboration and organization strategies (Evans, Needham, Wilson, & Brentnall, 2003).
6. The environment as a whole should be supportive of and promote strategic thinking and strategic behavior.

In the absence of sensitivity to these principles, strategic compensations for cognitive or others impairments are unlikely to be maintained over time (Wilson & Watson,

TABLE 33–12

Teaching Compensatory Strategies

Note: These components of intervention are not necessarily hierarchical or mutually exclusive.

Component I: General Strategic thinking

A. Meta-cognitive Awareness

Goals: Clients will discriminate effective from ineffective performance; become increasingly aware of their strengths and needs; recognize implications of their deficits.

Rationale: Given the frequency of frontolimbic and right hemisphere damage in TBI, self-awareness is frequently compromised. Individuals are unlikely to acquire and use procedures designed to compensate for problems that they do not recognize as problems.

Procedures:

1. **Objective:** Improve the client's perception of successful versus unsuccessful task performance.
Procedures: Illustrate successful and unsuccessful performance of a functional task through role play or on videotape. With the client, analyze the performances in sufficient detail that the client can identify the features that account for successful versus unsuccessful performance.
2. **Objective:** Improve the client's ability to perceive functional impairments.
Procedures: Individually, request that the client make note of specific deficits of other clients in the program or of individuals observed on tape. Discuss these observations. Planned peer teaching is useful. Discuss the effects of TBI on cognitive and social functioning. If appropriate, read and discuss literature on the effects of TBI.
3. **Objective:** Improve the client's awareness of his or her own strengths and weaknesses.
Procedures: Videotape the client in activities designed to reveal strong and weak areas of functioning. (Alternatively, use role play.) Review the tapes (beginning with strong performance), first without commentary, subsequently inviting comments about what was done well and what needs improvement. Gradually turn over to the client the responsibility for stopping the tape when problems are noted. **Note:** Considerable desensitizing may be needed before video self-viewing is possible.
4. **Objective:** Improve the client's understanding of the relation between deficits and long-term goals.
Procedures: Discuss in concrete detail the individual's long-term goals and expectations. Jointly create a list of specific skills and resources needed to achieve these goals. Jointly identify the skills that are present and those that are weak relative to this goal.

Note: These meta-cognitive discoveries are facilitated if the activities are personally meaningful and intimately connected to the client's goals.

B. Value of Being Strategic

Goal: Clients will recognize the importance of being strategic and will identify the characteristics of strategic people.

Rationale: Since the ultimate goal of this intervention is to promote strategic thinking and strategic behavior in general—not simply to teach specific strategic behaviors as routines—it is important that the client understand what it is to be strategic and that these are valuable attributes.

Procedures:

1. **Objective:** Improve the client's understanding of strategy.
Procedures: Using games, sports, or other relevant model, clarify the concept of strategy as something that one does to achieve goals when there are obstacles.
2. **Objective:** Heighten the client's appreciation of strategic behavior.
Procedures: Together with the client, identify several individuals who are known to be very strategic (e.g., sports heroes or military heroes). Discuss why they are considered to be heroic. Clinicians also should clearly model their own strategic behavior and discuss the value of their own strategies.
3. **Objective:** Improve the client's understanding of the behaviors that are part of being strategic.
Procedures: Using models relevant to the client (e.g., military, sports, or business analogies), brainstorm about the characteristics of people who are known to be very strategic. Include high level of motivation and initiative; ability to identify and clarify obstacles to goals; ability to plan procedures to overcome obstacles; ability to monitor and evaluate performance; willingness to engage in ongoing problem solving.

Component II: Selecting Specific Strategic Procedures

Goal: Clients will identify specific procedures useful in overcoming important personal obstacles.

Rationale: It is important that clients participate in the selection of strategic procedures that they will use and that the procedures be truly useful in achieving their goals.

(continued)

TABLE 33–12

Teaching Compensatory Strategies (continued)

Procedures: 1. Use group brainstorming procedures to identify possible strategies. 2. Use “product monitoring” tasks to test the value of strategies: Have the client perform a task with and without the strategy or with a variety of different strategies. Objectively compare the results. (Video analysis may be useful here.) 3. Have advanced clients demonstrate the value of certain procedures or offer testimonials. 4. Discuss the widespread use of compensatory procedures (e.g., lists, memos, tape recorders, and so forth) by people who do not have brain injury. Component III: Teaching Specific Strategies Note: If the discovery procedures in Component II (e.g., brainstorming and product monitoring) are effective, there may be little need for specific teaching procedures. Procedures: A. Modeling: The steps in the strategy can be modeled by the therapist, by a peer, or by means of videotape or other media. Modeling is initially accompanied by overt verbalization of the strategy by the model. The client then rehearses the strategy with gradually decreasing cues and self-talk. B. Direct Instruction: The carefully programmed behavioral teaching procedures of direct instruction can be used to teach strategies. If this is the only approach used, however, the best result likely will be the acquisition of a learned sequence of behaviors (which may be a desirable outcome) without positive movement in the direction of becoming a strategic person. C. Functional Practice: However the strategy is acquired, it must be frequently rehearsed in natural settings using functional activities. Component IV: Generalization and Maintenance Generalization of strategic behavior beyond the context of training is a combined consequence of the perceived utility of the strategy for the individual, the inherent generalizability and utility of the strategy, widespread environmental support for strategic behavior and thinking, intensive practice in a variety of real-world contexts, and specific teaching procedures designed to enhance generalization. Note 1: Generalization includes generalized use of specific strategies as well as strategic behavior in general. Note 2: Generalization may not be a separate phase if the acquisition stage takes place in the context of functional activities and natural settings. This is particularly important for very concrete people. Note 3: Generalization may be a relatively unimportant phase of intervention if the individual has acquired a strategic attitude and actively seeks occasions for transfer. Note 4: Some individuals may need environmental reminders indefinitely to use their strategic procedures. 1. Objective: Improve the client’s discrimination of situations that require or do not require a given strategy. Procedures: Use videotaped scenes or role playing to illustrate the correct use of a strategy in an appropriate situation, inappropriate use of the strategy, and failure to use the strategy when appropriate. Discuss the conditions that require the strategy. Use short videotaped scenes to train the client in efficient and accurate judgments as to whether a strategy is appropriate in a context. 2. Objective: Increase the client’s spontaneous use of strategies in varied situations. Procedures: Include family members, work supervisors, and teachers in strategy intervention to (1) provide varied opportunities for the use of specific strategies and of strategic behavior in general, (2) reinforce the client’s use of strategies, and (3) model strategic behavior themselves. Ask clients to keep a log in which they record their successes and failures in strategy use. Make generalization an explicit goal. 3. Objective: Increase the client’s acceptance of strategic behavior. Procedures: Ensure that the client is successful using strategies. Promote emotional acceptance of strategic behavior by using whatever motivating procedures work (e.g., personal images or metaphors, testimonials, and the like).

Key: TBI = traumatic brain injury.
Modified from Haarbauer-Krupa, Henry, Szekeres, and Ylvisaker (1985); with permission.

1996). The TBI literature contains an increasing number of reports regarding the effectiveness of compensatory strategy intervention (Carney et al., 1999; Cicerone et al., 2005; Kennedy et al., 2007, accepted), but a much larger evidence base exists in educational psychology (Baker et al., 2002; Gersten, Fuchs, Williams, & Baker, 2001; Martin et al., 2003; Pressley & Associates, 1990; Resnick, 1987; Sweet & Snow, 2002), which Pressley (1993) has attempted to apply to the field of cognitive intervention after TBI. Meichenbaum (1993) discussed the application

of a related set of intervention procedures, CBM, to TBI rehabilitation.

Strategies and Discourse Impairment

For language specialists, discourse represents the intersection of language skill, cognitive/organizational schemas, facility with perspective taking (to be sensitive to the needs of communication partners), and strategic direction of organizing schemas to specific contexts and material. Effective discourse requires action planning in the verbal domain (Alexander, 2002). Organizational difficulties, as a component of executive function impairment, often result in difficulty organizing thoughts and behavior for effective learning and performance of activities of daily living, complex work activities, efficient word retrieval, expressive discourse tasks (speaking and writing), extended text comprehension, and other complex social, educational, or vocational tasks that require organization.

Grafman's neuropsychological theory of specific event complexes and managerial knowledge units (Grafman, 2002, 1995; Grafman et al., 1993) maintains that the foundation for focused attention, organized thinking and talking, efficient remembering, effective planning, and success with any organizationally demanding task lies in the effective use of organized knowledge structures (schemas) of greater or lesser generality with respect to domains of content. "Managerial knowledge unit" is a particularly felicitous phrase in its identification of the need for neurologic management of complex behavior. Discourse, understood as the organization of language over many sentences, requires management for successful communication of complex ideas. Effective application of these knowledge schemas relies on the development of domain-specific knowledge and intactness of frontal lobe structures, explaining much of the disorganized discourse of individuals with impairment of executive function associated with prefrontal brain pathology.

Some discourse schemas or managerial knowledge units are tightly structured, such as the organizational structure of scientific reports, basic narratives, and menus. Others are less structured, such as describing a vacation or persuading a friend to give up smoking. Left hemisphere dorsolateral prefrontal damage tends to result in discourse that is impoverished in both words and themes. Individuals with right hemisphere damage may be verbose, tangential, and socially awkward in their discourse. Impaired theory of mind, associated with prefrontal damage (more right than left), causes inattention to the needs and tolerance of listeners and, therefore, socially ineffective discourse (Alexander, 2002).

Ylvisaker, Szekeres, and Haarbauer-Krupa (1998) discussed organizational impairment within a neuropsychological framework and presented a variety of intervention and support approaches. Advance organizational supports for complex tasks, including graphic organizers of a variety of

types, have become an evidence-based standard of practice in many settings in which disorganized individuals are supported. Bulgren and Schumaker (2006) reviewed 19 successful studies of advance organizers, all with adolescent participants with or without disability. Graphic organizers also are commonplace supports for nondisabled adults, including maps, blueprints, and sequences of pictures to guide individuals through the assembly of products that are sold unassembled.

Perhaps the most studied discourse structure in both children and adults is narrative structure or story grammar. Elementary students benefit from a clear flow diagram that includes the components of a narrative as they attempt to comprehend and produce stories more effectively. We have used a similar graphic organizer for adults with TBI in a literacy group. The organizer has three side-by-side boxes at the top for characters, place, and time. The remaining boxes progress downward in a linear manner and include the initiating event (that starts the narrative action), the main characters' reactions to that event, the plan that is developed, the ensuing action, and the resolution. Because this also is the organization of the mental representation of everyday events in life, this organizer is particularly important. As the components of narrative structure are internalized, the diagram can be gradually faded. Ylvisaker, Szekeres, and Haarbauer-Krupa (1998) presented a variety of graphic advance organizers and procedures for their implementation. A critical feature of organizers is that they accurately capture the organization of that which is to be organized. Many graphic organizers available in special education materials are visually attractive but fail to meet this obvious standard (e.g., representing a narrative as circular rather than linear).

Specific Cognitive Interventions

Cognitive rehabilitation, in a meaningful and broad sense of the term, includes all the interventions described in the previous sections under the heading of executive functions. For purposes of exposition in this chapter, we have separated out specific cognitive themes for discussion in the current section. After offering a functional operational definition of cognition, we present a critique of traditional, process-specific cognitive retraining exercises. We then discuss themes in cognitive rehabilitation that have received special attention over the past decade, memory aids, errorless learning, and the use of virtual reality in rehabilitation.

Cognition: An Intervention-Relevant Operational Definition

Because of the complexity of cognition and the relationships among its components, as well as the variety of theoretical descriptions of cognition and its development in childhood (see, e.g., Ashcraft, 1994; Barsalou, 1992; Dodd & White, 1980; Flavell, Miller, & Miller, 2002; Siegler & Alibali, 2004), the construction of a coherent and manageable

framework for cognitive-communication intervention becomes a major challenge. Just such a framework is critical, however, because it helps clinicians to avoid a haphazard and inefficient “workbook” approach to treatment, facilitates communication among professionals and between clinicians and clients, promotes systematic observation and program evaluation, and serves as a source of intervention principles and procedures.

Appendix 33.1 presents a scheme for organizing descriptions of behavior from a cognitive perspective. The scheme is based generally on information processing theories of cognition, wherein cognition is viewed broadly as the processing of information for particular purposes within specific mental structures and environmental constraints and directed by the executive control system (Dodd & White, 1980). In our clinical work, we have found it productive to describe cognitive functioning and recovery in terms of three general aspects of cognition: (1) processes, (2) systems, and (3) functional-integrative performance. Each of the processes and systems relates, in identifiable ways, to language and communication.

Profiles of cognitive impairment after TBI can be varied and complex, requiring thorough exploration with formal neuropsychological assessments and, more importantly for treatment purposes, context-sensitive hypothesis-testing, as described earlier. Treatment decisions are further driven by decisions about relationships among cognitive processes and systems. For example, a person with TBI may process information slowly, appear to be inattentive, forget easily, show evidence of disorganized thinking and behavior, misperceive social cues, respond impulsively, and appear to have lost social and vocational knowledge. These may be separate impairments, but more likely, at least some are related. For example, problems with memory, organization, and social perception all may be secondary to attentional impairment. Alternatively, difficulty attending and slowed processing may be caused, in part, by loss of organizing schemes and preinjury knowledge, which also may reduce memory efficiency. Hypothesis testing with alternative support strategies helps to answer these questions, which often are left unanswered by comprehensive neuropsychological assessment.

An understanding of cognition from a developmental perspective (Flavell, Miller, & Miller, 2002; Siegler & Alibali, 2004) is useful in avoiding common pitfalls in cognitive rehabilitation for adults. Clinicians who believe that cognitive processes are serially ordered in development are naturally inclined to embrace a hierarchical progression in rehabilitation, first addressing components of attention and then, perhaps, perception, organization and memory, and finally, executive control over cognitive processes. This model is inconsistent with the essential interrelations among components of cognition that dominate cognitive development in children and yields an inefficient and misguided approach to intervention.

Decontextualized Cognitive Retraining

In the early period of program development for survivors of severe TBI, cognitive rehabilitation was understood by many practitioners as being an enterprise that involved (a) hierarchical organization of cognitive processes and sub-processes (e.g., attention is more basic than organization, and maintaining attention is more basic than shifting attention), (b) creation of cognitive exercises that targeted specific aspects of cognition in a hierarchical manner, and (c) efficient delivery of exercises using massed learning trials outside the context of functional application of the cognitive processes being trained (Ben-Yishay & Diller, 1983; Ben-Yishay, Piasetsky, & Rattok, 1987; Sohlberg & Mateer, 1987). In the 1970s, customized retraining devices were designed for the delivery of cognitive exercises. In the 1980s, these devices largely were replaced by cognitive retraining software.

These early developments in TBI rehabilitation were remarkably similar in theory and practice to unsuccessful attempts in the early 20th century to cure mental retardation with hierarchically organized cognitive exercises and to largely unsuccessful efforts in the 1950s, 1960s, and 1970s to cure learning disabilities with decontextualized cognitive exercises (Kavale & Mattson, 1983; Mann, 1979). In both of these older fields of intervention (based on the 19th-century concept of separate “faculties of the mind” that can be strengthened with exercises), decontextualized cognitive training tasks have largely given way to context-sensitive efforts to improve cognitive processing and self-regulated learning within the context of meaningful academic, social, vocational, and other daily activities.

This sea change in cognitive rehabilitation has been motivated, in part, by a growing experimental literature documenting the failure of transfer from improvements on decontextualized training tasks to everyday performance in everyday settings. Park and Ingles (2001) subjected studies concerning the effectiveness of decontextualized attention process training in TBI rehabilitation to a meta-analysis and concluded that well-controlled studies showed a minimal effect size, whereas efforts to improve attention within the context of specific everyday activities demonstrated a substantial effect size. Thus, general attention process training has given way to a focus on attention within the context of specific tasks that require attentional skill, such as driving (Park & Ingles, 2001), or attention training with a meta-cognitive or compensatory strategy focus (Cicerone, 2002; Cicerone et al., 2005).

Similarly, efforts to improve memory functioning with decontextualized memory exercises have been found to be ineffective at any stage of recovery after TBI (Baddeley, 1999; Cicerone et al., 2005; Schacter, 1996; Thoene, 1996; Wilson, 1995). In recent years, memory rehabilitation therefore has focused on the use of external memory aids,

internal memory strategies, and errorless teaching/learning procedures specifically designed for individuals with severe memory impairment (discussed below). As often is the case, practice in the field of cognitive rehabilitation has not kept up with research. Thus, many practitioners continue to use exercise-oriented, cognitive retraining computer programs as well as workbooks with page after page of exercises in cognitive skills, such as sequencing, categorizing, associating, and the like, despite the well-documented failure of improvements with these exercises to transfer to everyday tasks (Carney et al., 1999; Ylvisaker, 2003).

Memory Aids

External memory aids are widely considered to be the most commonly used—and the most effective—intervention for chronic memory impairments (Evans, 2003; Wilson, 1992). External aids include environmental modifications (e.g., labeling rooms, cupboards, etc.; color coding; positioning to-be-remembered items; and training communication partners to be effective memory prosthetics), memory prosthetics actively used by the individual (e.g., memory books, appointment books/calendars, and electronic memory aids), and memory prosthetics requiring no activation by the person (e.g., pager systems).

Sohlberg and colleagues (2007) reviewed 19 studies concerning the effectiveness of memory aids involving 267 participants, all with significant memory impairments. Although most of the studies were single-subject designs or case studies, sufficient evidence was found for the authors to conclude that provision of memory aids to individuals with memory impairment after TBI should be considered a practice guideline. The most commonly used was the memory notebook, which also was the most commonly studied (nine studies). Training methods often were unspecified, and considerable variation existed among those studies that did describe the training.

Evans and colleagues (2003) studied the use of memory aids in 94 individuals with memory impairment, mainly associated with TBI. The most commonly used aids were a calendar or wall chart (68/94), memory notebook (60/94), lists (59/94), appointment diary (41/94), and asking others for reminders (46/94). Uncommonly used aids or procedures included electronic organizer (7/94), tape recorder (2/94), visual imagery (9/94), first-letter mnemonics (5/94), rhymes (2/94), and “chunking” (1/94). These numbers are worth attending to, because rehabilitation professionals often are drawn to sophisticated electronic devices (rarely used) and superficial internal mnemonics (rarely used). The infrequent use of internal mnemonics, however, may be an artifact of the participants (e.g., relatively few students who need to study for exams) and of the mnemonics sampled. Studies in educational psychology indicate that elaborative encoding strategies that go beyond superficial rhyming and

first-letter mnemonics are useful in deepening comprehension and, thereby, in facilitating retrieval.

Forty-seven percent of the 94 participants were considered to be independent in the sense that they worked for pay, were full-time students, lived alone, and/or played a major role in running a household and caring for children. Evans and colleagues (2003) identified a statistically significant association between independence and regular use of three or more memory aids. Thus, it may be that clinicians need to equip individuals who have memory impairment with a variety of memory aids or strategies to be used for specific material or on specific occasions. Those participants who maintained regular use of six or more types of memory aids tended to be younger, more recently injured, higher in intellectual ability, better at attending, and more aware of and distressed about their memory impairment. Higher executive function scores predicted more effective use of aids (versus simply more use).

Many people with memory impairment predictably forget to use their memory prostheses (Kapur, 1995). Therefore, reminder systems have been developed that do not rely on the individual's initiation or ability to remember to use the system. “Passive” systems of this sort are comparable to passive restraints in automobiles, such as air bags, that (unlike seat belts) do not rely on the individual to do anything to be protected. For example, NeuroPage is an integration of computer and paging technologies that enables people with memory, planning, organization, attention, or initiation problems to receive pre-dictated reminders at specified times through an alphanumeric pager (Hersh & Treadgold, 1994). The reminders can be typed into the system by the individual or a caregiver. This system has been sufficiently effective that it is covered by the British health system (Wilson, Emslie, Quirk, & Evans, 2001).

For people who cannot read effectively or who have other impairments that interfere with attending to a pager screen, voice reminder systems are available. Van den Broek, Downes, Johnson, Dayus, and Hilton (2000) found that the Voice Organizer, a hand-held, dictaphone-type voice output reminder device, benefitted five of five patients with prospective memory impairment. Yasuda and colleagues (2002) found that the recently developed Sony IC Recorder, a voice output memory aid capable of producing approximately 300 spoken messages (48 minutes) at programmed times, served as a successful prompt for five of eight patients with prospective memory impairment, creating a dramatic improvement in their everyday lives.

Intelligently prescribed passive reminder systems are capable of reducing caregiver burden, increasing the likelihood that people with memory impairment will stay healthy by eating and taking prescribed medications at appropriate times and improving quality of life by reducing painful reliance on others. However, a minimal level of initiation,

motivation, and self-awareness likely is necessary for such systems to succeed (Yasuda et al., 2002).

Implicit Memory and Errorless Learning

The practice of teaching habits (routines) of thought, communication, and social conduct using antecedent supports is additionally bolstered by recent findings in the areas of implicit and procedural memory and errorless learning. Significant damage to the hippocampus and para-hippocampal structures (common in TBI) typically impairs declarative memory (i.e., remembering that such and such is the case) and explicit memory (i.e., having a subjective sense that one possesses the memory) but may leave procedural memory (i.e., remembering how to do something, including motor sequences, skilled operations, or other habits) and implicit memory (i.e., possessing a memory trace that influences future behavior but lacking a subjective sense that one remembers) relatively intact (Bachman, 1992; Izard, 1992; Pascual-Leone, Grafman, & Hallett, 1995; Schacter, 1996; Squire, 1992).

In their now-classic studies, Glisky and Schacter (1988, 1989) have found that people with apparently dense amnesia after brain injury are still capable of implicit memory and procedural learning. Similarly, Shum, Sweeper, and Murray (1996) found that subjects with TBI performed relatively poorly on explicit memory tasks but comparable to controls on implicit memory tasks. In their “good guy/bad guy” experiments, Tranel and Damasio (1993) found that individuals with severe amnesia associated with damage to para-hippocampal structures nevertheless create implicitly stored affective memories about people with whom they have had positive or negative experiences despite no explicit memories for those people.

In the presence of such neuropsychological profiles, which are common in varying degrees after TBI, Barbara Wilson, Jonathan Evans, and others have found errorless learning procedures to be a critical component of rehabilitation (Evans et al., 2000; Kessels & De Haan, 2003; Kessels et al., 2005; Riley & Heaton, 2000; Tailby & Haslam, 2005; Wilson & Evans, 1996; Wilson, Baddeley, Evans, & Shiel, 1994). Therapy tasks for individuals with significant memory problems should be organized in such a way that potential errors are anticipated and prevented with advance cues. Apprenticeship (“scaffolded”) teaching procedures can achieve this goal as the teacher/collaborator ensures successful and error-free performance during learning tasks. Similarly, the need for error-free learning is one of the supports for VR technology in rehabilitation. Cues can be given before a response and then systematically withdrawn (Brooks et al., 1999; Rizzo, Schulteis, Kerns, & Mateer, 2004). In the case of less severe memory impairment, trial-and-error learning may be preferable to errorless learning, because it encourages deeper processing and

improved explicit memory (Squires, Hunkin, & Parkin, 1997).

When people with severe explicit and declarative memory impairment make errors and experience a rush of embarrassment or anger when those errors are corrected, they are likely to store the erroneous response, but not associated with an awareness of the response as an error. Thus, the erroneous memory influences future behavior in an insidious manner. That is, people who seem to have severe memory impairment may encode and store some memories effectively, particularly when associated with strong emotional reactions—and errors often elicit strong emotional reactions. Under these circumstances, clinicians must ensure that the information being processed and the behaviors being rehearsed are the correct information and the desired behaviors. These neuropsychological considerations have revived a decades-old tradition of errorless learning in animal training (Terrace, 1963) and in developmental disabilities (Sidman & Stoddard, 1967), and they serve as an additional buttress for a supported, everyday, routine-based approach to rehabilitation for people with significant cognitive impairment after TBI.

Virtual Reality and Cognitive Rehabilitation

Rizzo and colleagues (2004) summarized the potential benefits of VR technology in neuropsychological rehabilitation. The central theme of VR as applied to cognitive rehabilitation is ecological validity and context-sensitivity of the training tasks and task environments, thereby addressing the failure of much traditional rehabilitation at the level of transfer of treatment gains to real-world settings and activities. Current applications of VR technology (in research centers) enable the creation of real-world virtual environments, including virtual cities, supermarkets, homes, kitchens, school environments, workspaces, and more. Within these realistic environments, a variety of ecologically valid assessment and training tasks can be constructed.

Compared with both traditional artificial tasks and real-world tasks, advantages of VR intervention include the following (as summarized by Rizzo et al., 2004):

1. Precise presentation and control of dynamic multi-sensory, three-dimensional stimulus environments. For example, it is possible to gradually build up complexity of tasks within a realistic VR environment for development of compensatory strategies or just practice under increasingly complex circumstances (e.g., driving, meal preparation).
2. Advanced methods for recording behavioral responses and delivering immediate performance feedback.
3. Provision of pre-planned systematic cueing to support error-free learning.
4. Potential for “after-action reviews” from a variety of virtual perspectives.

5. Safe testing and training environments.
6. Improved access to assessment and training for persons with sensorimotor impairments via adapted interface devices and tailored sensory modality presentations.
7. Increasingly realistic virtual human representations (avatars). This technologic development may create the possibility of VR training in social interaction, naturalistic communication, and awareness of social cues. Related procedures are now used in treating anxiety disorders and public speaking phobias.

Evaluation of the effectiveness of VR interventions is in its infancy; however, preliminary studies are promising, with documented success, including transfer of training, on tasks such as meal preparation (Fidopiastis et al., 2006), route finding (Brooks et al., 1999), and driving (Schultheis & Mourant, 2001). Until such procedures are well validated and the technology reasonably priced, VR may remain only a promise in TBI rehabilitation.

Behavioral and Psychosocial Rehabilitation

Importance of Behavioral and Psychosocial Issues

In the earlier section on outcome, we highlighted the frequency of personality changes, behavioral problems, and associated social interactive weakness after TBI. Difficulties in this domain may be a result of the injury but often are complicated by preinjury challenges and postinjury social, academic, and vocational failure and consequent adjustment problems. Our work with several hundred adolescents and young adults with chronic school and work problems and general community reintegration difficulty suggests that behavioral and psychosocial themes often are at the core of these problems, although in most cases, complex patterns of interaction exist between cognitive and behavioral consequences of the injury.

Furthermore, costs associated with failure of rehabilitation and community support efforts are staggering. In recent years, we have served more than 1,000 young adults through a New York State community support project for individuals with TBI, some degree of chronic behavioral impairment, and demonstrated lack of success in community reintegration using standard services and supports. Conservative Department of Health estimates regarding the cost of serving these individuals without a targeted community support program, based on expenses for the year before their introduction to the program, exceed \$40,000,000 annually. Because most of the people served by the program were more than 5 years postinjury at the time of referral and had failed in previous rehabilitation attempts, the state had projected enormous lifetime costs for this population (Feeney et al., 2001).

Speech-language pathologists have a natural role in this domain of service delivery under the headings of pragmatics

of language and teaching positive communication alternatives to challenging behavior. Pragmatics has a long history within the profession—and in other professions—under the label of social skills. The role of speech-language pathologists in behavior management may be somewhat more controversial but is included in the ASHA's scope of practice and has become commonplace in many settings where individuals with developmental disabilities are served (Carr et al., 1994; Reichle & Johnston, 1993; Reichle & Wacker, 1993; Ylvisaker & Feeney, 1994). In this section, we outline and offer a rationale for a context-sensitive, self-coaching approach to social skills weakness; a positive, antecedent-focused approach to challenging behavior; and a collaborative, context-sensitive approach to teaching positive communication alternatives to negative behavior.

Building Repertoires of Positive Social Communication Routines

Traditional Social Skills (and Pragmatics) Training

Social skills include general competencies (e.g., self-control), personal attributes (e.g., concern for others), and situationally relative social behaviors (e.g., communication scripts appropriate for the workplace, classroom interaction, church groups, bar room conversations, and others) that enable a person to be socially successful in selected settings. Historically, social skills intervention, a component of which is pragmatics training, has been understood as an effort to equip individuals with knowledge of social rules, roles, and routines along with the communication competencies that are components of those routines. Thus, the primary goal of the service is to impart social knowledge, both declarative (knowing that certain behaviors are desirable in specific contexts) and procedural (knowing how to perform the behaviors).

Traditional social skills training (SST) often takes place in social skills or pragmatics groups—outside of the context of real social interaction—guided by a curriculum that specifies the social competencies needed by the group members and the types of modeling and role playing that are used to teach and rehearse the skills. Many structured SST programs have been developed for individuals representing varied populations (see, e.g., Goldstein, Sprafkin, Gershaw, & Klein, 1980; Sheinker & Sheinker, 1988; Waksman, Messmer, & Waksman, 1989; Walker et al., 1988; Walker, Todis, Holmes, & Horton, 1988). Designed for children, adolescents, or adults from culturally diverse backgrounds or with developmental disabilities, learning problems, or psychiatric disorders, the programs are organized around training groups within which the participants practice social behaviors considered to be relevant to their social success. Such training programs differ with respect to the degree to which

they emphasize discrete trial training or social problem solving. The common thread, however, is repeated practice in a socially decontextualized training setting.

In part because of the logistical ease with which such group SST can be implemented in rehabilitation hospitals and outpatient clinics, SST or pragmatics groups enjoy considerable popularity in TBI rehabilitation. Limited evidence suggests that SST of this sort can be somewhat effective with some adolescents and young adults with TBI, particularly with an emphasis on self-monitoring (Braunling-McMorrow, Lloyd, & Fralish, 1986; Brotherton, Thomas, Wisotzek, & Milan, 1988; Gajar, Schloss, Schloss, & Thompson, 1984; Johnson & Newton, 1987). Concerns about the usefulness of decontextualized role play-based SST, however, arise at several levels.

First, traditional SST (defined above) has received little support in the many experimental studies of its use with a variety of clinical populations. Gresham and colleagues (2001) reviewed several narrative reviews and meta-analyses of this extensive research literature and concluded that "SST has not produced large, socially important, long-term, or generalized changes in the social competence of students with high-incidence disabilities" (p. 331). Specifically, they described two meta-analyses. The first included 99 studies of SST applied to students with emotional and behavioral disturbance, with a small mean effect size of 0.20. The second included 53 studies of SST applied to students with learning disabilities, with a similarly small mean effect size of 0.21. Likewise, the randomized, controlled clinical trial by Abikoff and colleagues of interventions for students with ADHD (a population similar in pathophysiology and symptomatology to those with TBI) found that decontextualized SST added nothing to the effect size produced by medication alone (Abikoff et al., 2004; Hechtman et al., 2004).

Second, even at the level of theoretical rationale, a clear disconnect exists between traditional SST and the types of social interaction problems that are common after TBI. The success of traditional SST groups (including pragmatics groups typically led by speech-language pathologists) assumes that the participants (1) lack knowledge of relevant social rules, roles, and routines; (2) are motivated to change their social behavior; (3) possess the capacity to transfer skills acquired in a training setting to varied real-world application settings; (4) modify their behavior in response to planned contingencies; and (5) are reasonably self-regulated. Unfortunately, the profile of many individuals with TBI is the opposite of that suggested by these assumptions. With relatively damaged anterior brain structures and relatively preserved posterior structures, individuals with a common profile after TBI typically possess relevant declarative social knowledge but are poorly regulated, have difficulty transferring social knowledge to daily living, respond inefficiently to behavioral contingencies, and may lack the motivation to change, particularly if the injury has reduced their awareness

of their interactive social competence and the effects of their behavior on others. Thus, no reason exists to believe that traditional SST (or pragmatics training) holds promise for those individuals with TBI with the most common neuropsychological profiles. Rather, the combination of inhibition, initiation, planning, working memory, and resource allocation impairments common in TBI lends itself to intervention designed to create positive habits of interaction in the social contexts in which the skills in question are needed. Creation of positive habits of interaction requires individualized selection of teaching targets and extensive coached practice in context.

Self-Coaching and Scripts of Social Interaction

Since the early 1980s, Ylvisaker and colleagues have used self-coaching as a metaphor and set of procedures in TBI rehabilitation (see, e.g., Ylvisaker & Holland, 1985). Because TBI disproportionately affects active young people who typically have personal experiences and positive associations with sports as participants or fans, the self-coaching metaphor yields insight regarding self-regulatory/executive system concerns and potential social strategies. Individuals who have self-regulatory impairment but desire higher levels of success in their social, educational, and vocational lives often agree to organize themselves around self-coaching procedures ("plays") despite possible opposition to other intervention approaches. The term "play" refers to an organized strategy, plan, or script, such as that performed during a football game or other athletic contest.

The general goal of self-coaching is to improve playful goal-oriented and, ultimately, successful behavior while decreasing impulsive and reactive behavior. Applied to social interaction, self-coaching plays include specific scripts that enable a person to successfully negotiate personally relevant social environments. Self-coaching has its historical roots in the view that self-regulation is, at its core, self-regulatory self-talk, even if that self-talk is automatic and minimally conscious.

As a psychological therapy, self-coaching most closely resembles cognitive-behavior therapy and, more specifically, cognitive-behavior modification (Meichenbaum, 1977), but with the important caveat that self-coaching is, ideally, an everyday, context-sensitive (versus clinic-bound) intervention, with "plays" that also specify roles for ECPs. According to Berk (2001), this "everyday routine" approach to self-regulatory self-talk is consistent with the views of Vygotsky, which were distorted when self-talk therapies became clinical interventions delivered in a manner insensitive to everyday contextual realities.

Self-coaching plays (including self-regulatory self-talk scripts) can be designed to address a variety of obstacles common after TBI: poorly controlled emotions, impulsive or otherwise ineffective social interaction, difficulty interpreting

others' social behavior and reading others' emotional states, difficulty managing everyday routines, problems at work or school, personal goals (e.g., sobriety, money management, hygiene, and weight loss), and others. The key procedural concepts are:

- Negotiate personally appealing and effective plays/scripts of self-regulation or interaction designed to solve specific problems or overcome specific obstacles.
- Associate those plays/scripts with compelling images, goals, heroes, and the like to make their meaning clear and personally appealing.
- Rehearse the plays/scripts repeatedly, possibly using video learning trials ("game films"), with the goal of automatic elicitation of the self-coaching play by natural everyday stimuli.
- Negotiate acceptable reminder plays or partner scripts that can be used by ECPs.
- Try the plays in real "games" (i.e., real-world interaction), and evaluate their effectiveness and comfort level.
- Modify the plays, or design new plays, in the event of failure, frustration, or discomfort.
- Ensure celebration of everyday successes that result from using the self-regulatory self-coaching plays/scripts successfully.

Table 33-13 lists the principles underlying this self-coaching approach. All self-coaching interventions are organized within the general goal-obstacle-plan-do-review framework discussed earlier. That is, participants are encouraged to (1) describe what they want to accomplish or get better at (goal), (2) identify what is blocking successful achievement of that goal (obstacle), (3) create a play (plan, script), (4) try it under highly supported and then real-world conditions (do), and (5) review what is working and what is not working, making modifications as needed (review).

Particularly for individuals with limited space in working memory and weak online decision making, habituating or automatizing the self-coaching plays and scripts is critical. Furthermore, the plays need to be automatized within the settings and routines in which the difficulties arise. Thus, the intervention must take into account the routines of everyday life and ensure considerable practice with the self-coaching scripts within those routines. This is one of the reasons for the involvement of ECPs. Ideally, relevant ECPs understand the plays and their rationale, know and are comfortable with their roles (e.g., prompting the play), and can execute their roles without irritating or boring the person with brain injury. The need for automatization also is one of the reasons for using self-coaching videos to ensure large numbers of learning trials for habituation. These short videos typically include content outlined in Table 33-14 but can be customized to meet individual needs.

If well constructed, the self-coaching videos serve three purposes beyond habituation of the plays. First, following

TABLE 33-13

Principles of Self Coaching as a Social Competence Intervention

1. **Automatic Self-Regulation:** The ultimate goal of self-coaching is to create situations in which relevant environmental cues automatically trigger effective self-regulatory/self-coaching thoughts and behaviors rather than triggering poorly controlled, impulsive, negative, unsuccessful, or self-destructive behavior.
2. **Participant Involvement:** Self-coaching requires creative and respectful collaboration with the participants in identifying difficult situations and negative behaviors, personally meaningful goals, useful self-talk plays/scripts, and acceptable supports from others.
3. **Specificity of Real-World Needs:** Self-coaching targets specific issues that have a direct and measurable effect on the quality of the individual's life.
4. **Negotiation of Scripts and Metaphors:** Plays/scripts and metaphors are individually negotiated to be as personally meaningful as possible.
5. **Motivating Associations:** The self-regulatory plays/scripts should be creatively associated with motivating images, people, or other symbols of strength and success.
6. **Self-Coaching Plays/Scripts and Communication Partner Scripts:** Ideally, "coaching" scripts are negotiated and developed for the individual (self-coaching scripts) and also for everyday communication partners (e.g., how to cue self-coaching without eliciting oppositional responses).
7. **Practice:** Automaticity of self-coaching "plays" cannot be achieved without a great deal of practice. One of the reasons for video self-modeling is that many of these learning trials can be logged as the individual watches the video ("the game film").
8. **Monitoring, Revisions, and Celebration:** The effectiveness of self-coaching plays must be carefully monitored, with revisions as necessary and ample celebration of success.

From Ylvisaker (2006); with permission.

TBI, many people have relatively weak self-monitoring and self-awareness, both of which might be improved with video self-observation. These self-coaching videos allow the participants to observe themselves being successful using the self-coaching plays and scripts. In some cases, they allow the participants to observe themselves being unsuccessful without the self-coaching play/script. Because self-observation can be emotionally challenging, authorization for self-observation should be granted by a relevant clinician (e.g., clinical psychologist, psychiatrist, or social worker).

Second, the video can include the negotiation and agreements that led to the play. This short circuits later objections based on faulty recollection of the rationale for the play.

Third, the videos can contain simple educational content about the person's injury and its effects. When we create

TABLE 33–14

Possible Content for Self-Coaching Videos

1. Introduction to the concept and importance of self-coaching. This may be a videotaped live discussion within the group and then used as the introduction to many or all of the individual self-coaching videos. Brain injury–related information may be included in this segment, ideally using a model of the brain to make the information as concrete as possible.
2. Explanation of the individual's specific difficulty that requires self-coaching. Often, this statement is made collaboratively by the person and the therapist. Person-specific brain injury information may be included in this segment—again using a model of the brain. If an appropriate level of comfort and mutual respect has been established in the group, then statements about the person's difficulty can and should be clear and direct—for example, “Bob, you see this part of the brain? It helps us to control our impulses. Your brain is injured here; that's why you're an impulsive guy. You have a hard time stopping yourself from doing or saying the first thing that pops into your head, right? But that doesn't mean you can't be successful. Think about Ben Rothlisburger, quarterback of the Pittsburgh Steelers. Last week he had a banged up knee and broken thumb, but he still played and played very well. But he had to wear special equipment, use special strategies, and accept special help—and it wasn't easy. But he did it. It's not easy for you to control your impulses; that's why we're working out these special plays; and that's why you're going to get the video and watch it many times to make the plays automatic!”
3. Brief vignette demonstrating what the difficult social situation looks like without self-coaching (e.g., participant loses his temper, or the participant misinterprets another person's behavior).
4. Brief vignette demonstrating what the difficult social situation looks like with the self-coaching script—that is, successful negotiation of the difficult situation. This segment could include an admired peer using the self-coaching script so that it has positive associations as it is viewed on the video.
5. Possibly an everyday communication partner demonstrating an acceptable cue for the participant to use self-coaching script.
6. Possibly a description of what changes in behavior will demonstrate success of the self-coaching script.
7. Possibly some “cheerleading” from group members for motivational purposes.
8. For some individuals, it may be desirable to include in the video the entire discussion and negotiation that leads to the scripts. This may be particularly valuable for those with significant memory impairment.

From Ylvisaker (2006); with permission.

self-coaching videos, we routinely begin with a few minutes of educational content about brain injury and the individual's specific injury. During these few minutes of presentation, we typically sit next to the participant and, while holding a model of a brain, point out relevant areas and their importance. Participants who are many years post-injury often report that this information is new and important for them and their ECPs.

Behavior Management and Communication**Concerns About Traditional Consequence-Based Behavior Management**

Traditional operant applications of applied behavior analysis, dating back to Skinner's early work (Skinner, 1938), have explained behavior as a consequence of both antecedents and consequences but have placed the major burden on manipulation of consequences in teaching new behaviors or modifying undesirable behavior. Within this tradition, intervention strategies largely are reactive, specifying positive consequences for desirable behavior and negative or no consequences for undesirable behavior. Furthermore, to the extent that antecedents are targeted in behavior management, it largely has been the immediate and observable antecedents (e.g., the trainer's commands, cues, and prompts as well as environmental stressors at the time of the behavior). An enormous literature and impressive technology of behavioral change have evolved within this tradition. Furthermore, reports have documented some success with traditional consequence management applied to both adults (see, e.g., Alderman, 2003; Alderman & Ward, 1991; Pace & Ivancic, 1994; Wood, 1987, 1990) and children (see, e.g., Slifer, Cataldo, & Kurtz, 1995; Slifer et al., 1996) with TBI.

Unfortunately, clinicians who work with individuals who have frontal lobe impairment, whether congenital (e.g., ADHD) or acquired (e.g., TBI), often report a frustrating lack of success or, at best, inefficiency in their implementation of primarily consequence-oriented behavior modification programs (Barkley, 1987; Hallowell & Ratey, 1994). This inefficiency has been documented in the frontal lobe research literature, which offers at least four potential explanations, which are summarized in Table 33–15. Damasio and colleagues (Bechera, Damasio, Damasio, & Anderson, 1994; Bechera, Tranel, Damasio, & Damasio, 1996; Damasio, 1994; Damasio et al., 1991; Tranel, 2002) have suggested that favorable or unfavorable consequences of behavior can influence future behavior only if somatic markers, or feeling states, are associated with the stored representation of the original behavior. Their neuropsychological investigations indicate that ventromedial prefrontal cortex is critical to laying down somatic markers and connecting them to memories of past

TABLE 33-15

Possible Explanations for Inefficiency of Consequence-Oriented Behavior Management in Rehabilitation of Traumatic Brain Injury

Hypothesis	Discussion
Disinhibition Hypothesis (Rolls et al., 1994)	Because of the high frequency of orbitofrontal injury in TBI, impulsiveness is a common impairment. People who are impulsive, like young children, are capable of learning from consequences, but immediate impulses easily overwhelm learned behaviors on the occasion of action.
Working Memory Hypothesis (Alderman, 1996)	Because of the relative frequency of dorsolateral prefrontal injury in TBI, reduced working memory is a common impairment. Alderman found a correlation between impaired working memory and difficulty learning from consequences, perhaps suggesting that reasonably adequate working memory is needed for correct selection of learned responses.
Somatic Marker Hypothesis (Damasio, 1994)	Because of the high frequency of ventromedial prefrontal injury in TBI, attachment of somatic markers (feeling states associated with rewards and punishments) to stored representations of past experiences is inefficient. According to this theory, somatic marker storage is critical to learning from consequences and is weak in individuals with ventromedial prefrontal damage.
Initiation Hypothesis (Stuss & Benson, 1986)	Because of the relative frequency of dorsal (especially dorsomesial) prefrontal injury in TBI, some individuals lack organically based initiation/activation capacity to act in situations in which they have learned the correct behavior and are adequately motivated to act.
Infantilization and Oppositionality Hypothesis (Ylvisaker & Feeney, 1998a)	Because many people with TBI, especially adolescents and young adults, react negatively to attempts by others to manage their behavior with consequences, traditional behavior management systems may be counterproductive. The common complaint is that reward and punishment systems are child-like or that external manipulation beyond their control and approval is in general offensive to them.

Key: TBI = traumatic brain injury.

behavior, thereby explaining the inefficiency of consequence-oriented behavior management in many people with CHI, given its high frequency of ventral prefrontal damage.

Rolls (2002) as well as Rolls, Hornak, Wade, & McGrath (1994) highlighted inflexibility in response to changing contingencies and impulsiveness, associated with orbitofrontal lesions, as a hypothesis capable of explaining the maintenance of behaviors that have resulted in a history of seriously punishing consequences. Alderman (1996) concluded that weakness in the central executive component of working memory may explain the failure of many individuals with frontal lobe injury to respond to traditional operant

training techniques, including reinforcement, extinction, and time-out interventions. In some cases, reduced initiation/activation, associated with dorsal (especially dorsomesial) prefrontal injury, may explain failure to act despite possession of the appropriate learned response (Stuss & Benson, 1986). In individual cases, a satisfactory explanation for the inefficiency of traditional behavior management may include a combination of these four phenomena, possibly exacerbated by oppositionality, which may grow in response to ineffective consequence-oriented management (Ylvisaker & Feeney, 2000a). For our purposes, the research literature at least directs clinicians to focus their attention on both immediate and remote antecedents of behavior.

Positive, Antecedent-Focused Behavior Management

In Table 33–16, we outline alternative approaches to the role of antecedent manipulation in behavior management (based on Carr, Carlson, Langdon, Magito-McLaughlin, & Yarbrough, 1998). Historically, the narrow “molecular” approach co-existed with a primary focus on consequences. Until recently, relatively little attention has been paid to remote events (e.g., an unpleasant interaction earlier in the day) or internal states of the individual (e.g., anger resulting from loss of friends, anxiety over lost skills, or frustration associated with an unsatisfying job or no meaningful role in life) as potentially modifiable antecedents that increase or decrease the likelihood of certain behaviors.

Over the past 20 years, momentum has grown within the field of applied behavior analysis favoring an approach to teaching and supporting individuals with challenging behavior that places greatest emphasis on the manipulation of antecedents, including immediate and remote as well as observable and unobservable antecedents (the “molar” approach in Table 33–16). Although most of the research and clinical discussions within this new tradition address behavioral issues associated with developmental disabilities (Carr, et al., 1999), application of antecedent technologies has entered the experimental and clinical literatures in TBI rehabilitation (Feeney & Ylvisaker, 1995, 1997; Jacobs, 1993; Ylvisaker et al., 2003; Ylvisaker & Feeney, 1996, 1998a, 2000a; Ylvisaker, Turkstra et al. (2007), Zencius, Wesolowski, Burke, & McQuade, 1989). Furthermore, the molar approach to antecedent-focused behavior management is completely consistent with the theoretical and procedural discussion of positive, everyday, routine-based intervention presented earlier.

Building Positive, Everyday Behavioral and Communication Routines

Earlier, we offered a rationale for a positive, everyday, routine-based approach to rehabilitation equally applicable to intervention for individuals with chronic cognitive, behavioral, and communication impairment. Behavior management within this approach can be divided into two overlapping efforts: preventing negative behaviors, and building repertoires of positive behaviors, including communication routines.

Preventing Negative Behavior with Antecedent Manipulations

Part 2 of Table 33–3 in *Framework for Cognitive and Psychosocial Rehabilitation* lists several categories of antecedent procedures designed, in part, to avoid negative behavioral routines and increase the likelihood that positive behaviors will become habitual. Critical to antecedent management is the concept of “setting events” (Michael, 1982, 1993), which are potentially remote occurrences or conditions that increase or decrease the likelihood of a behavior and deter-

TABLE 33–16
Behavior Management Via Control of Antecedents: Alternative Approaches
Molecular Approach to Antecedent Control: The Tradition in Applied Behavior Analysis Antecedents: Discrete measurable stimuli that precede a behavior and increase or decrease its likelihood of occurrence (e.g., a specific instruction, cue, warning, or promise). Assessment: To identify these antecedents for purposes of control (a-b-c analysis, including active experimentation with antecedents), often in controlled settings (i.e., analog assessment). Intervention: To increase or decrease specific behaviors by manipulating the specific immediate antecedents related to the behavior (e.g., eliminate triggers, modify antecedents, and fade antecedents in or out).
Molar Approach To Antecedent Control Antecedents: Broad, potentially continuous, often hard to measure variables that may increase or decrease the likelihood of occurrence of positive or negative behavior: • Internal states (e.g., illness). • Living arrangements. • Social relationships. • Education (e.g., placement, demands, and level of success). • Work (e.g., placement, demands, level of success, and perceived meaningfulness). • Leisure (frequency and quality of enjoyable activities). • The relation between the person’s needs, competencies, and environmental demands. • Self-perception, including implicit metaphors that guide thinking and behavior. Assessment: • To identify the background antecedents or non-immediate “setting events” that may be related to positive or negative behaviors, generally in natural settings. • To assess the “goodness of fit” between the person’s needs, competencies, and social, educational, and vocational demands. Intervention: Primary Purpose: To influence major background setting events and conditions with the goal of helping the individual to create a satisfying lifestyle: • May be most efficiently met by educating and training everyday communication partners and, in other ways, creating a “best fit” between the individual and his or her living, work, social, and/or educational environments and activities. Secondary Purpose: To indirectly increase desirable and decrease undesirable behaviors.

TABLE 33–17

Categories and Examples of Setting Events that Potentially Influence Behavior

Internal States of the Individual

• **Neurologic States**

Positive setting events: normal neurology.

Negative setting events: overactivity of the limbic regions; seizures; neurotransmitter disruption; decreased cerebral blood flow.

• **Other Physiologic States**

Positive setting events: rest, relaxation, satiation, and appropriate levels of medication.

Negative setting events: pain, illness, hunger, over medication, under medication, motor deficits, and sensory deficits.

• **Cognitive States**

Positive setting events: orientation to task, familiarity with routine, adequate recall of relevant events, and adequate recognition of things and people.

Negative setting events: confusion, disorientation, frustration, and inadequate recall and recognition.

• **Emotional States**

Positive setting events: sense of accomplishment, success, achievement, acceptance by others, respect from others, meaningful role, sense of self consistent with life circumstances, and feeling in control.

Negative setting events: anxiety, anger, depression, and sense of loss and failure.

• **Perception of Task Meaningfulness and Difficulty**

Positive setting events: belief that assigned tasks are meaningful and can be accomplished.

Negative setting events: belief that assigned tasks are meaningless, infantilizing, or impossible.

External Events and Conditions

• **Living Arrangement**

Positive setting events: living in a self-selected environment without excessive restrictions.

Negative setting events: living in an excessively restrictive setting; living at home with parents after having lived independently.

• **Presence or Absence of Specific People**

Positive setting events: presence of preferred people and reciprocal friendships.

Negative setting events: absence of preferred people, loss of friends, and presence of nonpreferred people.

• **Recent History of Interaction**

Positive setting events: recent positive and pleasurable interactions.

Negative setting events: recent conflict or disrespectful interaction.

• **Other Environmental Stressors**

Positive setting events: appropriate and desirable environmental stimulation.

Negative setting events: irritating environmental stimulation (e.g., ambient noise, improper lighting, and other distractors).

• **Time of Day**

Positive setting events: alertness; best time of day relative to the individual's natural cycles.

Negative setting events: bad time of day relative to the individual's natural cycles.

From Ylvisaker and Feeney (1998a); with permission.

mine whether a specific behavioral intervention will be effective (Baer, Wolf, & Risley, 1987). Because the concept of setting events is unfamiliar to some rehabilitation specialists and bears meaning that is not transparent (e.g., “event” is not restricted to temporally discrete occurrences but, rather, can include internal states and conditions), we include in Table 33–17 a list of positive and negative setting

events that can be used as a checklist in working with individuals with difficult behavior after TBI.

Attention to setting events is particularly critical in working with people who have acquired brain injury because of the cumulative negative effect on behavior of chronic discomfort, restrictions on activities and choices, limited control over major life events, frequent changes in living situation and

Figure 33–9. Relationship between negative setting events and challenging behavior. (Modified from Feeney & Ylvisaker, 1997; with permission.)

routines, and perhaps most critically, failure to achieve goals consistent with preinjury expectations and aspirations. A background of negative setting events lowers behavioral thresholds that, as a result of the injury, already may be low (Fig. 33–9). Conversely, a background of positive setting events elevates those thresholds and increases the likelihood that the individual will become productively engaged in difficult tasks (Fig. 33–10). The developmental disabilities behavioral litera-

ture is rich in reports of experiments demonstrating the positive effects on behavior of inducing positive setting events, including creating positive behavioral momentum before introducing difficult tasks (Carr et al., 1997; Fowler, 1996; Kennedy, Itkonen, & Lindquist, 1995; Mace et al., 1988, 1990; Mace, Mauro, Boyajian, & Eckert, 1997) and offering choice and control (Bannerman, Sheldon, Sherman, & Harchik, 1990; Brown, Belz, Corsi, & Wenig, 1993; Dunlap

Figure 33–10. Relationship between positive setting events and positive behavior. (Modified from Feeney & Ylvisaker, 1997; with permission.)

et al., 1994; Harchik, Sherman, & Bannerman, 1993). Harchik and colleagues (1993) reviewed more than 100 experimental reports in the developmental disabilities literature and concluded that increasing an individual's opportunities for choice and control decreases challenging behavior, increases participation, and increases subjective reports of satisfaction derived from that participation.

The Role of Consequences

In emphasizing antecedents in behavior management for people with TBI, we do not wish to recommend inattention to consequences. First, many people with TBI escape frontolimbic injury entirely and, therefore, can be expected to be as efficient as their uninjured peers at learning from consequences. Furthermore, the frontolimbic threats to efficiency of consequence-oriented behavior management come in degrees and, in individual cases, may not be serious. Third, the positive, everyday routines that antecedent supports are designed to facilitate are positive, in part, because they result in extrinsic or intrinsic rewards for the person. Fourth, the possibility of serious punishment (e.g., jail) may serve as motivation for participation in the development of antecedent-supported routines. Finally, even those who are inefficient at learning from consequences benefit from a positive culture in which there is ample noncontingent reinforcement, successful performance is greeted with encouragement and praise, and failure and negative behavior elicit efforts to help the person succeed rather than punishment that may breed anger and additional failure.

In using consequences, some basic rules apply. First, individuals who are impulsive and concrete in their thinking need consequences that are immediate (versus delayed) and salient. As cognition improves, consequences can become progressively more delayed and less salient.

Second, with the goal of helping people to succeed in the real world, rewards and punishments should be as natural and logically related to the individual's behavior as possible. For example, a good grade is a natural and logical consequence of effective preparation for a test; a raise or promotion is a natural and logical consequence of hard work on the job; and an enjoyable social interaction is a natural and logical consequence of socially appropriate initiation. On the punishment side, cleaning one's room is a natural and logical consequence of "trashing" the room during a tantrum, and receiving a poor grade is a natural and logical consequence of failing to prepare for an examination. In contrast, the following contingent responses are not related in a natural and logical way to the behavior and, therefore, are not likely to help shape enduring, positive behaviors:

- "Nice talking, John."
- "I liked the way you responded to Jeremy; I'll give you a point for that."

- "That's not an appropriate way to request cigarettes; you will not be allowed to go on the outing tonight."

Token economies, which are popular components of consequence-oriented behavioral programs, often fail to promote understanding of natural and logical relationships in the real world. For example, if an appropriate conversational bid from a person known for acting out sexually is rewarded with a token that can be exchanged later for a cigarette, the natural connection between appropriate conversational openers and subsequent satisfying conversations is violated. Furthermore, liberal use of extrinsic rewards can create dependence on such rewards and interfere with internally driven motivation, a finding that has been replicated many times in many contexts over the past 30 years (Deci, 1995; Deci & Ryan, 2002). Finally, our experience suggests that many oppositional young people become increasingly oppositional in an environment that they perceive as being dominated by arbitrary authority figures who arbitrarily dispense rewards and punishments that are not personally meaningful.

Teaching Positive Communication Alternatives to Challenging Behavior

Behavior management and SST come together in the process of helping people with challenging behavior to substitute a socially acceptable mode of communication for behavior that is unsuccessful or considered to be inappropriate in their social contexts. As an organized approach to behavior management, positive communication training has its roots in work with individuals who have mental retardation, autism, or other developmental disabilities (Bird, Dores, Moniz, & Robinson, 1989; Carr & Durand, 1985; Carr et al., 1994; Donnellan, Mirenda, Mesaros, & Fassbender, 1984; Doss & Reichle, 1989; Reichle & Wacker, 1993). Functional analysis of problem behavior in those groups typically indicates that the behavior serves a communication function, often expressing an intention to gain access to a desired activity, person, thing, or place or to escape an activity, person, demand, or place. Organized procedures for assessing the communication value of challenging behavior (see, e.g., Durand & Crimmins, 1992) and for teaching positive alternatives are available in the developmental disabilities literature, along with evidence of the effectiveness of these efforts.

In Table 33-18, we present a summary of the communication approach to behavior management, including the premises underlying the approach, considerations in assessment, preteaching activities, categories of teaching procedure, and finally, obstacles to success, along with suggestions for overcoming the obstacles. Elsewhere, we have discussed, illustrated, and demonstrated the effectiveness of this approach to behavior management for individuals with TBI in greater detail (Feeney & Ylvisaker, 1995, 1997, 2003;

TABLE 33–18

Behavior as Communication: Teaching Positive Communication Alternatives to Challenging Behavior

Premises

1. All behaviors (potentially) communicate something to someone. One cannot not communicate, although not all communication is intentional.
2. Few behaviors are truly maladaptive; most apparently maladaptive behaviors (e.g., aggression, self-injury, and withdrawal) achieve a social, communication goal.
3. The messages communicated with challenging behavior often can be understood as communicating the individual's need to escape (e.g., escape a task, person, place, or activity), to access/acquire (e.g., access a task, person, place, activity, thing, form of stimulation, or attention from others), or to protest (e.g., protest restrictions on behavior or disrespectful interaction).
4. The behavior of communication partners is a critical part of the context of behavior (antecedent conditions and consequences that potentially elicit and maintain types of behavior) and must figure prominently in intervention efforts.
5. Clearly defined communication routines of everyday life, supported by well-trained everyday communication partners, are the ideal context within which communication and behavior goals are optimally achieved.
6. Communication specialists and behavior specialists play essentially the same role in helping individuals with communication-related behavioral problems.

Assessment

1. Collaboratively identify and describe the unacceptable behavior and the contexts in which it occurs.
2. Collaboratively interpret the meaning of the challenging behavior:
 - a. Systematic, passive observation: What are the stimuli and responses that trigger and maintain the undesirable behavior in varied everyday contexts?
 - b. Systematic, active experimentation with hypotheses regarding the meaning/purpose of the challenging behavior (e.g., if communication partners routinely reward verbal requests for a desirable activity, does the challenging behavior disappear? If so, the meaning/purpose of the challenging probably was "I want that activity!").
 (See also Durand & Crimmins, 1992, and the discussion of collaborative, context-sensitive, hypothesis-testing assessment earlier in this chapter.)
3. Collaboratively explore potential positive alternatives to the challenging behavior.

Preteaching

1. Collaboratively decide under what circumstances the individual will be allowed to control tasks and settings with positive communication (e.g., escape undesirable tasks, people, settings; gain access to desirable tasks, people, settings).
2. Collaboratively select a positive communication alternative to the negative behavior. Ideally, the communication alternative should have the following characteristics:
 - Easy to produce: If the alternative is harder for the individual to produce than the behavior it is intended to replace, it is unlikely to be adopted.
 - Satisfying: The positive communication alternative should fit the person's personality and communication milieu.
 - Effective: The alternative must be at least as effective for the individual as the negative behavior it is replacing.
 - Promptable: There is an advantage to physically promptable communication alternatives (e.g., signing, gesturing, or pointing to a picture on a board) versus those that are not promptable (e.g., talking) during the initial stages of teaching, but this often is not possible.
 - Interpretable: The communication must be interpretable by all relevant communication partners.

Teaching the Positive Communication Alternative

1. Collaboratively ensure many successful positive communication routines daily (i.e., successful, rewarded use of the positive communication alternative) throughout the day and in a variety of contexts:
 - a. Naturally occurring opportunities.
 - b. Contrived opportunities.
2. Initially attempt to achieve a high ratio of positive communication alternatives to challenging behavior (e.g., 10:1), with prompts and other supports as necessary.
3. Gradually reduce prompts and other supports.
4. Gradually re-introduce normal demands:
 - a. This may require explicit teaching of the difference between choice and no-choice situations.
 - b. This may require considerable focus on antecedent supports (e.g., positive behavioral momentum or other positive setting events) to ensure that the individual does not revert to challenging behavior during stressful tasks.
5. Monitor and modify as necessary.

(continued)

TABLE 33-18

Behavior as Communication: Teaching Positive Communication Alternatives to Challenging Behavior (continued)

Obstacles to Teaching Communication Alternatives

1. **Staff Insularity:** The success of this teaching depends on all or most everyday communication partners being generally consistent in their communication with the person with challenging behavior.
Possible Solutions:
 - a. Try to include everybody in the initial functional assessment of behavior.
 - b. Negotiate the behavior plan so that all relevant people agree that the plan is reasonable and do-able.
2. **Concern about Contributing to the Behavior Problem:** Many staff and family members are concerned that rewarding positive escape or access-motivated behavior will give the individual too much control.
Possible Solutions:
 - a. Point out research and experience that shows that this natural fear is unfounded if the teaching is implemented correctly.
 - b. Emphasize that normal demands will be reintroduced once the challenging behavior is substantially eliminated.
3. **Concern that Some Activities Are Mandatory, Others Forbidden.**
Possible Solutions:
 - a. Try to achieve agreement about those activities that are mandatory and, therefore, cannot be escaped (e.g., taking medication) and those that are forbidden and, therefore, cannot be chosen (e.g., harming others, interacting with dangerous materials, and placing oneself at risk).
 - b. Try to help all everyday communication partners agree that improving behavior and communication is a high priority at this time, necessitating considerable control by the individual using positive communication alternatives.
4. **No Choice Times Heavily Outweigh Choice Times:** It is unlikely that the individual will change old communication habits in the absence of a large number of meaningful, successful, rewarded learning trials with the positive alternative.
Possible Solutions:
 - a. Create—artificially if necessary—a large number of choice occasions so that the individual has many opportunities to practice and be rewarded for the positive communication alternative.
5. **Behavior Management Is Somebody Else's Job:** Some people believe that behavioral problems should be dealt with by behavior specialists and not by others.
Possible Solutions:
 - a. Ensure that all relevant communication partners are involved in identifying the need for behavioral change, in implementing the functional analysis of behavior, and in modifying everyday routines of communication so that the individual has many opportunities to practice positive communication alternatives.
6. **Difficulty with Timing.**
Possible Solutions:
 - a. Ensure that communication partners know that they must respond to the positive communication alternative promptly—knowing that if they wait, the individual is likely to revert to the challenging behavior—and will likely be unintentionally rewarded for the challenging behavior.
7. **Concern about Power/Authority Roles:** Some adults, particularly those who are personally insecure, resist creating the impression that a client or student or employee is in a position of power or authority over them.
Possible Solutions:
 1. Work with resistive staff to help them understand that this teaching strategy ultimately gives them more, not less, authority.
 2. Help everybody to understand the importance of substituting positive for negative communication and that this may require giving the individual a sense of power with positive communication.
 3. Help everybody to understand that normal expectations will be re-instituted once the challenging behavior is under adequate control.

2006; Ylvisaker & Feeney, 1994, 1998a; Ylvisaker et al., 1999; Ylvisaker, Feeney, & Szekeres, 1998).

We have used the approach outlined in Table 33-18 with a large number of children and adults who show challenging behavior after TBI. In some cases, particularly people with significant cognitive, behavioral, and possibly also motor impairment, the messages communicated in problematic

ways were relatively simple to decipher (e.g., a desire to escape demands), and the intervention process was not unlike that described in the developmental disabilities literature. In other cases, particularly people with relatively good cognitive and motor recovery but complex behavioral and emotional profiles both before and after their injuries, the messages delivered in challenging ways were more complex,

and the process of intervention involved a higher level of collaboration with the individual. In these cases, motivation and negotiation (discussed in the next section) are central to the intervention.

Behavioral Interventions: Evidence

In a systematic review of the evidence regarding behavioral interventions for individuals with behavioral problems after TBI, Ylvisaker, Turkstra, and colleagues (2007 located 65 studies with a total of 172 participants). Two of the studies were randomized, controlled trials (Class I), 2 were group studies with inadequate controls (Class II), 36 were well-controlled, single-subject experiments (Class III), and 25 were case studies or poorly designed, single-subject experiments (Class IV). All the studies showed positive effects of the intervention, supporting the conclusion that behavioral intervention in general (i.e., not a specific intervention protocol) for behavioral problems after TBI in both children and adults should be considered as a practice guideline at both acute and post-acute stages of recovery. The authors concluded that individuals with challenging behavior after TBI should be provided with systematically organized behavioral interventions and supports consistent with the available evidence and based on individualized functional behavior assessments. Furthermore, specific behavioral interventions grouped under the headings of traditional contingency management and positive behavior interventions and supports can be considered as evidence-based treatment options. Because most of the evidence is Class III or Class IV, and because intervention protocols vary from study to study, stronger recommendations (i.e., practice standards or intervention guidelines) for specific behavioral intervention protocols cannot be supported by the available evidence. Interestingly, the review documented a sharp movement in the direction of positive behavior interventions and supports over the past 30 years.

The Role of Individual and Group Therapy within an Everyday Rehabilitation Framework

In highlighting the importance of context and the role of supported routines of everyday life as the core of rehabilitation for individuals with chronic cognitive, psychosocial, and communication impairment after TBI, we do not wish to suggest that both individual and group therapy have no role. First, many of the traditional roles played by speech-language pathologists in relation to swallowing, motor speech, and aphasic deficits are appropriate and necessary for some individuals with TBI.

Second, the meaning of “context” is not restricted to setting. Clinicians can contextualize therapy sessions with personally meaningful activities and materials (e.g., academic texts and tasks for a college student) and also people (e.g., including family members in communication therapy sessions).

Third, individual and group therapy sessions can be used to brainstorm about and explore the usefulness of alternative

strategies, supports, or self-coaching “plays” (Step 2 of everyday intervention in Table 33–4). Having identified what works—and what does not work—under controlled conditions, plans can be implemented for context-sensitive practice in the routines of everyday life, possibly supported by everyday people and even self-managed.

Fourth, the intimacy of individual therapy sessions often is necessary to address the sensitive issue of self-awareness of ongoing impairment.

Finally, individual or group sessions are a useful venue for the motivational and supportive interaction needed by individuals who struggle to maintain the level of effort needed to be successful after their injury (Step 3 of everyday intervention in Table 33–4).

Having highlighted the potential value of therapy sessions, however, we wish to stress the goal of transforming every hour of reimbursed therapy into several hours of well-conceived rehabilitation by virtue of effective alliances with everyday people and creative use of the routines of everyday life.

Motivation, Metaphor, and Collaboration with the Person with Disability

In the case of adolescents and young adults who are struggling unsuccessfully to reestablish preinjury activities and levels of success, challenging behaviors such as aggression, withdrawal, sexual acting out, and others often communicate messages like the following:

- “You just treated me disrespectfully and I won’t take it!”
- “I know I can’t do this and it’s driving me crazy, but it’s just too hard to ask for help!”
- “I find you very attractive, and I would like to spend time with you.”

Because loss of friends, difficulty maintaining work, and increasingly stressful family interaction may be the result of negative communication behavior, intervention designed to substitute positive alternatives can be critical to social, vocational, and familial success. Proud and oppositional adolescents and young adults, however, particularly those from cultural backgrounds in which communication often is somewhat unrefined, are most unlikely to accept alternatives such as the following:

- “Excuse me, but I think we need to spend some quality time working on our relationship because I find your attitude unacceptable.”
- “Since my accident I have a hard time doing even simple things. I need a lot of help. Please help me.”
- “Is there any chance we could spend some time talking? I would like to get to know you better.”

In our experience, the most critical component of intervention is the negotiation that leads to communication scripts or a general communication style enabling the

person to be successful in chosen educational, vocational, and social contexts and that is, at the same time, consistent with his or her sense of self (Step 3 of the intervention sequence outlined in Table 33-4). Often, this negotiation is facilitated by collaborative identification of a positive role model or metaphor that can help the individual to overcome emotional barriers to positive communication alternatives to negative behavior.

Compelling metaphors have the added advantage that they combine into one thought unit a set of social behaviors or scripts that otherwise could be difficult to remember when considered separately, particularly under stress. Thus, for one young adult with a post-injury history of aggressive behavior and multiple psychiatric hospitalizations and incarcerations, calling up the image of Clint Eastwood when stressed yielded a compelling image of self-control as well as a script that included a few words designed to extricate himself from potentially volatile situations. At the same time, the Clint Eastwood metaphor motivated positive, self-regulated behavior and compensated for reduced space in working memory. Functioning in this manner, effective metaphors are components of the “implicational code” or organized set of “emotional beliefs,” as those concepts have recently emerged in new interpretations of cognitive psychotherapy (Teasdale, 1997).

Ylvisaker and Feeney (2000a) explored the facilitating role played by positive metaphors for individuals with cognitive impairment and oppositional behavior following TBI. They illustrated this role by describing their intervention for a fiercely oppositional adolescent who had been in serious trouble with the law and threatened several staff members in his residential program. His initial resistance to any intervention was overcome by hiring him as a consultant to develop a training video about oppositionality. In his capacity as a paid consultant, he revealed that his overriding goal in interacting with authority figures and many peers was to avoid being a “suck up” (his term). The only “non-suck-up” role with which he was familiar was that of a fiercely oppositional and defiant bulldog, which he played effectively—and which routinely got him into serious trouble. He agreed to refer to this role with a vulgar metaphor (to cast it in a negative light) and worked with the clinicians to identify a third way of acting, that of “winners”—successful people who are not suck ups but, rather, who do what needs to be done to achieve their goals. He then agreed to practice negotiating many everyday social interactions in three ways: (1) as a suck up, (2) as his traditional defiant self, and (3) as a winner. These interactions were videotaped (as part of developing the training program), and he reviewed the tapes as part of his responsibilities as a consultant to the project and as part of his communication therapy.

During his context-sensitive practice, a social skills coach (speech-language pathology intern) mediated his experience with discussion of which of these three interactive styles

were comfortable for him (predictably, the suck-up style was never comfortable) and which were successful (the defiant style was never successful). Success and adequate comfort came to be associated with a wide range of positive (“winner”) interactive behaviors. Social cues could then be reduced to one positive reminder—“You can be a winner”—as opposed to the top-down admonitions that he had routinely interpreted as nagging and to which he had routinely reacted with oppositional behavior. Perhaps more important, success came to be associated with a conviction that “winner behavior” was his route to freedom, a good job, and other personally significant goals. This metaphorical transformation at least brought him onto the playing field of successful social interaction, which he continued to practice with considerable success.

Other metaphors described by Ylvisaker and Feeney (2000a) and used successfully in TBI rehabilitation include:

1. **Social skills as basketball plays.** A former basketball player whose impulsiveness had led to substance abuse and serious trouble with the authorities came to agree that he needed “to be like Mike [Michael Jordan] and use set plays rather than running around the court like a crazy kid.” Social skills training then became a process of defining successful plays, putting them in his play book, and videotaping him while engaged in these plays so that he could review the game films as part of routinizing the plays. Social cues for this extremely disinhibited person were then reduced to the nonthreatening “What’s the play?” and “Is this play in the play book?” as opposed to the cues (i.e., nagging) that staff had previously used and that had routinely elicited oppositional behavior.
2. **Requests for clarification as journalistic behavior.** A well-educated young woman with a commitment to feminism before her injury overcame her reluctance to asking communication partners for clarification of their message (and increasing social withdrawal) once she associated these requests for clarification with the journalistic practices of her heroine, the well-known feminist and journalist Gloria Steinem.
3. **Cognitive prostheses as common workplace practices.** A young man who before his injury had been a truck driver at a gravel pit overcame his resistance to compensatory procedures, such as a small memory notebook, when he connected these strategies with the common practice at his former job site of having unused trucks and drivers available for emergency purposes if the others broke down.
4. **Risk-taking behavior as red-card violations in soccer.** A former soccer player, who had been arrested twice on drug charges after his injury, began to work hard on his recovery after formulating the following

metaphorical insight: “I want to play the game, but I have two yellow cards. The next time, it’s a red card, and I’m off the field. But my teammates will still be playing—and playing at a disadvantage because I got myself thrown out of the game. I can play and enjoy playing and win, but I’ve got to pay attention to the rules.”

5. **Ignoring provocation as cool behavior.** A young adult who before his injury was a drug user and drug dealer in New York City was placed in a developmental disabilities workshop as part of his community reintegration plan. John routinely reacted with physical and verbal aggression when co-workers irritated him at work. His resistance to ignoring these provocations was overcome after discussion of his hero, the rap musician LL Cool J, who not only delivers fiery lyrics in his performances but also is a successful and self-controlled businessman and family man. Ignoring provocation at work came to be seen not as weakness but, rather, as an aspect of the strength of LL Cool J.

In a self-advocacy videotape that we helped John (see illustration 5 above) produce and that he asked his work supervisor to watch, he explained that it was difficult to overcome instincts and communication styles fashioned during his years on the streets. He described his efforts to resist impulsive aggressive responses and to use the behavior that he had chosen as a substitute (a somewhat sarcastic, dismissive comment, followed by turning away). He ended his video with a plea to the supervisor, “Please, let me be me.” Subsequently, this supervisor used a subtle written cue (“Cool J”) at the first sign of John’s loss of control, resulting in his successful effort to regain control because of its association with his positive self-metaphor.

People will be who they are. With this in mind, one responsibility of rehabilitation professionals is to assist people in becoming who they are. It is not the job of communication specialists to force individuals to communicate in ways that are foreign to their understanding of who they are but, rather, to help them communicate in ways that contribute to the achievement of meaningful goals in their lives, consistent with the needs of others. That this aspect of communication intervention enters the domain of self-discovery and self-acceptance counseling should not frighten away communication specialists inadequately trained as counselors but, rather, cause them to redouble their collaboration with other rehabilitation professionals. Through such collaborative efforts, including collaboration with colleagues, the person with disability, and everyday people in the environment, functional intervention is allowed to take root in the real world, facilitated by positive alliances among all relevant stakeholders. These intervention themes are further elaborated by Ylvisaker and Feeney (2000b).

COLLABORATION WITH EVERYDAY PEOPLE THROUGHOUT RECOVERY

In this chapter, we have placed major emphasis on the role played by everyday people (e.g., family members, direct care staff, teachers, work supervisors, coworkers, friends, and others) in the long-term rehabilitation of individuals with chronic cognitive, communication, and behavioral impairment after TBI. This emphasis is motivated, in part, by the economic realities governing neurologic rehabilitation at the turn of the century but also, in part, by the enduring principles of sound, appropriately context-sensitive intervention. Rehabilitation within this framework mandates effective collaborative alliances with everyday people. In Appendix 33.4, we list reasons for such alliances, along with obstacles to establishing collaborative alliances, strategies for overcoming the obstacles, characteristics of effective everyday coaches/facilitators, and training and support options.

In medical rehabilitation, many obstacles to the creation of such collaborative alliances exist. Appendix 33.4 lists some of these obstacles and offers a menu of strategies to overcome them. In our experience, managers in rehabilitation facilities play a critical role in supporting a culture of rehabilitation that values alliances with everyday people. In such facilities, therapists’ schedules are creatively designed so that they have natural opportunities to interact collaboratively with one another, nursing staff (in an inpatient facility), assistant-level staff, and family members. In addition, training opportunities and materials (e.g., peer coaching and customized training videos) are available for orientation of staff who did not learn collaborative principles and procedures in their professional training programs.

Appendix 33.4 includes a list of characteristics of people who are effective in their role as everyday coach and facilitator for people with chronic impairment after TBI. Some family members, therapists, direct care staff, work supervisors, and others have these characteristics in abundance. Others need considerable help to play their role effectively. Appendix 33.4 concludes with a list of procedures that can be used to put everyday people in a position to play this role. Traditional training procedures (e.g., brief in-services for direct care staff and family conferences) are notoriously insufficient. Situational coaching and support typically are necessary to change behavior (just as clinical practicum experiences are critical for clinicians in training). Strong support systems are critical for people whose resilience and optimism become severely strained. Specific scripts may be needed by those people who are not, by nature, flexible or enthusiastic problem solvers but, rather, who need to create everyday routines of flexibility and effective problem solving. Because of their expertise in communication, speech-language pathologists often play a central role in developing interaction scripts and in general staff and family training.

Ylvisaker and Feeney (1998a, 1998b) explored these themes in greater detail.

Communication Partner Conversational Support Competencies

Speech-language pathologists often are called on to train direct care staff and others in the interactive competencies needed to communicate effectively with patients in neurologic rehabilitation settings (Ylvisaker, Feeney, & Urbanczyk, 1993a). It is less common, however, for communication partner training to be considered as a critical component of cognitive rehabilitation. Recent research in developmental cognitive psychology has emphasized the role of parent-child conversations about the past in facilitating children's development of thought organization and autobiographical memory (Fivush, 1991; Fivush & Fromhoff, 1988; Fivush & Haden, 2003; Fivush & Reese, 1992; Haden, Haine, & Fivush, 1997; Hudson, 1990; Lucariello, Hudson, Fivush, & Bauer, 2004; McCabe & Peterson, 1991; Nelson, 1992; Reese & Fivush, 1993; Reese, Haden & Fivush, 1993). The evolving view is that parents who interact frequently with their preschool children in a collaborative, elaborative, and socially enjoyable way have children who develop internal cognitive organization and autobiographical memory more effectively than comparable children whose parents interact with them less frequently or in a way that is not similarly supportive. Although these interactions can focus on a variety of topics, developmental investigations in this area largely have targeted parent-child interaction while jointly talking about events that they have experienced together—that is, socially co-constructed narratives about the past.

In Appendix 33.5, we attempt to capture the competencies associated with a cognitively facilitative style under two general headings: collaboration and elaboration. In other words, conversation partners who are effective in facilitating cognitive growth in children or people with cognitive impairment tend to participate with them in conversation rather than demand performance from them. In addition, facilitators use conversational procedures to help their conversation partner understand how things, people, and events in the world are organized—that is, they gradually clarify the many ways in which things in the world go together. In effect, within this Vygotskian framework, facilitative conversationalists, whether parents, teachers, therapists, aides, or others, are able to teach their partner how to think and how to organize their thoughts while, at the same time, enjoying pleasant conversations about topics of mutual interest.

We have used the competencies listed in Appendix 33.5 in the training of family members and staff serving children and adults with cognitive impairment after TBI. In addition to enhancing the cognitive value of everyday interaction, these competencies often have the effect of reducing tension between people with TBI and staff members. In our experi-

ence, many well-meaning people interact with adults who have cognitive impairment in an inquisitorial and nonelaborative manner, a style of interaction that tends to elicit negative behavioral responses and that is the opposite of facilitative from a cognitive perspective. An additional component of staff communication training, associated with an everyday, routine-based approach to intervention, is the development of scripts that promote problem solving and flexibility in individuals who otherwise are rigid and disorganized in their approach to everyday problems. Appendix 33.5 concludes with examples of such scripts.

Self-Advocacy Videotapes

As part of a general focus on collaboration and executive functions in rehabilitation, it is useful to engage individuals with TBI, working collaboratively with staff and family members, in the production of a videotape that has as its primary purpose to orient and train future (or current) staff in how to teach, help, coach, and otherwise work with the person. This can be a project for the last 2 or 3 weeks of the inpatient rehabilitation program or at any time when such a training vehicle may be useful. The person with disability is engaged in a meaningful and important project that has a concrete and very legitimate goal—namely, to help others understand their strengths and needs and become oriented to the teaching or support procedures that are most helpful.

This project also has several secondary purposes, including consolidation of collaborative alliances through product-oriented efforts. Furthermore, this process helps the person with disability, family members, and other relevant everyday people to gain insight regarding postinjury issues. Their learning often is enhanced when important information and procedures are processed to teach someone else. A general protocol (that can and should be modified to meet the needs of specific individuals and situations) and its rationale are presented in Table 33-19. In at least two New York State TBI community support programs, protocols are in place that enable all participants to create and use self-advocacy videotapes.

CLINICAL DECISION MAKING IN THE FACE OF INCOMPLETE EVIDENCE

Throughout this chapter, we have cited key pieces of experimental literature and general reviews of the efficacy literature in TBI rehabilitation and, importantly, in closely related fields of intervention. In our view, serious consideration of these literatures, combined with clinical experience in many practice settings, supports the general approach to intervention described in this chapter. At this time, however, evidence from well-designed clinical trials with large numbers of subjects is insufficient to draw strong conclusions. Therefore, clinicians must make responsible clinical judgments in the absence of accepted standards of practice.

TABLE 33–19

Transitional/Self-Advocacy Video: Rationale and Procedures

Goals

Primary Goal: To produce a videotape that can be used to orient and train people (e.g., school staff, employers, family members, home health aides, and others) who may need to be trained in how to teach, interact with, or otherwise support the person with disability.

Important Associated Goals:

The individual with disability will:

- Gain a sense of empowerment.
- Gain progressively more insight regarding their strengths and needs.
- Progressively become more strategic in their thinking about themselves and their rehabilitation and school careers.

Family members will:

- Gain a sense of empowerment.
- Gain progressively more insight regarding the child's strengths and needs and share their insights with staff.
- Gain an appreciation of the importance of executive functions and the student's participation in goal setting, planning, and strategic thinking.

Staff will:

- Strengthen their collaborative relationships with other team members (including parents) as they work together to produce the video.
- Gain greater appreciation for the perspective of students and parents.

Procedures (Subject to Considerable Variation in Individual Cases)

1. Several weeks before a substantial transition (e.g., discharge from inpatient rehabilitation, return to work or school) staff, individual with disability, and family members hold a **planning meeting**. The purposes of this meeting are:

- a. To decide what **content** would be most important to demonstrate on video. This could include:
 - **Physical** strengths, weaknesses and intervention/support issues (e.g., seating, positioning, mobility, dressing, and eating).
 - **Cognitive** strengths, weaknesses, and intervention/support issues (e.g., types of advance organizers needed; types of environmental or materials modifications needed because of attentional, perceptual, or other processing problems; types of cues and prompts needed).
 - **Communication** strengths, weaknesses, and intervention/support issues (e.g., use of an augmentative communication system; demonstration of partner communication styles that facilitate comprehension).
 - **Behavioral/social** strengths, weaknesses, and intervention/support issues (e.g., procedures for preventing behavioral problems, ways to diffuse behavioral outbursts, and ways to facilitate peer interaction).

It is critical that both **strengths** and the **goals of the individual with disability and family members** be highlighted.

- b. To decide what **format and scripts** would be most effective in demonstrating critical points:

1. It often is effective to show the individual (1) succeeding at a task that he or she is good at; (2) failing at an important but difficult task when appropriate procedures, modifications, or equipment are **not** in place; and then (3) succeeding when they are in place.
2. It often is effective to communicate content by means of a **conversation** between individual with disability and staff or between staff and family members, as opposed to simply videoing a "talking head."
3. It is ideal to videotape the individual's own orientation to and commentary about the video segments and then edit these into the tape as orientation for the viewer. This videoing can be made after the person has watched the other segments.

- c. To decide **who should play what role** in the video. If possible, the person with disability should play a leading role (possibly with considerable support). If the person is extremely impaired, family members can play a leading role.

- d. To work out **logistics** of videoing and editing.

The individual and family members may be more or less involved in this planning, depending on many factors.

2. During the following weeks, the planning of video demonstrations can be included in therapy sessions. For example, development of scripts can be part of speech-language therapy sessions; development of presentation of strengths and needs can be part of counseling sessions; and development of physical demonstrations can be part of PT, OT, ST, and other therapies.
3. The actual videotaping may be no more than a camera in a therapy session capturing an important demonstration. If other individuals are present, they must have signed releases. The videotape may or may not be edited, depending on the skills of staff and time available.

(continued)

TABLE 33-19

Transitional/Self-Advocacy Video: Rationale and Procedures (continued)**Advantages of this Transitional/Self-Advocacy Routine**

Beyond the obvious goal of orienting future staff and caregivers, the transitional, self-advocacy videos serve a number of purposes:

1. **Incidental Learning: Individual with Disability**—People acquire important information about themselves and about their rehabilitation program by being engaged in a fun, product-oriented activity.
2. **Incidental Learning: Staff**—Staff members acquire important information about the person with disability, the family, and their own program by being engaged in a fun, product-oriented activity.
3. **Incidental Learning: Family Members**—Family members acquire important information about the individual and the intervention program by being engaged in a fun, product-oriented activity.
4. **Efficient Cross-Training**: Staff currently working with the person may learn important things from other staff or from family members without the stigma associated with being singled out for remedial instruction.
5. **Development of a Shared Conceptual Framework**: The intervention team refines its own shared conceptual framework by being engaged in a fun, product-oriented activity.
6. **Fun**: Producing this video can be fun.
7. **Permanent Record**: If this practice becomes routine, the person with disability and family will have an invaluable permanent record of the recovery process.
8. **Costumer Satisfaction**: In general, people with disability and family members are pleased when staff accord them the respect that is implicit in this activity. Indeed, this can be a vehicle for overcoming an adversarial relationship if that exists.

Modified from Ylvisaker, Szekeres, Feeney (1998); with permission.

In domains of impairment in which the need for clinical services is undeniable but published experimental guidance is, at best, incomplete, responsible clinicians make decisions about intervention for specific individuals with disability based on informed consideration of the following factors (Ylvisaker et al., 2002):

- Is the proposed intervention supported by any intervention outcome studies with subjects who have TBI and who possess the same impairments and needs as the client?
- Is the proposed intervention supported by intervention outcome studies with related populations (e.g., those with learning disabilities, developmental disabilities, ADHD, or behavioral disorders)?
- Is the proposed intervention supported by trial intervention with the client?
- Is the proposed intervention supported by extensive clinical experience with clients who have TBI?
- Is the proposed intervention supported by theory, including neuropsychological, cognitive, behavioral, pedagogical, and other theories?
- Is the proposed intervention supported by negotiation with the client and relevant stakeholders in the client's life?
- Is the proposed intervention consistent with known constraints, including expertise of service providers, availability of support personnel, time to complete the intervention, and adequate resources?
- Can the proposed intervention be judged as preferable to known alternatives—in relation to predicted functional outcome for the client—based on the previous considerations?

- Is the proposed intervention humane, morally justifiable, and consistent with the scope of practice and relevant licensing laws governing the provider of services?

In our experience with several hundred children, adolescents, and adults who have chronic disability after TBI—disability in the territory in which communication, cognition, executive functions, and behavior overlap and interact—the approach outlined and illustrated in this chapter requires creative effort, but can be effective and functional, based on all these considerations. Furthermore, data from our work with the New York State Department of Health TBI Medicaid Waiver Program demonstrates the cost effectiveness of this approach (Feeney et al., 2001).

FUTURE TRENDS

At the beginning of the 21st century, managed care and associated reductions in funding for rehabilitation have become thoroughly established as dominant themes in adult neurogenic rehabilitation. Inpatient lengths of stay have decreased dramatically over the past 20 years, and funding for traditional outpatient therapies also has been substantially reduced (AHCPR, 1999). The staggering cost of catastrophic neurologic rehabilitation, which was estimated in 1993 to be approximately \$4 billion a year, increasing at a rate of 15% a year (Cope & O'Lear, 1993), has motivated draconian cost-cutting measures. Even as they cut funding, however, funders of services increasingly demand meaningful

evidence of improved functional outcomes. Clinicians, attempting to meet the challenge of having a greater effect with fewer resources, have attempted to create efficiencies in the form of increased use of group therapy and indirect therapy using adequately trained support staff, volunteers, family members, and others. Reason exists to believe that these trends will continue.

We urge professionals in brain injury rehabilitation to increasingly look to other disability groups for insights regarding the provision of effective, community-based services and supports. Community-based models of service delivery have a longer (although not uniformly successful) history in developmental disabilities, mental health, and spinal cord injury compared with brain injury rehabilitation. More generally, professionals serving other populations of people with chronic cognitive, communication, and behavioral impairment may offer wisdom regarding the process of contextualizing and “de-medicalizing” long-term services and supports.

Although driven by economic forces, some of the new directions in service delivery may simply be good practice finally come of age. Following severe TBI, even the best combination of medical and other clinically based interventions generally leave survivors with some degree of impairment and associated disability. Because a majority of these people are relatively young, the ongoing impairments affect social life, work, family life, and community living in dynamic and evolving ways. Therefore, we believe that demands will continue to increase for community-based services and supports, including appropriate supported housing and work, recreational possibilities, behavioral services, and family supports. Cognitive, behavioral, and communication competence plays a critical role in real-world success in these domains. Therefore, specialists trained in community-based cognitive, behavioral, and communication intervention likely will be in increasing demand.

In our experience, delivery of services and supports becomes increasingly challenging years after the injury, particularly if the person with TBI has experienced considerable failure in attempting community reintegration and, possibly, has made unfortunate choices, such as abuse of alcohol and drugs, to escape the pain of ongoing failure. We expect that more states will recognize the combined rehabilitative, humanistic, and budgetary advantages of long-term community support services, like those provided through the New York State TBI Medicaid Waiver Program, for individuals with TBI who are particularly difficult to serve (Feeney et al., 2001; Ylvisaker, 1999; Ylvisaker, Feeney, & Capo, 2007). Potentially lifelong supports through community support agencies, including the services of professionals with expertise in cognition, communication, and behavior, will be found cheaper and more effective than periodic crisis services (e.g., psychiatric hospitalization or jail). Communication specialists will need to be comfortable delivering services

within teams that necessarily include the person with disability and in nonstandard venues, such as the workplace, private residences, and other community settings. Furthermore, specialists in rehabilitation will increasingly deliver their services indirectly, through everyday people in the life of the person with disability.

Developing technologies continue to hold promise for individuals with disability. In particular, the world of electronic communication and access to the Internet have been opened to individuals with varying cognitive disabilities. Sohlberg, Fickas, Ehlhardt, and Todis (2005) evaluated the effectiveness of adapted e-mail access for four adults with severe cognitive impairments after TBI and associated social isolation. The investigators found that all four participants became independent users of the system and continued to e-mail at a 9-month follow-up. The participants endorsed the benefits of e-mailing and reported feeling more connected with family and friends. Earlier, we described the promise that VR technology holds in potentially providing ecologically valid training within a clinical setting.

Reports from animal laboratories regarding the potential usefulness of neuropharmacologic agents in the treatment of individuals with TBI continue to be promising. Despite the trumpeting of this promise for at least two decades, however, “there are currently no drugs available that are of demonstrated benefit in promoting cognitive and motor recovery from TBI” (National Institutes of Health, 1999, p. 269). Clinicians are well advised to remain alert to developments in this field and to ensure that significantly impaired individuals receive needed evaluations from a physician with expertise in TBI pharmacology. Hopefulness, however, must be muted by the realistic expectation that, into the foreseeable future, the greatest effects for individuals with chronic impairment will be derived from a combination of behavioral interventions and environmental supports.

KEY POINTS

1. Because most individuals with severe TBI are relatively young and, therefore, live for several decades with ongoing impairment, the prevalence of TBI is high, and the costs to society are extraordinary.
2. Although virtually any combination of preserved and impaired functions is technically possible after TBI, there are central tendencies within the population, associated, in large part, with damage to the vulnerable frontal lobes, limbic structures, and neural connections among these regions.
3. TBI does not randomly select its victims. Disproportionately large numbers of people with TBI are adolescents or young adults and, in many cases, had preinjury predisposing factors, including

weak academic and vocational histories, risk-taking behavior, and possibly, substance abuse.

4. Among the common consequences of TBI is weak executive control over behavior, including cognition, communication, and social behavior generally.
5. Historically, the dominant intervention approach in medical rehabilitation has been characterized by a focus on reducing the underlying impairment with decontextualized exercises administered by specialists in specialized treatment settings. An alternative approach that has gained increasing acceptance focuses flexibly on impairment, activity/participation, and context—often starting with context modifications (or threats to participation)—involves context-sensitive practice of successful everyday routines and is supported, in large part, by everyday people.
6. Context-sensitive, everyday, routine-based intervention has its rationale in the special needs of people with frontal lobe injury, in recent developments in learning theory, and in the economic realities of neurologic rehabilitation.
7. Context-sensitive, everyday, routine-based intervention is associated with an approach to assessment that is ongoing, sensitive to real-world contexts, and collaborative and that involves the testing of intervention hypotheses.
8. At the center of executive system intervention is the concept of an executive function routine, wherein the individual with disability contributes as much as possible to identifying goals and potential obstacles to achieving the goals, creating plans for achieving the goals, reviewing the usefulness of the plans, and reflecting on what does and does not work for that person in attempting to achieve his or her goals.
9. Functional, individualized rehabilitation plans are centered around goals and activities that are important to the individual, with varied impairments and disabilities targeted within the context of these activities in an attempt to routinize improved cognitive functioning.
10. For reasons that are in part neuropsychological and in part psychological, behavior plans for individuals with TBI should be largely antecedent-focused, understanding antecedents broadly to include both immediate and remote setting events.
11. Communication/behavior plans for individuals with TBI often focus on teaching positive communication alternatives to negative behavior. Positive communication scripts must be integrated into the individual's sense of personal identity that may have to be revised after the injury.
12. Helping individuals with TBI to increase their participation in chosen life activities, improve perfor-

mance of activities of everyday life, and ultimately, reduce their impairments (i.e., improve neurologically mediated processing) frequently requires massive amounts of supported practice in the routines of everyday life. In turn, ensuring adequate amounts of practice requires that specialists collaborate with everyday people who become the primary facilitators of improved performance.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Explain the difference between incidence and prevalence.
2. Explain why TBI is associated with extraordinary societal costs.
3. Why are the frontal lobes especially vulnerable in TBI? List and explain common communication-related impairments associated with frontal lobe injury.
4. What are the most important reasons for contextualizing assessment for individuals with TBI?
5. List and explain several possible hypotheses that could explain why a specific individual with TBI speaks very little and only when spoken to. How would you test the hypotheses?
6. List and explain several possible hypotheses that could explain why a young adult with TBI becomes verbally aggressive when reminded to perform a routine task. How would you test the hypotheses?
7. List and explain several possible hypotheses that could explain why a specific individual with TBI speaks in a way that is disorganized, tangential, and verbose? How would you test the hypotheses?
8. What are the most important reasons for contextualizing intervention for individuals with TBI?
9. Describe differences in executive function routines for people in the middle and late stages of recovery from TBI.
10. What is meant by “supported cognition,” and why is it important?
11. What are the most important reasons for focusing on antecedents in TBI behavior management?
12. Why is it important for speech-language pathologists to be included on behavior management teams?
13. Describe strategies for maximizing the effects that can be obtained from shrinking resources available for long-term rehabilitation.

APPENDIX 33.1

Aspects of Cognition

COMPONENT SYSTEMS

WORKING MEMORY (system for holding and acting on information in consciousness)

- Structural capacity (7 ± 2 units of information) versus functional capacity (information organized for efficient processing)
- Phonologic, visuospatial, and other holding spaces versus supervisory control system

KNOWLEDGE BASE (system for long-term storage of information, rules, schemas, word meanings, and other memories)

- Episodic (autobiographical) versus semantic memory
- Declarative (remembering that . . .) versus procedural (remembering how to . . .) memory
- Explicit (including awareness of the memory) versus implicit (no awareness) memory
- Remote memory (memory for preinjury events, associated with retrograde amnesia) versus recent memory (memory for postinjury events, associated with anterograde amnesia)

EXECUTIVE SYSTEM (system for initiating, directing, and regulating all cognitive processes)

RESPONSE SYSTEM (system for expressing knowledge, including speech, writing, and other modalities)

COMPONENT PROCESSES

ATTENTION

- Arousal and alertness
- Preparing attention
- Maintaining/sustaining attention
- Selecting a focus of attention (concentrating attention)
- Suppressing/filtering distractions
- Shifting/switching attention
- Dividing/sharing attention

PERCEPTION

MEMORY AND LEARNING

- Encoding (placing items in memory), storage (holding memories over time), and retrieval (retrieving items from memory)

- Involuntary (memory as a by-product of functional activity) versus deliberate (effortful or strategic) memory
- Retrospective (memory for the past) versus prospective (memory for appointments and other future events) memory
- Verbal versus nonverbal memory
- Sensory modality-specific (e.g., auditory versus verbal) memory

ORGANIZATION

- Feature identification
- Organization by categories
- Organization by temporal sequences
- Organization by analysis into parts
- Organization by integration into wholes, main ideas, themes, and scripts

REASONING

- Deductive (formal inference) versus inductive (inference from experience) reasoning
- Analogical reasoning (drawing indirect inferences from experience, perceiving relationships)
- Evaluative reasoning (value judgments)
- Convergent (identifying main ideas and themes) versus divergent (exploring possibilities) thinking

FUNCTIONAL INTEGRATIVE PERFORMANCE

EFFICIENCY of information processing

- Rate of performance
- Amount accomplished

SCOPE of processing, including settings and knowledge domains in which processing is efficient

MANNER of processing, including impulsive/reflective, dependent/independent, rigid/flexible, active/passive processing

LEVEL: Developmental, academic, linguistic, or vocational level at which information can be processed

APPENDIX 33.2

Conventional Versus Functional Approaches to Intervention after Brain Injury: Communication, Behavior, and Cognition*

Scope of Intervention

Conventional Approach

1. **Speech-Language Pathology.** The focus is on speech and specific aspects of linguistic competence (semantics, syntax, morphology).
2. **Behavioral Psychology.** The focus is on management of specific problem behaviors in a narrow sense.
3. **Cognitive Rehabilitation.** The focus is on neuropsychological assessment and intervention that sequentially targets separate components of cognition, arranged in a hierarchy for treatment purposes.

Functional Approach

1. The focus of each profession is on helping individuals with brain injury achieve their real-world goals in real-world contexts, including academic, vocational, and social success.
2. Correctly understood, applied behavior analysis in psychology, pragmatics in speech-language pathology, and social-cognitive intervention in cognitive rehabilitation are essentially the same service, necessitating close collaboration among service providers.
3. Each profession recognizes the overarching importance of executive or self-control functions for academic, vocational, and social success.

Integration of Intervention: Collaboration

Conventional Approach

1. Cognition, communication, and behavior are targeted for assessment and intervention by separate professionals working in relative isolation.
2. Evaluation reports, including proposed goals, objectives, and plans to achieve the objectives, are produced separately by three professionals.

Functional Approach

1. Although behavioral psychologists, cognitive rehabilitation specialists (including special educators), and speech-language pathologists are recognized as possessing special and unique expertise, the important overlap in their services is explicitly acknowledged.
2. Assessments are conducted, and plans for intervention are developed in an integrated manner. Ideally, reports are written as integrated, cross-disciplinary documents.

3. Individuals with disability and significant everyday people in their lives are included as contributing members of the collaborative assessment and intervention teams.

Orientation of Intervention: Deficits and Strengths

Conventional Approach: Deficit Orientation

1. The cognitive rehabilitation specialist attempts to remediate cognitive deficits and restore specific preexisting cognitive skills in areas of impairment.
2. The speech-language pathologist attempts to remediate communication deficits and restore specific preexisting speech and language skills in areas of impairment.
3. The behavioral psychologist attempts to eliminate undesirable behaviors (e.g., noncompliance, agitation, and combativeness) and increase specific desirable behaviors (e.g., participation and “socially appropriate” behaviors).

Functional Approach: Strength Orientation

1. Each professional begins with existing strengths and builds on them with:
 - a. Attempts to ensure success in functional activities at the individual's current level of capacity.
 - b. Apprenticeship procedures (including chaining and shaping).
 - c. Compensatory strategies, using strengths to compensate for weaknesses.
2. Success is a goal throughout intervention, using whatever antecedent supports may be necessary to succeed at functional tasks at the individual's current level of ability.
3. Undesirable and challenging behaviors, including explicitly communicative behaviors, are never simply extinguished without an attempt to substitute a positive alternative that achieves the same goal.
4. Preservation and enhancement of the individual's self-esteem is a background goal for all professionals.

Service Delivery: Settings and Activities

Conventional Approach

1. The speech-language pathologist uses repetitive drill and practice in isolated settings that bear little resemblance to real-world communication settings (e.g., pull-out therapy). Activities in therapeutic settings are not necessarily related to real-world communication activities.
2. The cognitive rehabilitation specialist uses repetitive drill and practice in isolated settings that bear little resemblance to real-world settings (e.g., pull-out therapy using workbook or computer exercises that are insensitive to context and to personally meaningful content). Activities in therapeutic settings

*Modified from Ylvisaker and Feeney (1998a); with permission.

are not necessarily related to real-world activities that require the targeted cognitive skill.

3. The behavioral psychologist delivers targeted behavioral services on a behavior unit, in a neurobehavioral rehabilitation facility, or in a behavior classroom, with little opportunity to facilitate transfer of training to real-world settings and tasks.

Functional Approach

1. Each profession focuses on real-world needs in real-world contexts. This focus includes supports for achieving real-world goals in real-world contexts and practice of functional communication, social, and cognitive skills in real-world contexts. Specific aspects of the individual's environments and demands in those environments are considered in choosing objectives.
2. As much as possible, communication and behavioral services are delivered in meaningful social groups, in settings that resemble settings in which the skills will need to be used, and in the context of meaningful activities.
3. Pursuit of cognitive, executive function, communication, and behavioral goals largely is in the context of everyday routines, involving modification of those routines with supports that gradually are withdrawn as the individual's skills improve.

Providers of Service: Involvement of Everyday Communication Partners

Conventional Approach

1. Professionals are considered to be the primary agents of change in the individual with disability.
2. Each profession focuses primarily on remediation of deficits in the individual; that is, the intervention is impairment oriented.

Functional Approach

1. Each profession focuses on improvement of function within everyday routines. Therefore, everyday communication partners (e.g., family members, paraprofessional aides, supervisors, teachers, coworkers, and friends) are critical deliverers of rehabilitation services and supports.
2. A primary role of rehabilitation specialists is to train and provide ongoing supports for everyday communication partners. Within a rehabilitation facility, evening and weekend staff are recognized as being particularly critical to the development of a positive and therapeutically efficient rehabilitation environment.

Source of Control

Conventional Approach

1. There is near total reliance on external control of behavior. Little emphasis is placed on helping the individual to set goals and make good choices, plan how to achieve selected goals, monitor and evaluate behavior in relation to those goals, and make strategic decisions in the face of failure. Professionals assume responsibility for most executive dimensions of behavior.
2. The individual with disability is not included as a member of the team of people who perform assessments, select goals and objectives, plan intervention, monitor and evaluate performance, and create strategic solutions to problems as they arise over the course of intervention.

Functional Approach

1. The ultimate goal is to ensure that the individual controls his or her behavior as much as possible by means of effective decision making, strategic thinking, self-regulation of behavior, and self-regulated control over environmental contingencies.
2. The individual with disability is included as a member of the team of people who perform assessments, select goals and objectives, plan intervention, monitor and evaluate performance, and create strategic solutions to problems as they arise over the course of intervention.

Intervention Procedures

Conventional Approach

1. Prescriptive behavioral objectives specify isolated targets; for example, specific language behaviors are selected for training.
2. Modification of behavior largely is a result of manipulating the consequences of behavior. Within training tasks, correct performance of the target behavior is consequted with presumably desirable objects or events; failure to use the target behavior is followed by a withholding of rewards, a cost of some kind, removal from the situation, or some other neutral or undesirable consequence.

Functional Approach

1. The goal is an acceptable range of behaviors (versus a specific behavior) that may vary in their effectiveness in achieving the communicative objective.
2. Modification of behavior (including cognitive and social behavior) is considered to be a result of manipulating the consequences as well as antecedents of the behavior, but the focus is on antecedents. Antecedent-control procedures include creating environmental supports, avoiding triggers for negative behavior, inducing positive setting events, generating positive momentum, creating opportunities for choice and control, establishing familiar, positive routines and effective procedures for deviating from routines, providing advance organizers for difficult tasks, teaching scripts for negotiating difficult social situations, and ensuring that the individual has maximal self-management skills.
3. Contingency management (i.e., manipulation of consequences of behavior) focuses on positive consequences for desirable behavior (versus punishing consequences and "time out" for negative behavior) and on natural contingencies (versus artificial rewards).
 - a. As much as possible, rewards are internally related to the action performed (e.g., when people request something appropriately, they get it; when people initiate social interaction, they are rewarded with a pleasant interaction; and when people use strategies, they succeed in their endeavors).
 - b. As much as possible, feedback (positive or negative) is given by natural communication partners (e.g., peers or family members).
4. As much as possible, teaching and learning take place within an apprenticeship relationship. The teacher and the learner are jointly engaged in projects designed to achieve meaningful goals. Initially, the teacher assumes much of the responsibility for achieving the goal, but he or she turns over responsibility to the learner/apprentice as soon as possible.

APPENDIX 33.3

Examples of Compensatory Strategies for Individuals with Cognitive Impairments*

Attention and Concentration

External Aids

- Use a timer or alarm watch to focus attention for a specified period.
- Organize the work environment to reduce distractions.
- Use a written or graphic task planner, with built-in rest periods and reinforcement; move a marker along to show progress.
- Place a symbol or picture card in an obvious place in the work area as a reminder to maintain attention.
- Alternate low-interest tasks with high-interest tasks.

Internal Procedures

- Set increasingly demanding goals for self, including work time.
- Self-instruct (e.g., “Am I wandering? What am I supposed to do? What should I be doing now?”). Written cue cards may be needed.

Orientation (To Time, Place, Person, and Events)

External Procedures

- **Time.** Use a watch that included day and date.
- **Schedule.** Use a daytimer or other user-friendly schedule form; use an alarm watch or pager system to stay oriented to schedule.
- **Person.** Use photos of persons not readily identified (e.g., in log book).
- **Place.** Refer to customized maps or diagrams for spatial orientation; label places or routes.
- **Event.** Use a log book or journal or tape recorder to record significant information and events of the day.

Internal Procedures

- Select anchor points or events during the week, and then attempt to reconstruct previous or subsequent points in time (e.g., “My birthday was yesterday—Wednesday—so today must be Thursday and I have to go to work.”).
- Request time, date, and other information from others.
- Scan environment for landmarks.

Input Control/Comprehension

External Procedures

- Give feedback to speakers (e.g., “Slow down; speed up; break that down for me”).
- Request repetition in another form (e.g., “Could you write that down please?”).
- Request longer viewing time or repeated readings.
- Create charts or graphs to assist in comprehending complex material.
- Use a finger or index card to assist in scanning and reading.
- Use symbols to mark right and left margins of written material.
- Use large-print books.
- Use books on tape; request a verbal description if reading is weak.
- Place items to be viewed in the best visual field and eliminate visual distractions.
- Turn head to compensate for visual field cut.

Internal Procedures

- Use self-questioning (e.g., “Do I understand? Do I need to ask a question? How is this meaningful to me? How does this fit with what I know?”).
- Prepare self for new information by presetting with questions and building frames of relevant background information.
- Attempt to summarize and explain information to oneself; check with speaker or source.
- Use a study guide for complex material (e.g., SQ3R: survey, question, read, recite, and review).
- Impose organization using diagrams or other advance organizers (see below).

Memory

External Procedures

- **Retrospective memory.** Use a log book, journal, tape recorder, or computerized information storage system to record significant information and events of the day.
- **Prospective memory.**
Nonelectronic. Use memos, pictures, post-it notes, calendars, graphic time lines, and the like as self-reminders.
Electronic. E-mail self reminders. Use pager system, telememo watch, beeping watch, or handheld personal information storage system.
- **Encoding.** See attention, comprehension, and organization strategies.
- Keep items in a designated place (e.g., keys). Label the places.

*Please see text for suggestions and cautions about the teaching and facilitating process.

Modified from Ylvisaker, Szekeres, Henry, Sullivan, and Wheeler (1987); with permission.

Internal Procedures

- See attention, comprehension, and organization strategies.
- Rehearse to-be-remembered information (covert or overt; pantomime).
- Instruct self about when and why the information will be needed.
- Relate information to personal life experiences and current knowledge.
- Use knowledge of common scripts to reconstruct to-be-remembered events.
- Use mnemonics (e.g., meaningful/novel imagery, method of loci, and rhymes).
- Visualize verbal information; verbalize visuospatial information.
- At the time of retrieval, reconstruct the environment at the time of encoding.

Word Retrieval

External Procedures

- Circumlocute, describing the items in an organized way (e.g., “What kind of thing is it? What does it do? What is it used for? What are its parts? What are its attributes? Where is it found? What do I associated with it?”).
- Use gestures of signs.
- Start a sentence with a carrier phrase (e.g., “I eat with a . . .”).
- Attempt to write the word.

Internal Procedures

- Search lexical memory using an organized feature analysis system (e.g., “What kind of thing is it? What does it do? What is it used for? What are its parts? What are its attributes? Where is it found? What do I associated with it?”).
- Attempt to cue self with phoneme cues, proceeding through the alphabet (slow, and appropriate only for items in a limited category, such as proper names).
- Create an image of the item in a scene, then attempt to describe the scene.
- Attempt to retrieve the overlearned opposite.
- Engage in free association, having an image in mind.
- Associate person’s names with physical characteristics or a known person of the same name.

Thought Organization, Task Organization, and Organized Expression

External Procedures

- Use a graphic organizer or flow chart appropriate for the task or content.
- **Task organizer.** Goal, materials needed, people and their responsibilities, sequence of steps, timeline, and evaluation of results.

- **Narrative discourse organizer.** People, places, time; initiating event, main character’s response, plan, action, and resolution.
- Prepare work space; assign space as task demands.
- Construct a timeline to maintain appropriate sequence of events.
- Alert others before shifting topic in conversation.
- Watch others for feedback in conversation; ask, “Am I being clear?”
- Use outlining software

Internal Procedures

- Use a mental representation of a graphic organizer or flow chart appropriate for the task or content.
- Use knowledge scripts (e.g., discourse scripts like narrative form; event scripts like going out to eat, applying for a job, visiting a doctor scripts).
- Note topics in conversation; self-question about the main point.
- Rehearse important comments; listen to self.
- Set limits of time or allowable sentences in any turn of conversation.

Reasoning, Problem Solving, and Judgment

External Procedures

- Ask others for advice or problem-solving guidance.
- Use others for reality checks.
- Post important social rules to follow

Internal Procedures

- Use an organized problem-solving guide (e.g., “What exactly is the problem? What do I need to know in order to solve it? What are some possible solutions? What are the pro’s and con’s of each? Which is best? [Following action] How’d I do?”).
- Use self-questioning for alternative courses of action or consequences.
- Examine possible courses of action from at least two perspectives.
- Scan environment for cues to appropriateness of action.

Self-Monitoring and Self-Evaluating

- Post reminder: goal-plan-do-review.
- Post reminders or use alarms that mean “Pause and review: How am I doing?”
- Place monitoring reminder cards in books, at work station, and wherever needed (e.g., “How am I doing?” or “Summarize what you have read or done.”).
- Set aside a review time at the end of the day or at the end of the workday.

APPENDIX 33.4

Rationale for Collaborative Relationships with Everyday People

Purposes Served by Collaboration with Everyday People

1. To communicate respect.
2. To integrate useful insights and skills of everyday people.
3. To increase the intensity, consistency, and duration of services by ensuring concordance among all relevant people.
4. To enhance generalization and maintenance of treatment gains.
5. To infuse reality, common sense, and functional goals into professional practice.
6. To ensure appropriate services and supports over the long term as unpredictable problems are encountered (often associated with major life transitions).
7. To enhance community inclusion by creating networks of community support. (Individuals rely more on community supports than on rehabilitation professionals over the long term.)
8. To stretch limited professional resources in an era of managed care.
9. To increase the amount of available data on the basis of which intervention decisions are made.

Obstacles to Collaborative Alliances with Family Members and Other Everyday People

1. Distrust; adversarial relationships based on:
 - Judgmental attitudes (staff or everyday people).
 - Failure to respect the other's perspective.
2. Professional self-perception that as experts, they do not collaborate with everyday people.
3. Insufficient access to everyday people, possibly because services are provided entirely outside of natural contexts.
4. Potential barriers to learning:
 - Quantity and complexity of information and skills.
 - Family: accepting need to learn is a threat to hope.
 - Family: severely competing priorities: exhaustion and stress.
 - Time.
5. Conflict of priorities between rehabilitation professionals and everyday people.
6. Language barriers: vocabulary, cross-cultural barriers.

Strategies to Overcome Obstacles to Alliances with Everyday People

1. Be available to interact with everyday people in contexts that facilitate collaborative activity.
2. Listen actively and nonjudgmentally.
3. Be respectful: "I am a guest in your home."
 - Respect diversity.
 - Seek capacity.
 - Respect expertise.

- Be sensitive to differences in behavior in different circumstances.
 - Acknowledge mistakes.
 - Understand grieving.
 - Identify effective communicator.
 - Ensure that everyday people are supported.
4. Clarify roles and expectations.
 5. Collaborate in assessment (see section on collaborative assessment).
 6. Use in vivo coaching—demonstrate competence in context.
 7. Provide training videos.
 - Generic videos.
 - Customized videos.
 - Collaboratively produced transitional/self-advocacy videos.

Characteristics of Effective Everyday Coach/Facilitator

1. Knowledge
2. Interactive competence
3. Competence in facilitation procedures
4. Optimism
5. Flexibility
6. Creativity
7. Problem-solving ability and enthusiasm
8. Maturity, nondefensiveness
9. Sense of humor
10. Empathy based on rich experience with the realities of the individual's life

Collaborating with Everyday People: Training and Support Options

1. Informational in-services
2. Family conferences
3. Creation of support networks
4. Competency-based training sessions
5. Apprenticeship teaching
 - Teaching in vivo
 - Self-observation on video
 - Collaborative formulation of scripts, including problem-solving, flexibility, and optimism scripts
 - Community meetings
 - Peer teaching and support
 - Staff and family training chains
 - Child peers
6. Training videos
 - Generic videos
 - Customized videos
 - Collaboratively produced transitional/self-advocacy videos

APPENDIX 33.5

Communication-Partner Competencies for Supporting and Improving Cognition in Individuals with Cognitive Impairment*

These conversational support procedures are designed to ensure participation (overcome handicap) and, with repetition, improve cognitive function (reduce impairment). Illustrations of associated interactive scripts also are provided.

Collaboration Procedures

Implicit message: “We are doing this together as a cooperative project”

Supportive Collaborative Style	Noncollaborative Style
<i>Collaborative Intent</i> • Shares information • Uses collaborative talk (e.g., “Let’s think about this.”) • Communicates understanding of partner’s contribution • Invites partner to evaluate own contribution • Confirms partner’s contributions • Shows enthusiasm for partner’s contributions • Makes effort to establish equal leadership roles	<i>Noncollaborative (e.g., Teaching, Testing) Intent</i> • Demands information • Talks as teacher or trainer • Fails to communicate understanding of partner’s contribution • Fails to invite partner to evaluate own contribution • Fails to confirm partner’s contribution • Expresses lack of enthusiasm • Takes leadership role, despite other’s attempt to contribute
<i>Cognitive Support</i> • Gives information when needed (within statements or questions) • Makes available memory and organization supports (e.g., calendar, photos, memory book, gestures) • Gives cues in a conversational manner • Responds to errors by giving correct information in a non-threatening, nonpunitive manner	<i>Lack of Cognitive Support</i> • Does not give information when needed; continues to quiz • Fails to use cognitive supports at appropriate times • Fails to give necessary cues • Corrects errors in a punishing manner
<i>Emotional Support</i> • Communicates respects for other’s concerns, perspectives, and abilities • Explicitly acknowledges difficulty of the task (e.g., “It’s hard to put all these things in order, isn’t it?”)	<i>Lack of Emotional Support</i> • Fails to communicate respect for other’s concerns, perspectives, and abilities • Fails to acknowledge difficulty of the task
<i>Questions: Positive Style</i> • Questions in a nondemanding manner • Questions in a supportive manner (e.g., questions include needed cues, such as “Do you need a wake-up call in the morning?”)	<i>Questions: Negative Style</i> • Questions in a demanding manner (i.e., performance-oriented quizzing) • Questions in a nonsupportive manner (e.g., questions lack needed cues, such as “How are you going to get that done?”)
<i>Collaborative Turn Taking</i> • Takes appropriate conversational turns • Helps partner express thoughts when struggle occurs (e.g. word finding difficulties)	<i>Noncollaborative Turn Taking</i> • Interrupts in a way that disrupts partner’s thought process and statements • Fails to help partner when struggle occurs

Elaboration Procedures

Implicit message: “I am going to help you organize and extend your thinking”

Positive Elaborative Style	Nonelaborative Style
<i>Elaboration of Topics</i> • Introduces/initiates topics of interest with potential for elaboration • Maintains topic for many turns • Contributes many pieces of information to topic • Invites elaboration (e.g., “I wonder what happened . . .”)	<i>Nonelaboration of Topics</i> • Introduces topics of marginal interest, with little potential for elaboration • Changes topic frequently • Fails to add adequate information to topic • Fails to invite other to add information
<i>Elaborative Organization</i> • Conversationally organizes information as clearly as possible: • Sequential order of events (e.g., “First we . . ., then we . . .”) • Physical causality (e.g., “The radio’s not working because it got wet.”) • Psychological causality (e.g., “Maybe you’re avoiding it because you’re scared.”) • Similarity and difference (e.g., “Yes, they’re similar because . . .”) • Analogy and association (e.g., “That reminds me of . . . because . . .”) • Reviews organization of information • Makes connections when topics change • Makes connections among day to day conversational themes	<i>Nonelaborative Organization</i> • Fails to organize information • Fails to review organization of information • Fails to make connections explicit when topics change • Fails to make connections among day to day conversational themes; meaning is vague
<i>Elaborative Explanation</i> • Conversationally adds explanation for events (e.g., “Maybe the fact that you were drunk at the time had something to do with it.”) • Invites explanations for events • Invites discussion of problems and solutions (e.g., “I wonder whether we can think of a better way to handle this if it comes up again.”); invites partner to address problems and solutions • Reflects on other’s physical and psychological status (e.g., “You must have felt miserable about that.”), and invites other to reflect on his or her physical and psychological states	<i>Nonelaborative Explanation</i> • Offers few explanations • Fails to invite explanations • Does little problem solving or all of the problem solving; fails to invite partner to address problems and solutions • Fails to reflect on or invite the other to reflect on other’s physical or psychological status

Problem-Solving Conversation Script

Problem arises:

Staff or Person with TBI Identifies the problematic issue.

Staff Invites reflection about what might work (e.g., “Let’s see; there’s gotta be something that can be done about this.”).

Person with TBI Expresses frustration.

Staff Outlines a few possible solutions.

Person with TBI Rejects one or more.

Staff Continues review of possibilities until person with TBI chooses one to try.

Staff Facilitates an experimental attitude, reflection about what does and does not work.

Flexibility Conversation Script

Person with TBI resists an activity:

Staff “Alright, maybe my idea wasn’t such a good one. There’s got to be another way to do this. Let’s try your idea. (OR Let’s think about it . . .) What are we trying to make happen here? You’re trying to be successful at . . . ? Am I right?”

Alternatively, person with TBI perseverates on an action or thought:

Staff: “This isn’t working real well. You have another thought? (OR Here’s another way (or thought) . . .and another.)”

Chapter 34

Communication Disorders Associated with Right-Hemisphere Damage

Penelope S. Myers and
Margaret Lehman Blake

OBJECTIVES

Upon completion of this chapter, readers will be able to (1) describe the major communication deficits associated with acquired right-hemisphere damage (RHD) and apply that knowledge to clinical work; (2) recognize the impact of deficits in arousal, orienting, vigilance, and selective attention on the communicative performance of adults with RHD; (3) explain the potential impact of neglect on discourse as well as on reading and writing in adults with RHD; (4) describe the extralinguistic deficits associated with RHD and their impact on communication; (5) distinguish cognitive from true affective deficits caused by RHD; (6) describe deficits in specific prosodic parameters and recognize that prosodic production and comprehension can be impaired independently of one another; (7) distinguish process-oriented from task-oriented treatment strategies and apply that knowledge to management of RHD deficits; and (8) generate appropriate stimuli, and apply various treatment suggestions and scoring systems to their clinical work with adults with RHD.

Patients with damage confined to the right hemisphere (RH) may have a variety of processing deficits, including impairments in attention, visual perception, cognition, and communication. Not all patients with right-hemisphere damage (RHD) have communication impairments, but it is generally accepted that those who do are not aphasic. Their command over basic linguistic structures is usually adequate, and they may do well in superficial or straightforward conversation. Their communication problems typically become apparent in more complex communicative events in which

verbal and nonverbal contextual cues must be used to assess and convey communicative intent. Before discussing these problems in detail, it might be useful to draw a very general portrait of a typical patient with RHD, Mr. Smith.

An initial and fairly casual encounter with Mr. Smith may leave the visitor with an overly optimistic picture of his cognitive and communicative capacity. Questions about the weather, treatment by the hospital staff, the quality of the food, and so on will elicit responses that seem not only linguistically accurate, but appropriate as well. He may seem a bit less responsive, and may speak in a monotone, but these characteristics might easily be attributed to fatigue and to the general effects of his recent trauma. The visitor may even be cheered by Mr. Smith's occasional jocularity and blithe assurances about resuming all aspects of his former life.

During subsequent visits, however, the very factors that led to a firm belief in his full recovery seem suspect. He may deny a need for rehabilitative services, refusing to take his physical limitations seriously. His assessment of his capabilities may be at odds with his progress in simple self-care. He may be unable to groom himself properly or to figure out how to put on his shirt. He may talk about returning to work next week, yet be unable to transfer himself from bed to wheelchair. Once in his wheelchair, he may demonstrate difficulty finding his way to the nearby nurses station, or back to his room.

Mr. Smith may have trouble recognizing friends and may deny that they have visited him before. In extended conversation he may seem excessively bound up in himself. He may not respect conversational rules. He may interrupt, fail to assess, and appear not to care about his listener's reaction. He may not maintain eye contact, and he may seem unresponsive to the emotional tone of verbal and nonverbal messages. His tendency to personalize abstract topics, his seeming difficulty in grasping the point of a conversation, and his tendency to digress furthers the impression that he is either confused or that he operates in isolation during conversation.

His jocularity will now strike a discordant note, and he may trivialize topics and focus on tangential and unnecessary detail. Although quick to provide a response, he may

take an excessive amount of time to actually answer substantive questions. He may seem verbose and disorganized. His responses, then, may seem inefficient and lacking an organizational base. His ready answers may seem impulsive, produced without internal reflection.

In short, despite an apparently adequate linguistic system, many patients with RHD neither respond to nor participate in communicative events as they once did. The near-universal refrain of friends and families associated with communicatively impaired adults with RHD is, "He (she) can talk, but it isn't the same."

As this portrait suggests, individuals with RHD not only have communication impairments, but may also suffer from a variety of other cognitive impairments. Regardless of whether these deficits affect communication directly or indirectly, the clinician must recognize their potential impact on the patient.

NONLINGUISTIC DEFICITS

Nonlinguistic deficits associated with RHD include left-sided neglect, attentional deficits, and visuoperceptual problems. Neglect and attention can affect communication and are discussed below.

Neglect

Unilateral or hemispatial neglect is a complex disorder in which patients fail to report, respond, or orient to stimuli on the side opposite their brain lesion (the contralesional side), despite the motor and sensory capacity to do so (Heilman, Watson, Valenstein, & Damasio, 1983). Although it may occur with left-hemisphere damage (LHD), neglect is usually longer-lasting, more severe, and more common in individuals with RHD lesions (Bowen, McKenna, & Tallis, 1999; Mesulam, 1985). Neglect most often occurs with lesions of the *frontal*, *temporal*, or *parietal* cortex (Buxbaum et al., 2004; Mesulam, 1981, 1985; Vallar, 1993; Vallar & Perani, 1986), but can occur as well with subcortical lesions, specifically in the *thalamus* (Hillis, Newhart, Heidler, Barker, Herskovits, & Degaonkar, 2005; Rafal & Posner, 1987; Vallar & Perani, 1986) and the *basal ganglia* (Buxbaum et al., 2004; Damasio, Damasio, & Chui, 1980). Hillis and colleagues (2005) have suggested that neglect due to subcortical lesions may be related to decreased perfusion to distant cortical areas. Neglect may occur in the visual, tactile, auditory, or olfactory senses, or in combinations thereof, but it is most commonly observed in the visual modality.

Patients with RHD with neglect fail to attend to left-sided input; that is, to input from contralesional space. They may not eat food on the left side of their trays, nor notice people on the left side of their beds, nor localize sounds to their left (and thus may look to the right when a phone rings on the left). Neglect can differentially affect body space

(e.g., lack of grooming or dressing the left side of the body), peri-personal space (within arms' reach), or far space (Appelros, Nydevik, Karlsson, Throwalls, & Seiger, 2004; Buxbaum, 2004). More severe manifestations of neglect may co-occur with somatoparaphrenia, which is the failure to recognize paralyzed or weakened limbs as one's own ("I'd be all right if I had my own arm."). This type of delusion can be part of a more generalized disorder called "anosognosia," which is a lack of awareness of illness. Denial of neglect and other deficits is characteristic of patients with neglect.

Patients with neglect have difficulty processing stimuli to the left of their midline, a difficulty that can extend to the left side of any item, regardless of where it appears in the environment (Duncan, Bundesen, Olson, Humphreys, Chabada, & Shibuya, 1999; Gainotti, D'Erme, Monteleone, & Silveri, 1986). The imaginary line dividing their world into neglected and non-neglected space can also shift based on how many things are in the environment and on instructions or cues given. It can be worse in the lower quadrants of space than in the upper quadrants.

Neglect can have a motor as well as a sensory component. According to Mesulam (1981), neglect may disrupt the motor sequences (including eye movements) necessary for exploring and manipulating stimuli in contralesional space. Thus, patients with neglect may fail to perform tasks that require visual exploration or movements on both sides of the body. They may not include left-sided detail in their drawings (sometimes called "constructional apraxia"). They may not be able to dress or groom themselves properly because they fail to reach over to the contralesional side of their bodies.

Reduced attention to the left may be combined with a "magnetic attraction" to stimuli on the right (Bartolomeo & Chokron, 1999), making it difficult to disengage attention when it is captured by right-sided stimuli (Posner, 1980; Posner, Walker, Friedrich, & Raphal, 1984). For example, subjects with RHD canceled more lines in a cancellation task when asked to erase (rather than cancel) the lines, thus removing the attention-attracting right-sided stimuli as they progressed through the task (Mark, Kooistra, & Heilman, 1988). This phenomenon can occur in the auditory as well as the visual modality (Farah, Wong, Monheit, & Morrow, 1989; Robin & Rizzo, 1989). Magnetic attraction may be related to the phenomenon of "extinction," in which the presence of bilateral competing stimuli can increase the severity of neglect (DiPellegrino & DeRenzi, 1995; Duncan et al., 1999). Clinicians should take the level of right-sided stimulation into account in tasks designed to measure or alleviate left-sided neglect.

Most theories of neglect hold that it is a deficit in attention, and many types of attention are implicated, including (1) arousal (Coslett, Bowers, & Heilman, 1987; Heilman, Schwartz, & Watson, 1978; Heilman, Valenstein, & Watson, 1984); (2) sustained attention (Bub, Audet, & Lecours, 1990;

Duncan et al., 1999); (3) the capacity to disengage attention from ipsilesional space (Heilman, Bowers, Coslett, Whelan, & Watson, 1985; Posner et al., 1984); and (4) selective and directed attention (Bartolomeo, Sieroff, Chokron, & Decaix, 2001; Mesulam, 1981; Rapcsak, Verfaellie, Fleet, & Heilman, 1989).

Neglect may be one manifestation of a larger, more generalized attentional impairment (Cherney, 2002; Duncan et al., 1999; Husain & Rorden, 2003; Mesulam, 1985; Myers 1999a). Attention has an obvious impact on cognition. Some studies have reported that neglect has significant negative ramifications for the recovery of independence (Buxbaum et al., 2004; Jehkonen et al., 2001; but see Odell, Wollack, & Flynn, 2005). It may also interfere in some of the cognitive operations involved in communication (Myers & Brookshire, 1996; Rivers & Love, 1980), and even if recovered, individuals initially diagnosed with neglect often demonstrate greater cognitive-communicative deficits than those who never had neglect (Myers & Brookshire, 1996; Tompkins, Bloise, Timko, & Baumgaertner, 1994).

Evaluation of Neglect

Professionals participating in the evaluation of neglect include physicians, occupational therapists, neuropsychologists, and speech-language pathologists. The presence of neglect can be established by published tests or by the informal tasks described below.

Typical paper-and-pencil tests of neglect include *cancellation*, *line bisection*, *scanning*, and *drawing* tasks. Cancellation tasks require patients to look at an array of stimuli (e.g., lines, letters, numbers, or shapes) that are distributed in equal numbers on the left and right across a sheet of paper (Albert, 1973). The patient is asked to make a mark through ("cancel") all occurrences of the stimuli. Neglect is measured by comparing the number of left-sided to the number of right-sided stimuli missed by the patient. Generalized attention can be measured by the total number missed, regardless of their spatial location. Because the target stimuli do not differ from each other, this type of cancellation task is considered *simple*.

Complex cancellation tasks involve selective attention. The stimuli may differ in shape, size, or color. The patient is asked to cancel instances of a particular target in a field of foils (e.g., red triangles in an array of red and blue triangles and squares). Selective attention deficits may exacerbate neglect in complex visual search and cancellation tasks. Thus, a patient may not only omit left-sided stimuli, but may miss targets on the right and may miss more targets on the left in a complex compared to a simple cancellation task. By using both simple and complex cancellation tasks, one can assess the influence of selective attention on a patient's neglect. Task difficulty can be increased by increasing the field density, by placing targets and foils in random arrays

(versus rows), and/or by having targets and foils differ in more than one feature, such as shape and color (Myers, 1999a).

Line bisection requires patients to bisect a horizontal line by making a vertical mark through its center. Performance on line bisection helps determine the degree to which the patient's sense of space is skewed to the right by measuring how far to the right of center the patient's vertical line is placed. Several studies have found that there is wide variability in the normal population in accuracy of line bisection and that deviations of approximately 1/4 inch on a 10.5-inch line can be considered within normal limits. In general, the shorter the line, the more accurate people are in judging its center (Halligan, Manning, & Marshall, 1990; Halligan & Marshall, 1988; Marshall & Halligan, 1989; Tegner, Levander, & Caneman, 1990).

Scanning tasks, used to assess the influence of neglect on reading, require patients to scan an array of letters, numbers, or shapes in which instances of a target stimulus are embedded in a row of foils (e.g., finding all the instances of the letter "A" in a line of letters). Neglect is measured by the number of target stimuli missed to the left of the midline.

Patients can also be asked to read compound words, sentences, or paragraphs presented at their visual midline. The longer the material, the more likely neglect will surface in the form of left-sided omissions (e.g., "able" for "table") or inaccuracies (e.g., "tree" for "three"). A particularly sensitive test requires the patient to read a paragraph in which the left margin is randomly indented from 2 to 25 spaces (Caplan, 1987). The unpredictability of the left margin makes this test well-suited to detecting mild neglect. The score consists of the number of words read aloud by the patient.

The effect of neglect on writing can be assessed by asking patients to write or copy sentences or a short paragraph. Patients may omit the left half of sentences and words (e.g., "house" for "greenhouse"), and their writing samples may contain excessive left-sided margins, iterations and/or omissions of letters and words, and words trailing down the right side of the page.

Finally, patients may be asked to draw from memory or copy symmetrical objects such as a flower, a man, or a geometric form. Neglect is measured by comparing the number of left-sided details to those included on the right in the patient's rendition (see Myers, 1999a, for a scoring method for scene-copying). Drawings can also be inspected for overall structure and integration of object parts. Typically, drawings from patients with LHD are somewhat primitive. Those from patients with RHD may not only be primitive, but also disorganized and disconnected.

Several researchers (Beis et al., 2004; Horner, Massey, Woodruff, Chase, & Dawson, 1989; Ogden, 1985) have reported that because no one task is substantially better than another at detecting neglect, combinations of tasks should be administered. Severity can be estimated by combining

scores across tasks. Establishing the presence of neglect helps clarify whether or not reading and writing deficits are linguistically based. It helps establish the patient's capacity to attend to stimuli in other diagnostic and therapeutic material. Finally, as a reflection of a general attention deficit, neglect may signal a decrease in the patient's general level of arousal and his or her readiness to respond and to produce and sustain effortful, directed attention during complex communicative events.

Treatment of Neglect

There have been many studies of treatment for neglect, and several reviews of the efficacy of treatment of neglect (Calvanio, Levine, & Petrone, 1993; Cicerone et al., 2000, 2005; Manly, 2002). Scanning treatments generally are effective, although generalization of gains to functional tasks such as reading and writing does not always occur.

Management of neglect revolves around the issue of treating the symptoms versus the cause. Symptomatic treatment attempts to compensate for neglect by external aids that are meant to encourage leftward scanning. However, verbally cuing the patient to look to the left, highlighting stimuli on the left (e.g., drawing a red line down the left margin of a printed page), and other external reminders to increase visual scanning are rarely effective because while they may improve performance in therapy, they rarely translate into internal self-cues or generalize to more functional tasks (Calvanio et al., 1993; Halper & Cherney, 1998; Manly, 2002; Tompkins & Lehman, 1998).

Examples of tasks that are thought to encourage internal self-cuing include (a) internally motivated leftward search tasks and (b) tasks designed to stimulate unconscious perception (see Myers, 1999a and 1999b for specific tasks). For example, one can present a very simple leftward search task in which patients are required to find only one or two target objects (e.g., colored cubes) within specified borders. Because the number of targets is low, patients typically continue the search voluntarily until the total number is found. Cubes can be placed on a flat board that has been divided into quadrants. One may begin such a search-and-find task with as few as two cubes of a single color. Task difficulty can be increased by changing cube placement (e.g., placing cubes to the left as well as the right of midline, then in the lower-left quadrant as well as the upper-left quadrant), by increasing the number of cubes, and by having target cubes differ in color from foils. This type of task has been described in detail by Myers (1999a) and Myers and Mackisack (1990). The underlying theory is that by enlisting voluntary attention without external cuing, the potential for generalization of leftward search increases. A second advantage, noted clinically, is that it appears to increase patients' general level of attention and thus may be a good start-up task for cognitive and communication therapy.

Tapping into unconscious perception of left-sided details is another potential way to stimulate leftward movement of attention without external monitoring. The literature contains numerous examples of the phenomenon of unconscious perception, the most common of which is letter substitution (versus omission) in single-word reading (e.g., reading "table" and not "able" for "sable"), which demonstrates that patients have processed left letters at some early level of processing. For example, stimuli that are contiguous, such as a person on the right side of a page holding hands with someone on the left side, can encourage movement of attention leftward such that the patient reports two people in the drawing, unconsciously perceiving them as a single object. Other tasks of this type are described by Myers (1999a) and Brooks, Wong, & Robertson (2005). Leftward search and unconscious processing tasks are theoretically motivated, but their efficacy has yet to be evaluated.

Finally, if one accepts that various types of attention are a significant factor in neglect and in RHD deficits in general, it makes sense to work on attention directly in tasks designed to increase the level of arousal, vigilance, and selective attention capacity. One such treatment with demonstrated generalization requires the clinician to knock loudly on the table and say "ATTEND!" at random times during a scanning task. This cue is then shared with the patient (he or she says "attend" when the clinician knocks), and eventually internalized by the patient (he or she subvocally says "attend" during tasks) (Robertson, Tegner, Tham, Lo, & Nimmo-Smith, 1995).

Clinicians should counsel patients about their neglect and its effects on activities of daily living, including communication, and if necessary, demonstrate the problems in a way that enables patients to overcome possible denial. Families should be included in understanding neglect as an attention disorder and its effects on communication.

Attention Deficits

Patients with RHD with and without demonstrable neglect may have attention deficits. Each type of RHD attention disorder is discussed briefly in the sections that follow.

Arousal and Orienting

Individuals with RHD are sometimes called "hypoaroused," and studies comparing them to those with LHD suggest they are generally less attentive and less alert (Coslett et al., 1987; Davidson, Fedio, Smith, Aureille, & Martin, 1992). Behavioral, anatomical, neurochemical, and autonomic evidence suggests that the right hemisphere (RH) plays a special role in arousal and in orienting to the external environment (Corbetta, Kincade, & Shulman, 2002; Sturm, Longoni, Weiss, Specht, Herzog, & Vohn, 2004; also see Myers, 1999a, for a review). Unlike the left hemisphere (LH), the

RH appears to be able to orient attention to both right and left hemispace. Evidence suggests that neurotransmitter pathways supporting arousal are to some extent lateralized to the right (Oke, Keller, Medford, & Adams, 1978; Oke, Lewis, & Adams, 1980; Posner & Petersen, 1990; Robinson, 1985; Tucker & Williamson, 1984). Physiologic correlates of arousal, such as electrodermal activity or galvanic skin response, indicate that subjects with RHD have significantly lower physiologic responses to pain and to emotional material than those with LHD or those without brain damage (Davidson et al., 1992; Heilman et al., 1978; Zahn, Grafman, & Tranel, 1999). Individuals with RHD also have slower reaction times in response to simple visual and auditory stimuli, such as a point of light or a simple tone (Ladavas, Del Pesce, & Provinciali, 1989; Yokoyama, Jennings, Ackles, Hood, & Boller, 1987), suggesting a reduction in arousal or general attention. Finally, neglect may inhibit the scanning necessary to generate the broad-based view that is fundamental to environmental scanning and for which the arousal and orienting systems are critical.

In functional terms, patients with RHD may need more intense stimulation or more time to get ready to attend than other populations of brain-damaged patients with focal lesions. They may not be as attuned to the environment, nor able to expand attention beyond a narrow focus. A narrowed focus of attention and poor orienting, characteristic of neglect, can reduce sensitivity to environmental cues that carry important pragmatic information.

Vigilance and Sustained Attention

Vigilance is a state of alertness in anticipation of an event. Reaction-time tasks have been conceptualized as measures of general attention and/or of vigilance. Participants must be ready to respond to stimuli that occur at unpredictable or random intervals. To measure attention adequately, reaction-time tasks elicit many responses that require sustained attention over long periods of time. Studies have found that the performance of participants with RHD is poorer than that of individuals with LHD (Sturm & Willmes, 1991), and deteriorates over time (Bub et al., 1990; Koski & Petrides, 2001) and with longer interstimulus intervals (Wilkins, Shallice, & McCarthy, 1987).

Studies of healthy adults indicate a RH dominance for sustained attention (Arruda, Walker, Weiler, & Valentino, 1999; Coull, Frith, Frackowiak, & Grasby, 1996; but see Audet, Mercier, Collard, Rochette, & Herbert, 2000, for conflicting results) and vigilance (Cherry & Hellige, 1999), and increased metabolic activity in the RH during vigilance tasks (Cohen, Semple, Gross, Holcomb, Dowling, & Nordahl, 1988; Deutsch, Papanicolaou, Bourbon, & Eisenberg, 1987; Pardo, Fox, & Raichle, 1991). Results from a recent study using functional magnetic resonance imaging (fMRI) suggest that RH attentional networks are activated

first in focused attention tasks, with recruitment of specific LH areas only with increased task difficulty (Nebel, Wiese, Stude, deGreiff, Deiner, & Keidel, 2005).

These results support the clinical impression that some patients with RHD have difficulty sustaining attention and remaining vigilant, factors that may affect their progress in therapy. Their level of attention during any demanding communicative situation can fluctuate such that they may not process crucial information even when prepared to do so.

Selective Attention

Selective attention enables one to screen out distracting stimuli and to recognize stimulus significance. It can be automatic or voluntary, and is dependent on the arousal, orienting, and vigilance systems. Studies suggest that the RH is particularly important for selective attention. For example, positron emission tomography (PET) studies have found prominent activation of the right anterior cingulate gyrus (Bench et al., 1993; Pardo, Pardo, Janer, & Raichle, 1990), and in the right as opposed to the left frontal cortex of non-brain-damaged (NBD) participants (Deutsch et al., 1987). In reaction-time tasks calling for selective attention patients with right frontal lesions performed slower and less accurately than those with lesions in other cortical areas (Ruff, Nieman, Allen, Farrow, & Wylie, 1992; Stuss, Toth, Franchi, Alexander, Tipper, & Craik, 1999).

In addition, neglect increases as the selective attention demands of tasks increase (Kaplan, Verfaillie, Meadows, Caplan, Peasin, & de Witt, 1991; Rapcsak et al., 1989; Riddoch & Humphreys, 1987). These findings support the notion that neglect is a symptom of a larger attentional deficit.

Effect of Attention Deficits on Communication

Attentional impairments have cognitive consequences that may affect all levels of experience, including communication. Attention deficits may impair the appreciation of the verbal and visual cues that specify the context within which communication takes place. Patients may be less able to shift attention, actively or covertly, during conversations. They may be less able to sustain attention to stimuli anywhere in the environment and to filter out distracters. Thus, they may not be able to attend selectively to important information during communicative events. Finally, attention deficits may place demands on patients' internal resources such that as interactions become more complex and demanding, cognitive resources are strained and patients become overwhelmed. These effects will be addressed more thoroughly in the section on extralinguistic disorders.

Evaluation and Treatment

It should be emphasized that most individuals with RHD will have some type of impaired attention, regardless of the

presence of neglect. Thus, all patients with RHD should be tested for attentional deficits, and the results should be included in family counseling and taken into account in evaluating and treating RHD communication impairments. Tests of attention and treatment techniques can be found in some of the RHD batteries, as well as in published materials designed for patients with traumatic brain injury and in the literature on cognitive rehabilitation (e.g., Turkstra et al., 2005).

Evidence of treatment efficacy is available primarily in the literature on traumatic brain injury (Cappa, Benke, Clarke, Rossi, Stemmer, & van Heugten, 2005; Sohlberg et al., 2003). Direct attention training is effective, although generalization to more functional tasks is limited. Tasks that require attention over time to the occurrence of simple but unpredictable stimuli may increase the capacity for vigilance (e.g., listening for a target word in a word list or monitoring a computer screen for the appearance of a target). Sturm and colleagues (Sturm, Longoni, Fimm et al., 2004) reported improvements in internal alertness in a computerized task with concomitant changes in the function of RH attentional networks, as observed on PET and fMRI scans. Selective attention may be addressed by modifying the complex cancellation tasks designed for evaluating neglect (Myers, 1999a). Additional tasks for treating attentional deficits subsequent to brain injury can be found in commercial materials, including computer software designed for attention training. Research is needed on the efficacy and generalization of attention treatments specifically for adults with RHD.

LINGUISTIC DEFICITS

Pure linguistic deficits are not considered a source of RHD communication impairments. It is true that some individuals with RHD may make errors on straightforward expressive and receptive language tasks such as naming, word discrimination, following simple commands, word definitions, verbal fluency, and reading and writing. However, the available data suggest that the problems are relatively mild, are not characteristic of aphasia, and rarely affect communication significantly (Archibald & Wepman, 1968; Deal, Deal, Wertz, Kitselman, & Dwyer, 1979; Eisenson, 1962). In addition, visuospatial deficits, neglect, and attentional impairments have been cited as possible contaminating factors in some studies investigating linguistic disorders in adults with RHD (Adamovich & Brooks, 1981; Archibald & Wepman, 1968; Swisher & Sarno, 1969).

In general, patients with RHD are able to structure sentences and paragraphs according to the rules of their language. They do not have particular problems in retrieving words, and they rarely make paraphasic errors. However, their control over linguistic structure may belie a more general problem with language use at the narrative and discourse

level of communication, as discussed in the section on extralinguistic deficits.

Evaluation and Treatment

If a true linguistic problem is suspected, subtests from aphasia batteries, designed to test language in constructions that are essentially context-free, are useful in assessing linguistic comprehension (e.g., following verbal commands rather than interpreting paragraphs) and expression (e.g., object naming rather than scene description). Errors should be examined in light of visuoperceptual and attentional deficits. If the clinician feels certain that the patient has a language problem rather than, or in addition to, signs of RHD, treatment should follow the traditional approaches used in the management of aphasia. It is important to remember that language is not always lateralized to the LH, particularly in left-handed people. Thus, although extremely rare, a patient with RHD could have aphasia.

EXTRALINGUISTIC DEFICITS

Although individuals with RHD typically do not have aphasia, many of them do have communication disorders. Extralinguistic deficits represent the heart of RHD communication problems. The term “extralinguistic” refers to factors that affect communication but are not strictly linguistic in nature. The extralinguistic and pragmatic aspects of communication specify the context within which communication takes place and allow one to understand and convey intentions, emotional tone, and implied meaning. These aspects of communication extend communicated meaning beyond the literal or surface structure of words and sentences. Context is conveyed through an array of sensory cues such as gesture, body language, facial expression, and prosodic contour, as well as through the choice and grouping of words themselves. Extralinguistic cues allow us to interpret intended meaning (what is meant from what is said) and to understand the relative formality and emotional tone of discourse, the roles played by participants in a conversation (e.g., peer versus subordinate), and whether someone is being funny or sarcastic or serious. These same cues help us express our own intended meanings.

Some patients with RHD appear to have difficulty using these cues to understand the implied meaning of complex discourse and narratives. Thus, they may miss the theme or point of a story. They may not recognize relationships among characters, their emotional state, and/or the motives behind their actions. In conversation they may not understand humor or the subtleties of irony. They may miss the main points a speaker is making because they focus on unimportant details and have difficulty integrating information into an overall theme. They may not attend to a speaker's facial expression, the prosodic cues that convey emotion and

emphasis, or to the physical setting in which the communicative act takes place.

Patients with RHD may also have difficulty expressing their own intended meaning. Their speech may be inefficient and uninformative, and lack specificity. They may have problems getting to the point they are trying to make. Finally, they may have difficulty using the extralinguistic cues that convey emotion and intention through gesture and prosody.

It is of note that we still use the term “right-hemisphere communication disorders” to describe these symptoms, a label that refers to a location in the brain rather than the nature of the problem. However, it has only been in the past 25 years that the notion of communication disorders associated with “minor” hemisphere damage gained credence. Early studies focused on describing the deficits and the conditions under which deficits may be observed. With descriptions more firmly established, studies have now begun to address underlying cause in a systematic way. By addressing the mechanisms of the impairments, we may eventually arrive at a more appropriate term to capture the nature of the extralinguistic deficits associated with RHD (see Myers, 2001, for further discussion of this topic). Hypotheses about underlying mechanisms will move management toward treating the cause, rather than the symptoms. Certainly, impaired attentional mechanisms contribute to all levels of cognitive processing, including communication. In addition, there may be specific *semantic* deficits that have an impact on the RHD communicative impairments.

Discourse Deficits

Macrostructure Deficits

A macrostructure is the overall theme, central message, or main point of narratives, pictured scenes, situations, or discourse. Individuals with RHD may have difficulty generating macrostructures in comprehension and expression of complex communication. They may miss the point of conversation and be unable to stick to the point or convey the gist of their own messages. They may produce fewer core concepts, have problems giving titles to or choosing a summary statement for story contents, and have difficulty extracting story morals and themes in linguistic and pictured stories (Benowitz, Moya, & Levine, 1990; Gardner, Brownell, Wapner, & Michelow, 1983; Hough, 1990; Joannette, Goulet, Ska, & Nespoulous, 1986; Lojek-Osiejuk, 1996; Mackisack, Myers, & Duffy, 1987; Moya, Benowitz, Levine, & Finklestein, 1986; Myers & Brookshire, 1996; Rehak, Kaplan, Weylman, Kelly, & Brownell, 1992; Wapner, Hamby, & Gardner, 1981).

Generating a macrostructure depends on the capacity to draw inferences or interpret information. According to Myers (1992), “an inference is a hypothesis about sensory

data such that input is not only sensed, but interpreted” (p. 9). Inferences about individual features must be integrated within the entire context to produce the overall theme we call a macrostructure. Initial inferences are beliefs or hypotheses about sensations. Later-stage inferences are hypotheses based on those initial beliefs. Thus, a viewer might interpret a picture of a man in a purple robe, wearing a crown, and holding a scepter as a king. The conclusion that he is a king is a hypothesis about the intended meaning of the visual image.

There are many levels of inference. In the above example, organizing the visual image into the form of a human is an inference, and determining that the image is that of a man is another inference. In general, the type of communication impairments experienced by adults with RHD suggests that inference breaks down at a later stage of processing, rather than at the level of translating light rays into shapes or sound waves into phonemes, or even linking pronouns to their antecedents (Leonard, Waters, & Caplan, 1997a, 1997b). The process of inferencing does not end once an inference is generated. The inference may have to be maintained in working memory until required for selection from one of several possible interpretations when more than one inference is generated (Blake & Lesniewicz, 2005).

Generation of inferences depends on at least four operations: (1) attention to individual cues; (2) selection of relevant cues; (3) integration of relevant cues with one another; and (4) association of cues with prior experience. In the above example, the color of the man’s hair would be considered an irrelevant cue. Relevant cues include the crown, the robe, and the scepter, and perhaps the color purple. These combined cues create the context from which the inference of royalty is made. That is, the elements must not only be recognized, but must be sorted for relevance, and those considered relevant must be combined or integrated to create a context or pattern or meaning beyond the superficial recognition of color, form, light, and shadow. The cues also must be associated with prior experience. These operations are not necessarily ordered sequentially, but more likely occur in parallel.

In similar fashion, recognizing the intended meaning of verbal communication requires that one go beyond the superficial, literal, or referential meaning of individual words to their implied or inferred meaning. In general, adults with RHD do not have difficulty with simple or automatic inferences (Brownell, Potter, Bihrlé, & Gardner, 1986; Lehman & Tompkins, 2000; McDonald & Wales, 1986). They may have more difficulty with “elaborative inferences,” which expand or embellish information and place demands on processing resources (McKoon & Ratcliff, 1989). Making predictions and determining the emotions or motives of story characters or conversational partners are elaborative inferences. Despite the fact that these inferences can be cognitively demanding, they can be generated by

adults with RHD when they are strongly suggested or supported by a context (Blake & Lesniewicz, 2005; Lehman-Blake & Tompkins, 2001). More likely, inferencing problems tend to arise when correct interpretations rely on integrating multiple cues or selecting one of several possible interpretations. These deficits are discussed below.

Selection and Integration Deficits

Problems generating an organizing principle or macrostructure for narrative discourse may be related to deficits in integrating contextual information (Hough, 1990; Wapner et al., 1981). As explained by Hough (1990) and Brownell (1988), understanding the theme or overall gist of narratives involves the extraction of meaning from individual sentences and the integration of their meaning into the context supplied by the other sentences. One must often infer the semantic links between sentences because not all the links are explicitly stated (Brownell, 1988; Joannette et al., 1986). Narrative discourse, then, requires the extraction and integration of individual units of meaning (explicit and implicit) into a larger whole. Similarly, interpreting pictured scenes or real situations involves the extraction of key individual objects and their integration with one another.

Impaired ability to extract and integrate selected bits of information can be demonstrated by patient descriptions of the familiar “cookie theft” picture (Fig. 34–1) from the Boston Diagnostic Aphasia Examination (Goodglass, Kaplan, & Barresi, 2001). Adequate interpretation of the scene (i.e., the overall implication of disaster) requires selecting and integrating relevant cues to build elaborative

inferences about individual elements upon which the overall theme or macrostructure rests. For example, calling the woman a mother (versus a woman) is an inference based on recognizing and integrating the appliances that suggest a kitchen, her apron, and the children behind her. Determining that the children are not just reaching for cookies, but stealing them, requires the integration of the action of the boy reaching in the cookie jar with the action of the girl who has her finger to her mouth in the gesture of “shhh.” Adults with RHD may say the boy has his hand in the jar, and the girl has her finger to her mouth without combining the two actions into the inference of “stealing.”

Clinical experience suggests that individuals with RHD often begin their descriptions of this picture by discussing irrelevant details such as the garden outside the window or the cups on the counter. This problem in selecting relevant information alters the overall interpretation. Myers (1979, 2005), and Myers and Linebaugh (1980) found that subjects with RHD produced significantly fewer inferential concepts in describing the “cookie theft” picture compared to NBD controls, and noted that they tended to list items without explicitly connecting them to each other or to the central action. Much of what they did list was irrelevant, an observation also documented in a study using Norman Rockwell illustrations in which subjects with RHD labeled more than twice as many items as did NBD controls (Mackisack et al., 1987).

Selection and integration deficits have also been reported in verbal-comprehension studies. Hough (1990) asked subjects to interpret the theme of short narratives and found that those with RHD tended to list information and “retained isolated pieces of paragraph data rather than

Figure 34–1. Cookie Theft Picture from the Boston Diagnostic Aphasia Examination (Goodglass, Kaplan, & Barresi, 2001)

integrating this information to deduce the meaning of the narratives” (p. 271). Brownell and colleagues (Brownell, Pincus, Blum, Rehak, & Winner, 1997; Brownell & Stringfellow, 1999; Kaplan, Brownell, Jacobs, & Gardner, 1990; Winner, Brownell, Happe, Blum, & Pincus, 1998) have demonstrated that adults with RHD have difficulty using cues such as familiarity between characters, relationships (friends vs. enemies), status (e.g., employer vs. co-worker), and understanding of another’s knowledge (sometimes referred to as “theory of mind”) to determine speakers’ intents and generate appropriate responses. They also may not use contextual cues effectively to constrain the generation of elaborative inferences. For example, they have been found to generate multiple possible predictions about a story’s outcome regardless of how specific the context is about the most plausible outcome (Blake & Lesniewicz, 2005).

Integration deficits also surface when adults with RHD are asked to organize printed sentences into paragraphs (Delis, Wapner, Gardner, & Moses, 1983) and to name object categories (Myers & Brookshire, 1995). Deficits in all of these tasks support the notion that although the command over basic narrative structure (i.e., script knowledge) is intact (Lojek-Osiejuk, 1996; Ostrove, Simpson, & Gardner, 1990; Rehak, Kaplan, & Weylman et al., 1992), RHD can interfere in integrating isolated pieces of information.

Macrostructure deficits can be influenced by other problems associated with RHD. For example, integration deficits also occur at the perceptual level. Piecemeal processing in the visuospatial realm is thought to be a factor in “constructional apraxia.” That is, a patient may draw a chimney extending straight out from the side of a house or the petals of a flower trailing away from the stem, suggesting that the patient grasps the components, but cannot put them together into a coherent structure. Benowitz and colleagues (1990) found a relationship between difficulty organizing spatial relations and problems integrating verbal information in subjects with RHD. Selective attention deficits may inhibit the ability to filter irrelevant information and recognize important contextual cues. As a result, individuals with RHD may have difficulty not only comprehending *external* information, but also in filtering, integrating, and organizing *internal* information in such a way as to generate efficient narrative expression.

Producing Informative Content

The conversational expression of some patients with RHD has been described as hyperfluent and digressive; that of others as truncated and abrupt (Myers, 1999a; Roman, Brownell, Potter, Seibold, & Gardner, 1987; Sherratt & Penn, 1990; Trupe & Hillis, 1985). These opposing patterns of output occur with approximately the same frequency (Blake, Duffy, Myers, & Tompkins, 2002). Patients with unelaborated output (paucity of speech) often seem perfunctory,

giving the most immediate response without reflection about or interest in its accuracy or adequacy. Excessive output (verbosity) is characterized as digressive and tangential.

Individuals with RHD may produce as many or more words than NBD adults, but what they say may convey less information. Studies investigating informative content have found that subjects with RHD produce narratives that contain fewer concepts, less relevant concepts, and less specific information than those of NBD participants (Bartels-Tobin & Hinckley, 2005; Bloom, Borod, Obler, & Gerstman, 1992; Cimino, Verfaellie, Bowers, & Heilman, 1991; Diggs & Basili, 1987; Joannette et al., 1986; Myers & Brookshire, 1996; Urayse, Duffy, & Liles, 1991). For example, Tompkins and Flowers (1985) noted that low concept scores were overwhelmingly associated with excessive verbal output, reflecting “repetitiveness,” and “irrelevant comments” (p. 529). As one of the first author’s patients said, “I know the point I want to reach, but as I get there my mind, like a vacuum cleaner, sucks up every thought along the way and spews it out.”

Tangential comments may not be off the topic altogether, but their presence signals difficulty in getting to the point. For example, asked what had happened to her and why she was in the hospital, one patient responded:

“My husband saw I wasn’t in bed, and he found me in the clothes that I came to the hospital in, same robe and gown and everything. And we have a very thick rug, what they call a sculptured pattern with swirls and all that. It goes down to the base—fiber base, about two, more than two inches down deep . . .”

Her comments about the carpet continued. They are tangential, but related—related to the fact that although she had fallen on the floor, the cause of her hospitalization was a stroke, not the blow to her head, because the carpet softened the fall. She was unable to make her point explicitly, and thus her listener was burdened with having to fill in the missing information.

Digressive and inefficient output may be related to impaired appreciation of listener needs. Rehak, Kaplan, and Gardner (1992) found that individuals with RHD were impaired in judging the effects of tangentiality on conversational partners. Their lack of sensitivity to the interference of other people’s tangential remarks seems to mirror insensitivity to their own tendencies in this direction.

Occasionally, tangential or irrelevant output appears to reflect uncertainty about the intended meaning of events. Failing to infer the examiner’s intended meaning when asked to describe a pictured scene, or perhaps confused by its contents, one patient with RHD discussed the size and weight of the paper, its plastic coating, and the type of ink used to create the drawing, without ever describing the action depicted in the picture. Sometimes, individuals with RHD confabulate when faced with uncertainty or nonsensical

information. For example, when re-telling stories with surprise or nonsensical endings, subjects with RHD made up details to make the events more plausible (Wapner et al., 1981). This same tendency can be seen in everyday situations when, for example, patients confabulate reasons for impaired performance.

It is possible that narratives based on visual stimuli contain less informative content because adults with RHD have problems perceiving what is in the pictures. However, several studies of scene description have demonstrated that individuals with RHD do not have problems recognizing objects and people in scenes as visually complex as Norman Rockwell illustrations and that the level of inference required to interpret a scene significantly affected performance, while levels of visual complexity did not (Mackisack et al., 1987; Myers & Brookshire, 1996). Reduced informative content has also been found in response to verbally presented narrative passages (Cimino et al., 1991; Wapner et al., 1981), suggesting that problems with content extend beyond visual material.

Generating Alternative Meanings

It often happens that we must generate different, less familiar, or alternative meanings during discourse. Sometimes this occurs because we need to accommodate new information that alters our original interpretation. Sometimes we need to call on a less familiar meaning for a word or set of words. For example, if we walk in on a conversation as someone says, "He was really flying," we might assume that he was talking about someone going at great speed. If we listen further and find it is a discussion about the Wright brothers and their first aircraft, we would have to revise our initial assumption and reinterpret the phrase to mean the person really *was* flying—in an airplane. Individuals with RHD have been found to have difficulty producing alternate meanings under effortful processing conditions.

Connotative and Metaphoric Meanings

Individual words may evoke a denotative or connotative meaning. Denotative meanings are like dictionary definitions and are appropriate for words taken out of context where further interpretation is not called for. Connotative meanings refer to alternative, nonliteral, or interpretive meanings. Thus, for example, the denotative meaning of the word "lion" is "large animal that lives in Africa." Its connotative meanings may include "regal," "king of the jungle," "ferocious," or even "MGM." Figurative language and idiomatic phrases have two meanings—the literal face value of the words, and the metaphoric meaning. Either meaning may be called upon, depending on the context.

Studies have demonstrated RHD impairments in generating connotative meanings for single words that are not

embedded in context (Brownell, Potter, Michelow, & Gardner, 1984; Brownell, Simpson, Bihrlé, Potter, & Gardner, 1990; Gardner & Denes, 1973), and in appreciating both metaphoric and nonmetaphoric alternative meanings for sentences and phrases (Brownell et al., 1990; Myers & Linebaugh, 1981; Van Lancker & Kempler, 1987; Winner & Gardner, 1977) and indirect requests (Foldi, 1987; Hirst, LeDoux, & Stein, 1984; Weylman, Brownell, Roman, & Gardner, 1989). As Brownell and colleagues (1990) suggest, these impairments "may not be restricted to metaphor; rather they may be but one reflection of a more pervasive impairment affecting appreciation of different types of alternative meanings" (p. 376).

Revising Initial Interpretations

Sometimes, one must change one's original interpretation of sentences or events to accommodate new information. Impaired ability to revise expectations may be a factor in problems with following everyday conversation. For example, Kaplan and colleagues (1990) found subjects with RHD impaired in interpreting whether or not conversational remarks between two speakers were to be taken literally. Nonliteral remarks occurred when one speaker was making fun, being sarcastic, or telling a white lie. Understanding the intended meaning of these nonliteral remarks required reinterpreting them in light of previous information.

Similarly, Brownell and Tompkins and their colleagues (Brownell et al., 1986; Tompkins, Baumgaertner, & Lehman, 2000; Tompkins, Lehman-Blake, Baumgaertner, & Fassbinder, 2001) found subjects with RHD impaired in interpreting the meaning of sentence pairs when misleading information was presented in the first as opposed to the second sentence, as in the example, "Barbara became too bored to finish the history book. She had already spent five years writing it." Taken in isolation, the first sentence implies that Barbara is reading a book, rather than writing one. When misleading information was presented first, RHD subjects had more difficulty than the NBD group in revising their original interpretations to accommodate the information contained in the second sentence. Impairments in revision have even been found in a lexical task that required revising the lexical function of a single word (Schneiderman & Saddy, 1988).

We are continually confronted with new information that alters our original interpretations as we negotiate the twists and turns in everyday events and conversations. For the person with RHD such seemingly automatic revisions may overtax resources, so that new information is processed inadequately and entire meanings are missed.

Explanatory Theories: Activation and Suppression Deficit

It has been postulated that the intact RH is more adept at processing multiple, alternate, less familiar, more loosely

connected meanings than the LH, and that the LH is more adept at automatic processing of dominant single meanings or several meanings that are tightly overlapped (Beeman, 1993; Brownell et al., 1984, 1990; Burgess & Simpson, 1988; Chiarello, Burgess, Richards, & Pollock, 1990). Two opposing theories have been proposed to accommodate impaired ability to manage alternative meanings and to revise initial interpretations (see Myers, 1999a, for a review).

The *activation theory* holds that brain damage impairs the normal RH functions noted above, such that patients have difficulty in activating multiple, distant, or subordinate meanings (Beeman, 1993). It may take more effort than normal to generate alternate meanings during discourse, interfering with efficient and accurate processing.

The *suppression theory* holds that individuals with RHD are able to activate multiple meanings, but have difficulty suppressing (versus activating) the less likely meanings for a concept. Continued activation of meanings that are not appropriate to the context interferes in the selection of the particular alternate meaning that is *most* appropriate (Tompkins et al., 2000, 2001).

More studies are needed to sort out which hypothesis best explains the problems adults with RHD have with alternate meanings. For now, it appears that RHD can interfere in the semantic processing of alternate meanings. This problem can disrupt the ability to manage complex discourse that contains ambiguities and/or requires revising initial impressions.

Summary

Problems in generating elaborative inferences, integrating information, and generating or selecting the most plausible meaning(s) can contribute to impaired discourse processing in adults with RHD. They may have problems inferring the links among sentences, integrating verbal information into an overall structure and theme, filtering unnecessary information, and revising original interpretations as new information unfolds. As a result they may fixate on irrelevant details and be vague, nonspecific, and uninformative. They may have problems selecting, integrating, and organizing information and be digressive and verbose. In some circumstances, they may not appreciate figurative and other nonliteral forms of language. Finally, they may have difficulty accommodating new, ambiguous, or seemingly conflicting information.

Evaluation of Discourse Deficits

Not every person with RHD has communication impairments (estimates range from 50% to 90%; Blake et al., 2002; Joannette & Goulet, 1994), so the primary goal in evaluation is establishing the presence or absence of deficits. Commercially available assessment tools can be used in conjunction with the informal approaches described below. Most, if

not all, of these tools have weaknesses in reliability or validity, and so must be carefully evaluated and selected. Additionally, many published tests are not sensitive enough to measure mild deficits associated with RHD.

Discourse and pragmatics are often assessed using informal tasks. It is important to obtain information from the patient's family as part of this assessment. There is a wide range of "normal" conversational and pragmatic behavior, and it is essential to determine which aspects are idiosyncratic to a patient's pre-stroke personality and which ones may be a result of brain damage. For example, Baron, Goldsmith, and Beatty (1999) reported that speech-language pathologists often rated pragmatic behaviors as inappropriate, while family members reported that these same behaviors were typical of the patient prior to the stroke.

Patient Interview

The purpose of the interview is to establish rapport and to obtain a sample of the patients' conversational speech, which can be assessed for content and structure. Establishing rapport is crucial for several reasons. First, patients with RHD may not recognize or may deny their problems. They may wonder why they are seeing a speech-language clinician when their speech sounds fine to them. Second, families often support the patient's denial unwittingly by exhibiting their relief that the patient "can talk." If patients have communication problems, families may not be immediately aware of them. One way of addressing denial is to explain in the initial interview that all stroke patients are tested for communication deficits, to agree with patients that they may not have any problems, and to explain that communication consists of more than speech and language.

Another reason patients may be resistant is that they are aware of some of their deficits (perhaps they have trouble following television shows and complex conversations, or have noticed problems in reading). They may be afraid to admit to these problems in the face of family relief that they can talk (and hence, "do not have communication problems"). They may fear they are mentally unbalanced or generally confused. Their fears can be allayed by clinician assurances that there may be very specific reasons why they are having difficulty that have nothing to do with their mental stability. The clinician can help patients overcome denial by demonstrating some specific problems they may have and by explaining that help is available. Explaining and demonstrating problems to the patient can decrease fear, make problems seem more manageable, and increase insight and cooperation.

The second goal of the interview is to obtain a sample of conversational speech on audio- or videotape that can be reviewed for structure and content. Questions should address patients' orientation, their assessment of their problems, their daily activities, something about their work

history or personal lives, and their plans for the future. The interview thus addresses memory, orientation, and insight. Responses can be assessed for the degree to which they observe pragmatic rules of conversation (e.g., turn-taking, listener burden, etc.), and the degree to which content is informative, accurate, organized, and efficient.

Picture Description

A pictured scene that tells a story or depicts a situation can be used to elicit narrative discourse for the evaluation of macrostructure and integration deficits. Commercially available pictures that require elaborative inferences, such as the “cookie theft” picture from the Boston Diagnostic Aphasia Examination (Goodglass et al., 2001) can be used. A picture-description task enables the clinician to quickly assess the patient’s abilities to attend to and interpret contextual or extralinguistic information. The advantages over asking patients to retell stories are that it elicits a more spontaneous production, it does not involve memory, and missed or inaccurate concepts can be pointed out by directing the patient’s attention to the visually present contextual cues.

The patient’s response can be scored in several ways. For example, the number of inferential concepts generated can be compared to the number of noninferential concepts. Such a scoring system for the “cookie theft” picture has been developed (Myers, 1999a). It can be adapted as clinicians see fit and used during treatment as a probe task to measure progress in therapy.

Transcribed picture descriptions can also be evaluated by techniques of discourse analysis (see Sherratt & Penn, 1990; Urayse et al., 1991) or other types of concept analysis (see Cherney & Canter, 1993; and Nicholas & Brookshire, 1993, 1995; also see Myers, 1999a, for a review of the advantages and disadvantages of these scoring systems). Pragmatic rating scales can assess problems in recognizing the limits of shared knowledge, turn-taking, topic maintenance, eye contact, and other pragmatic deficits.

Treatment of Extralinguistic Deficits

Management of extralinguistic deficits usually consists of a combination of functional or task-oriented and process-oriented methods (see Myers, 1999a and 1999b, for reviews of these two methods for deficits associated with RHD). Task-oriented treatments typically attempt to retrain performance on a specific task—usually through compensation—and address symptoms, rather than the underlying cause of deficits. Process-oriented treatments, on the other hand, address underlying processes and attempt to stimulate recovery of function. For that reason they may have greater potential for generalization across tasks. No studies have been conducted on treatment outcomes for extralinguistic deficits associated with RHD. As a result, therapy for these

problems relies on clinical experience and our current understanding of the deficits and their underlying cause.

One way of stimulating recovery of function for many of the extralinguistic deficits associated with RHD is to work directly on attention and neglect. One should also work on increasing informative content, on generating elaborative inferences, and on generating or selecting alternate meanings and inference revisions.

Clinicians must be creative in designing tasks and evaluating their impact on communication. Treatment tasks that are grounded in theory can be found in Myers (1999a, 1999b), Tompkins (1995), and Tompkins and Baumgaertner (1998). It is assumed that clinicians will use the techniques mentioned elsewhere in this book to establish cuing hierarchies and to probe patient progress. The next sections provide some general directions for designing therapy techniques for RHD discourse deficits.

Inference and Macrostructure Generation

Macrostructure tasks include asking patients to report the overall themes of pictured scenes, stories, or conversational interactions. This can be done by asking them to produce titles for pictures, headlines for news stories, or to state the main theme of the stimulus item. Task difficulty depends on the complexity of the inference to be generated. The less explicit or concrete the theme, the more difficult the inference. By manipulating the level of inferential complexity, one can stimulate the process of inference generation through repeated trials at a level at which the patient reaches a pre-set accuracy criterion.

One can also guide inference generation by working on scenes or stories for which the patient was not able to arrive at an inference. In this process, the clinician attempts to facilitate the patient’s conscious control over what was once a more automatic task. Patients can be asked to (1) label items in a scene; (2) specify the relevant or significant items in a scene; (3) point to items that are related; and (4) explain the relationships among items or some variant thereof. Obviously, to understand the significant items, one must have a sense of the overall theme in a “chicken-egg” conundrum. However, often the process of asking the patient to overtly specify significant items usually helps him or her come closer to the overall theme. For example, in the “cookie theft” picture, the insignificance of the bushes beyond the window and the dishes on the counter to which patients with RHD are often so attracted becomes clear when one asks, “What are the most important items in the picture?” Typically, patients will point to the mother and children and to the water overflowing from the sink and from there arrive at an integrated concept of the picture’s meaning.

Integration tasks include asking patients to organize printed sentences into a story or pictures into a logical

sequence. Stimuli can vary in number of details and in how explicit or implicit the content is. Tasks that require patients to recognize commonalities may also improve integration skills. Patients can be asked to group pictured objects, scenes, or printed words into categories. Categories can range from concrete (e.g., foods, tools, vehicles) to more abstract themes for pictured scenes (e.g., celebrations, disasters, suspicion). Prior to sorting, the clinician can identify the categories, or require the patient to generate them.

At the perceptual level, integration can be addressed in tasks that require patients to arrange puzzle pieces or identify fragmented objects from their individual parts. To make such materials, one can simply photocopy large line drawings of common objects, cut them into several pieces, and rearrange and re-photocopy them.

In addition, patients can be asked to provide an opinion for open-ended questions on current topics of interest. One-minute answers can be tape recorded, transcribed, and rated according to how integrated, complete, efficient, relevant, and coherent the answer is. Impairments in each of these areas can then be worked on separately. Audio or video recording of conversational interactions is a useful way to review various pragmatic deficits (e.g., topic maintenance, turn-taking).

Managing Alternative Meanings

Improving the ability to manage alternative meanings can be addressed in several ways. If one subscribes to the *activation deficit* hypothesis, one can ask the patient to provide two meanings for homographs (e.g., bank, bat, choke, knot, dough) or to group sets of words according to their denotative or connotative meanings.

If one subscribes to the *suppression deficit* theory, one can help the patient enlist conscious control over the suppression of alternate meanings by putting an ambiguous word or sentence into context. The different meanings of the ambiguity can be discussed; the clinician can then help the patient identify contextual cues that lead to the most appropriate interpretation, followed by a discussion of why the original interpretation was no longer accurate.

Tasks designed to improve the ability to formulate revisions may include presenting patients with two-sentence stories, the first of which leads one to a faulty conclusion unless it is reevaluated in light of the second sentence. For example, the sentence, "Ella grabbed her bag and rushed to the gate" might lead one to picture an airport scene until the second sentence, "Once there, she pulled out her key and unlocked it" leads to a different conclusion (Myers, 1999a, p. 106) (see Bloise & Tompkins, 1993; Brownell et al., 1986; Kaplan et al., 1990; and Tompkins & Baumgaertner, 1998, for other examples). Another type of stimulus is a brief story that ends in a statement by the main character. The final statement may be either congruent or incongruent with the

preceding information (Brownell et al., 1997; Brownell & Stringfellow, 1999). Stories can be followed by inferential questions that probe patients' abilities to revise their initial impressions of story content, and their ability to use cues within the text (e.g., familiarity between speakers, and character attitudes or emotions [Kaplan et al., 1990]).

Processing Emotional Content

Individuals with RHD may have difficulty interpreting and expressing emotional content. This can be seen in use and comprehension of (1) facial expression, (2) emotional prosody (aprosodia), and (3) emotionally laden words. In a recent study, reduced affective response was diagnosed in 30% of patients with RHD on a rehabilitation unit, and aprosodia specifically was diagnosed in 20% of the same population (Blake et al., 2002). Although it may seem logical that the two deficits might have similar underlying emotional processes, Blake and colleagues found that they did not frequently co-occur.

Several investigators have suggested that the RH plays a special role in processing emotional content (Bear, 1983; Borod, 1992; Silberman & Weingartner, 1986; Tucker, 1981). It is not clear whether these impairments are the result of an altered internal experience of emotion, reduced levels of arousal, cognitive interference, or some combination thereof. Evidence of an association between altered internal emotional states and site of lesion following stroke is inconclusive (Folstein, Maiberger, & McHugh, 1977; Robinson, Kubos, Starr, Rao, & Price, 1984; Robinson, Starr, Lipsey, Rao, & Price, 1984; Sinyor, Jacques, Kalpoupek, Becker, Goldenberg, & Coopersmith, 1986), although a recent study suggests that emotional deficits most commonly occur when lesions affect both basal ganglia and cortical structures (Karow, Marquardt, & Marshall, 2001). In adults with RHD, what is known as "indifference" and "flattened affect" may be associated with reduced arousal (Heilman et al., 1978). That is, these individuals may be less aware of and less responsive to external stimuli, including the cues that signal emotions. Cognitive-processing deficits may also interfere in emotional processing. Comprehension of emotion requires generation of elaborative inferences using contextual and other extralinguistic cues that enable us to recognize emotional states of story characters and conversational partners.

It is important to remember that "flat affect," reduced responsivity, and flattened prosodic production also can be signs of depression. Other signs of depression include feelings of hopelessness, sleep disturbance, reduced concentration, loss of energy, psychomotor slowing or agitation, and significant changes in weight. Depression occurs in 30% to 60% of stroke survivors in the acute phase (Andersen, Vestergaard, Riis, & Lauritzen, 1994; Cummings, 1994; Iacoboni, Padovani, DiPiero, & Lenzi, 1995; Ng, Chan, &

Straughan, 1995; Ramasubbu & Kennedy, 1994). Obviously, if other signs of depression are present or if depression is suspected in addition to the clinical signs of RHD, a referral for psychiatric evaluation should be made.

Facial Expression Deficits

Comprehension of Facial Expression

Decreased arousal and attention may affect patients' responses to the nonverbal cues that signify emotional expression. Numerous studies have reported that adults with RHD have difficulty interpreting facial expressions depicting emotions (Adolphs, Damasio, & Tranel, 2002; Benowitz, Bear, Rosenthal, Mesulam, Zaidel, & Sperry, 1983; Blonder, Bowers, & Heilman, 1991; Borod, Koff, Lorch, & Nicholas, 1986; Bowers, Bauer, Coslett, & Heilman, 1985; Cancelliere & Kertesz, 1990; Cicone, Wapner, & Gardner, 1980; DeKosky, Heilman, Bowers, & Valenstein, 1980; Karow et al., 2001). Areas of the brain thought to be important in recognizing facial expression include the amygdala, orbitofrontal regions, basal ganglia, and RH neocortex and somatosensory-related areas (Adolphs et al., 2002). The basal ganglia appears to play an important role in interpretation of emotional material (Karow et al., 2001), and some researchers speculate that emotional processing relies on a hierarchy ranging from low-level perception to cognitive selection and interpretation (Blonder et al., 1991; Karow et al., 2001).

Most studies investigating the interpretation of facial expression present faces in isolation without other contextual cues to specify the emotion. The expression must thus be determined by inspection and analysis of the spatial characteristics of facial features such as how close the eyebrows are, how wide open the eyes are, the degree to which the corners of the mouth are upturned, and so on. This type of perceptual-feature analysis depends on spatial or "metric" judgments that may be in the province of the intact RH (Kosslyn, 1987, 1988). Furthermore, individual features must be combined with one another to arrive at an accurate judgment. Thus, feature integration may also play a role.

Production of Facial Expression

Even in patients without "flat affect," facial expressivity may be reduced. Studies of spontaneous facial expression have found that subjects with RHD had reduced facial expression in response to slides depicting emotional situations in comparison to NBD subjects (Mammucari et al., 1988) and subjects with LHD (Borod et al., 1986; Buck & Duffy, 1981). Blonder and colleagues (2005) also reported reduced facial expression in subjects with RHD during casual conversation. While the earlier studies did not control for the effects of facial paresis, in the latter study subjects with LHD were more likely to have facial paresis but also to produce more facial expression.

Comprehension of Verbal Emotional Content

Comprehension of emotion has been assessed by asking patients to identify emotions depicted in pictures or described in sentences or stories, or to match emotional words (Blonder et al., 1991; Bloom et al., 1992; Borod, 1992; Cancelliere & Kertesz, 1990; Cicero et al., 1999; Cicone et al., 1980). Subjects with RHD are impaired relative to NBD controls primarily when tasks are more complex (Borod, 1992; Cicero et al., 1999), or when responses require conscious thought, such as answering questions or making explicit judgments (Rehak, Kaplan, Weylman et al., 1992).

Determining the emotional valance of situations, expressions, and narratives requires generation of elaborative inferences. For example, "He went into the house" is inferentially less complex than "He stole into the house." Most studies documenting problems in inferring emotions from stimuli have not included comparable tasks designed to test subjects' capacity to infer nonemotional or neutral content. Studies that have done so have produced mixed results. Thus, it is difficult to know whether the findings relate to emotional content independent of inferential complexity.

Verbal Expression of Emotional Content

Most studies of the verbal expression of emotional content involve a comprehension task, so it is difficult to know whether impairments are based on failure to comprehend emotions, failure to express emotions, or both. Some studies without a comprehension component still reported deficits in adults with RHD. For example, Cimino and colleagues (1991) asked subjects to recall episodes from their own lives in response to a cue word that was either emotional or neutral. Not surprisingly, the responses of subjects with RHD were rated as less specific than those from the NBD group regardless of the type of cue word. Although the emotional cue words produced higher emotionality ratings than neutral cues for both groups, the responses from the RHD group were significantly less emotional than those of the NBD group. Similarly, Bloom, Borod, Obler, and Koff (1990) and Borod, Koff, Lorch, and Nicholas (1985) found that adults with RHD used fewer and less intense emotional words when they described pictures.

Summary

Individuals with RHD may have problems both in interpreting and in expressing emotional content. However, it is not clear that they have an affective disorder per se. Studies investigating emotional status following stroke have produced conflicting results. Emotional "indifference" may be a component of a more general attention deficit that reduces responsiveness to the external environment, or it may be related to a patient's denial or lack of awareness of his or her deficits. Reduced responsivity may impair the appreciation

of the extralinguistic cues from which one can infer the emotional valence of situations and narratives. In addition, perceptual impairments in spatial judgment and feature integration may contribute to impaired ability to identify emotional facial expression.

Prosodic Processing

The prosodic features of speech convey both emotional and linguistic information. Alterations in pitch, volume, and the duration of utterances and pause time between words create intonational patterns that add extralinguistic information to linguistic content. Linguistic prosody disambiguates word and sentence types, distinguishing noun phrases from compound nouns (e.g., “green house” from “greenhouse”) and interrogative from declarative sentences, and clarifies meaning through the use of stress (“Joe loves *Ella*,” versus “Joe loves Ella.”). Emotional prosody captures not only emotional states, but intents such as sarcasm and irony.

Adults with RHD may be impaired in their appreciation and expression of these prosodic features of speech, a disorder termed “*aprosodia*” (Ross, 1981). One theory suggests that linguistic prosody is processed primarily by the LH, while emotional prosody is processed primarily by the RH, or by bilateral frontal regions (Van Lancker, 1980). One limitation of many studies designed to describe or explain the nature of prosodic deficits associated with RHD is that they generally test a group of individuals with damage to the RH, regardless of whether or not they have been screened for prosodic deficits. The group results may not be reflective of individuals, a minority of whom may actually have *aprosodia*. The results provide general information about incidence, but not necessarily about the characteristics of prosodic impairments in those who have them.

Prosodic Comprehension

A variety of tasks have been used to examine comprehension of both linguistic and emotional prosody. Recent studies suggest that adults with RHD are able to use prosody to identify word meaning (e.g., *OB*ject versus *ob*JECT), aid in syntactic parsing (“listen to the choir, boy” versus “listen to the choirboy”), and to differentiate questions from statements (Heilman, Bowers, Speedie, & Coslett, 1984; Walker, Daigle, & Buzzard, 2002; Weintraub, Mesulam, & Kramer, 1981).

Adults with RHD generally demonstrate more difficulty with emotional than with linguistic prosody. Compared to both healthy adults and individuals with LHD, they are less accurate in making same/different judgments, identifying emotion (e.g., sad versus happy), and in detecting or rating the amount of emotion conveyed prosodically. They also have been found to have impairments in discriminating emotions when speech was filtered so that prosodic features

remained while words did not (Denes, Caldognetto, Semenza, Vaggies, & Zettin, 1984; Heilman, Bowers et al., 1984; Tompkins & Flowers, 1985) and in identifying emotional prosody in nonsense sentences (Pell, 2006).

The cause of impaired prosodic comprehension is uncertain. Wunderlich, Ziegler, and Geigenberger (2003) suggest three components influence interpretation of prosody: (1) input—the type of perceptual processing required, either tonal/rhythmic or fast/spectral; (2) the processing components or complexity of the task, including linguistic and cognitive demands; and (3) the processing mode, be it explicit (and effortful), or implicit. These will be discussed in turn.

Prosodic-comprehension deficits may be related to a perceptual deficit in detecting changes in tonal patterns. The RH is thought to be more adept at processing nontemporal properties of spectral information, pitch, and harmonic structure, whereas the LH is specialized for processing temporal order, sequence, sound duration, and intervals between sound (Chobor & Brown, 1987; Robin et al., 1990; Sidsitis & van Lancker-Sidsitis, 2003). Pitch perception has been found to be selectively impaired subsequent to RHD (Chobor & Brown, 1987; Robin, Tranel, & Damasio, 1990; Sidsitis & Van Lancker-Sidsitis, 2003; Tompkins, 1991a; Tompkins & Flowers, 1985). Another hypothesis suggests that the LH is dominant for processing prosody at the word level, while the RH is involved with larger regions, such as phrases and sentences (Baum & Pell, 1999; Behrens, 1988).

Another processing component that may affect task performance is sustained attention. In many studies participants must listen to sentences but dissociate meaning from tone, forcing them to divide their attention in a rather unnatural task. Considering that neglect is associated with attention deficits, it is surprising to note that neglect is not often tested or reported in studies of prosody (even those that use picture stimuli). Some studies that have evaluated neglect report that subjects with RHD and neglect have difficulty with prosodic tasks (Heilman, Scholes, & Watson, 1975; Tompkins & Flowers, 1985; Tucker, Watson, & Heilman, 1977), while those without neglect may not (Schlanger, Schlanger, & Gerstman, 1976).

Another aspect of processing complexity involves determining communicative intent when the prosodic and linguistic meanings differ. Adults with RHD demonstrate a greater prosodic comprehension deficit when prosody is in conflict with linguistic meaning (e.g., hearing “I lost my purse” spoken in a happy voice). Other evidence comes from Tompkins (1991b), who found that increased semantic redundancy in the form of a word suggesting a given emotion improved accuracy of LHD, RHD, and NBD participants in judging the mood conveyed in a short paragraph. The redundancy also improved the RHD groups’ prosodic judgments of neutral sentences that followed the paragraphs.

The last component, processing mode, refers to whether the task is explicit, and requires off-line, metalinguistic

responses, or whether it measures more on-line, automatic responses from which comprehension of prosodic meaning can be inferred. Wunderlich and colleagues (2003) suggest that the task demands may increase the influence of the non-prosodic (linguistic and cognitive) factors. Most studies have used explicit tasks (e.g., point to the picture that matches the emotion), so it is difficult to determine the effect of task demands. However, given that such demands influence performance on a variety of other tasks (e.g., Tompkins & Baumgaertner, 1998), they likely play a role in prosody too.

The extent to which patients suffer from difficulty in prosodic comprehension in everyday conversation is not clear. Laboratory investigations of prosodic deficits attempt to control the variables that operate in natural conversation. Subjects with RHD are impaired in tasks that force them to select and detect relevant features, to attend to two things at once, and to ignore one thing while attending to another. Thus, it is uncertain whether or not prosodic impairments in the laboratory reflect true deficits in processing prosodic aspects of conversations in which multiple cues signal meaning and emotional content. It is likely that some individuals with RHD may not be able to mount the resources to attend to these important extralinguistic cues, and that they may have specific problems with pitch perception. The severity of the deficit may vary with the level of redundancy of contextual information specifying the speaker's intended meaning.

Prosodic Production

Emotional and linguistic prosodic production has been tested by asking subjects to repeat or read neutral sentences with a specified emotional tone, imitate the prosodic production of a speaker, and/or spontaneously produce emphatic stress. Prosodic productions have been analyzed perceptually and acoustically. The findings, particularly in studies using acoustic analysis, have been mixed. Adults with RHD who have prosodic production deficits (aprosodia) tend to rely less on pitch variation and more on shifts in intensity or volume to signal emotions, and tend to use consistent duration and pause time, giving a robotic quality to their speech. Patients with mild prosodic production impairments may sound fatigued. In more severe cases, they may sound mechanical and stilted.

Individuals with RHD generally do not have problems producing linguistic prosodic contours to distinguish noun phrases from compound nouns, to signal syntactic boundaries, or to differentiate statements from questions (Shah, Baum, & Dwivedi, 2006; Walker, Pelletier, & Reif, 2004). Acoustic examinations of speech waves suggest that individuals with RHD may have a fast rate, reduced acoustic contrast, and reduced energy in frequencies above 500 Hz (Kent & Rosenbek, 1982). Other studies report no significant differences between individuals with and without RHD in

terms of duration, amplitude, fundamental frequency, and pause duration on tasks requiring manipulation of linguistic prosody (Shah et al., 2006; Walker et al., 2004).

In general, it appears that damage to the RH can result in reduced use of pitch variation and increased use of intensity to convey emphatic emotional stress (Colsher, Cooper, & Graff-Radford, 1987; Ross, Edmondson, Seibert, & Homan, 1988; Ryalls, 1986). Of note, pitch variation is one of the most critical prosodic features used to distinguish emotional tone in NBD speakers (Shapiro & Danly, 1985; Van Lancker & Sidtis, 1992). Thus, attenuated pitch variation has the potential to have a negative impact on the production of emotional prosody.

Patients with RHD with prosodic-production impairments may complain of difficulty getting emotional tone into their speech (Ross & Mesulam, 1979; Ryalls, Joannette, & Feldman, 1987). A patient seen by the first author stated that she tried to get more inflection into her speech, but that it required "a lot of concentration" and was often ineffective. Patients in the Ryalls (1987) study reported a sense of reduced volume and pitch range and that their voices sometimes felt "hoarse" and "strangled." These findings, combined with problems in voluntary control over prosody, suggest that impaired prosodic production subsequent to RHD may be in part a motor execution disorder (i.e., a form of dysarthria).

Summary

Prosodic comprehension and production deficits may occur subsequent to RHD. Comprehension impairments may include both emotional and linguistic prosodic deficits, and may be related to impaired pitch perception and/or to attentional deficits in response to tasks designed to isolate prosodic from linguistic information. Whether or not prosodic-comprehension deficits found in the laboratory translate into similar deficits in natural conversation is not clear.

Prosodic-production impairments may also exist in some individuals with RHD. Clinical impressions of impaired prosody have been difficult to quantify. Patients tend to be aware of, but unable to correct, these deficits. It is possible that dysarthria plays a role in prosodic-production impairments in some adults with RHD, although this possibility has not been formally addressed.

Evaluation

Emotional prosodic comprehension can be assessed by asking patients to identify the emotion (happy, sad, angry) conveyed in prerecorded sentences with neutral content (e.g., "The boy came home"). For linguistic prosody, patients can be asked to match a spoken word to one of a set of two that vary in stress placement (e.g., "hot dog" versus "hotdog").

Prosodic production can be difficult to assess. Patients can be asked to produce or imitate prosodic contour that

distinguishes words or phrases from one another either in mood or in emphatic stress. Productions should be tape recorded and played for judges (e.g., other staff) who try to identify the emotion the patient was attempting to express. This method can be cumbersome, and it provides information only about how well a person can volitionally control and produce emotional prosody, which may be different from the spontaneous expression of emotion through prosody. Acoustic measures are more objective, but may not be available to clinicians, and there is uncertainty about whether acoustic measures translate into clinical relevance.

Treatment

Treatment for prosodic deficits may not be a priority in patient management if the patient has other extralinguistic deficits. However, prosodic impairment can occur in patients with few other RHD problems, and it may interfere in the resumption of their daily lives and work. Recent studies of treatment for aprosodia have been developed to treat the disorder as if it were a cognitive deficit (Leon et al., 2005; Rosenbek et al., 2004) or a purely motoric disorder (e.g., similar to a dysarthria) (Leon et al., 2005; Rosenbek et al., 2004; Stringer, 1996). The cognitive treatment is based on the theory that aprosodia is caused by reduced access to emotional words and prosody. Patients are asked to explain the prosodic characteristics used to convey specific emotions, and to match prosody to facial expressions. The motoric treatment involves imitation of productions of different emotions. Preliminary data suggest that both treatments are effective in increasing expressive prosody.

When using a motoric approach, clinicians should remember that such training is not like accent reduction therapy. Although aware of their deficit, patients may not have voluntary control over their production or the ability to improve, particularly if the effort required diverts resources from other types of extralinguistic processing. If the patient is free of other impairments, such training may be worth the attempt. In addition, patients and family members should be counseled about the problem, and the patient can be trained to state more explicitly the emotion they are trying to convey in everyday conversations.

FUTURE DIRECTIONS

We hope that the description of deficits and the framework in which they have been laid out in this chapter will help clinicians recognize and understand RHD communication disorders and design innovative therapy techniques for them. Improved treatment rests on clinical insights and on continued research aimed at:

- (1) mechanisms that underlie identified communication and cognitive deficits;
- (2) potential connections between nonlinguistic and extralinguistic deficits;
- (3) prognosis and recovery patterns subsequent to RHD;
- (4) incidence and prevalence of identified deficits;
- (5) theory-driven assessment tools based on new research findings; and
- (6) treatment efficacy.

Defining Core Deficits

Research and practice would both benefit from consensus about the core deficits that define communication disorders associated with RHD and an operational definition and label that adequately captures them. To understand how essential this is, one need only imagine the term “LHD communication impairment” to describe aphasia. There are many things that aphasia is and many that it is not (a motor speech disorder, for example), but as often as it may occur with LHD, its diagnosis does not rest on lesion localization. It is a condition that includes some features and excludes others—a disorder with some predictable consequences and defined subtypes. “RHD communication impairment,” on the other hand, identifies a location in the brain, but there is no common, agreed-upon understanding of the behavioral deficits it includes and excludes. Joannette and Ansaldo (1999) suggested the term “pragmatic aphasia.” Myers (2001) argued against the term “aphasia” and suggested instead “apragmatism,” because “pragmatics” relates to communicative intent, an apparently central feature of the extralinguistic deficits associated with RHD. Both terms avoid “RHD” in the label in recognition that not all those with RHD have communication disorders. Perhaps a term such as “cognitive-communication disorder of the RHD type” better captures the broad range of communication deficits that may be present with RHD.

In clinical work, lack of an adequate label that reflects an agreed-upon set of defining features makes it difficult to communicate about the disorders with colleagues, including other speech-language pathologists, rehabilitation professionals, neurologists, and other physicians. It makes it difficult to raise public awareness and to gain recognition from third-party payors. It makes it difficult to explain the deficits to families and patients, who often equate the ability to speak with adequate communication.

Research Needs

Arriving at the core deficits that define a label is the more difficult and vexing problem—one which requires continued research. In a chicken-egg conundrum, researchers would benefit from having a list of operationally defined core deficits for purposes of subject selection, and it is research that will lead us toward that list.

In the past, subjects were often selected only on the basis of a lesion site confined to the RH. While appropriate for

studies of incidence or prevalence, it is reasonable to ask if we now know enough about the disorders to move beyond lesion lateralization for subject selection when the research goal is to delineate the nature of a single disorder or group of RHD communication deficits. To understand the importance of subject selection for studies of this type, one need only consider how potentially misleading a study on the nature of anomia would be if subjects were selected on the basis of unilateral LHD, regardless of whether they had anomia or even aphasia.

How can we best achieve subject selection without reliable and valid measures of RHD communication disorders or an agreed-upon definition of them? We can start by using tasks from the literature that have demonstrated sensitivity to RHD communication deficits and/or to the specific deficit under study. Tests of cognitive function, neglect, and/or attention that have good psychometric properties can also be used. Subjects can be grouped according to the presence or absence or severity of the specific deficit under study or related deficits either *a priori* or during the study. Including subjects who do and do not have the deficits under study, but do have some related cognitive or communicative disorders, allows for examination of relationships among deficits. However, individuals with RHD who are free of any signs of communication impairment should be included only as a control group when the research goal is to further our understanding of RHD *communication* disorders.

Summary

We have made great strides over the past 30 years in recognizing that the RH, this once “silent” hemisphere, plays a role in communication and that damage to it can affect communicative function. We look to a future in which continued clinical insight and informed research bring us to a comprehensive definition of the core deficits, better understanding of their natural history and cause, and, most importantly, improved patient care.

KEY POINTS

1. This chapter is focused on the nature and characteristics of communication impairments that can occur subsequent to RHD. It is important to remember that not every person with RHD has communication impairment and that while we have come a long way in our understanding of these disorders, a core set of deficits that define “RHD communication impairment” has yet to be determined.
2. Neglect can occur across modalities, in ipsilesional as well as in contralesional space. As an attentional

deficit, neglect may affect cognitive processing, and hence communicative ability as well as recovery of independence.

3. Attentional deficits associated with RHD include hypoarousal and deficits in orienting, vigilance, maintenance, and selective attention. These deficits may have a significant negative impact on the cognitive processes that contribute to the pragmatic and extralinguistic aspects of communication.
4. Basic linguistic performance (e.g., word retrieval, sentence structure) is rarely affected by unilateral RHD.
5. RHD discourse impairments tend to be cognitively based and include deficits in generating a macrostructure, integrating information, disambiguating information, and drawing complex inferences based on contextual cues. These deficits may result in reduced levels of informative content in discourse production and reduced sensitivity to shades of meaning in discourse comprehension.
6. RHD may include pragmatic deficits in recognizing speaker intentions, understanding the internal motivations of others, and following conversational conventions.
7. RHD may affect the capacity to process alternative meanings in discourse, a capacity for which the intact RH is thought to be dominant.
8. RHD may reduce sensitivity to emotional content and can affect the ability to express emotion in facial expression, body language, gesture, and written and spoken discourse.
9. Prosodic impairments may include emotional and nonemotional prosodic comprehension and expression. They may occur independently of the nonlinguistic and extralinguistic deficits described in this chapter. They should be managed according to patient need relative to other potentially more pressing communicative impairments and the patient’s ability to exert volitional cognitive or motor control over prosodic features.
10. Assessment for extralinguistic deficits should consist of an initial screening that includes an interview, tests of neglect, and a discourse sample, followed by further testing using informal and/or formal measures.
11. Patient management should include task-oriented (i.e., functional) and process-oriented treatment approaches as well as patient and family counseling.
12. Treatment for discourse deficits should include tasks to reduce neglect and attentional deficits, as well as tasks to stimulate integration abilities, increase the ability to process alternate meanings and generate inferences, and improve the use of contextual cues.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Compare and contrast the communication deficits associated with RHD with those commonly associated with other neurologic disorders, such as aphasia, dementia, or traumatic brain injury.
2. List how deficits in various types of attention (e.g., arousal, vigilance, sustained attention) might affect a person's ability to communicate effectively in various situations, such as during a language evaluation, a conversation with a spouse, or a team conference at a rehabilitation center.
3. Imagine you are talking to a patient's family and have to describe visuospatial neglect. How would you explain the difference between visual neglect and homonymous hemianopsia? Think about the neurophysiologic bases for the disorders and the behavioral consequences of them.
4. Define "extralinguistic," explain why such factors are vital for effective communication, and describe three ways in they may be compromised in patients with RHD.
5. List the different ways that affect is portrayed in everyday communication situations. Discuss how you might conduct treatment to address deficits in each area of affective communication.
6. Select one attentional and one language goal for a hypothetical patient. Describe how you would design treatment to achieve each goal through (a) process-oriented treatment, (b) task-oriented treatment, and (c) a combination of the two methods.
7. Given the paucity of evidence-based practice data for deficits associated with RHD, discuss ways to evaluate and select appropriate treatments for patients with RHD.

Management of Neurogenic Communication Disorders Associated with Dementia

Tammy Hopper and Kathryn A. Bayles

OBJECTIVES

After reading this chapter, the reader will be able to:

1. Define the dementia syndrome and commonly associated diseases.
 2. Describe memory and the pattern of spared and impaired memory functions in dementia.
 3. Explain the effects of memory impairment on cognitive-communication abilities of individuals with dementia.
 4. Discuss assessment of individuals with dementia.
 5. Design treatment programs based on principles of dementia management.
-

Older adults (65+ years) comprise the fastest growing segment of the world's population, with the oldest old (85+) increasing most rapidly (Kinsella & Velkoff, 2001). This tremendous growth in the number of older adults translates to an increased incidence and prevalence of individuals with dementia. In 2000, an estimated 4 million people in the U.S. were living with Alzheimer's disease (AD), the leading cause of dementia, and this number is predicted to increase to 13.2 million by 2050 (Hebert, Scherr, Bienias, Bennett, & Evans, 2003) unless a cure or effective prevention is found.

Understanding the pathogenesis of AD and other diseases that cause dementia, and developing pharmacologic and behavioral strategies for improving quality of life for affected individuals, are national research priorities. The cognitive-communication difficulties experienced by individuals with dementia, and the contribution of these deficits to diminished quality of life, necessitate speech-language pathology services (ASHA, 2005a, b). The purpose of this chapter is to define the dementia syndrome, explain common causes of dementia, discuss the effects of dementia on

communication, and outline principles for cognitive-communication assessment and treatment. The chapter will conclude with examples of evidence-based treatment programs that promote clinically significant changes in individuals with dementia.

THE DEMENTIA SYNDROME

Dementia is a clinical syndrome defined by deterioration of memory and at least one other cognitive function that is severe enough to interfere with daily life activities. The *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., Text Revision) (DSM-IV-TR; American Psychiatric Association, 2000) specifies certain criteria that must be met for a diagnosis of dementia. Specifically, a patient must have multiple cognitive deficits that include both (1) evidence of short and long-term memory impairment, and (2) at least one of the following conditions: aphasia, apraxia, agnosia, or impaired executive functioning. These deficits must result in significant problems with employment and social functioning, not occur exclusively with delirium, and represent a significant decline from premorbid levels of functioning. Dementia is associated with many diseases, infections, trauma, and toxins, and although many cases of dementia are reversible, speech-language pathologists primarily deal with patients who have irreversible dementia caused by degenerative neurologic disease.

The cognitive-communication problems of dementia are a direct result of deterioration in higher cognitive processes, most notably memory. Therefore, understanding memory systems, and their neuroanatomy, is necessary to understanding why and how communicative functioning is affected in individuals with dementing diseases.

MEMORY

Memory can be defined as stored representations and the processes of encoding, consolidation, and retrieval through which knowledge is acquired and manipulated (Baddeley, 1999; Bayles & Tomoeda, 1997). Memory is not a unitary

phenomenon, but is better characterized as comprising multiple systems. Although the systems are interrelated, some degree of modularity exists. For example, patients with neurologic disease or injury that affects specific brain regions may demonstrate relative preservation of one type of memory whereas another memory system is severely impaired. The idea of memory systems is not without controversy; however, the distinction between short- and long-term memory systems is generally accepted.

Short-term, or working, memory is the system responsible for activating and retrieving information, holding information in consciousness, and focusing attention (Baddeley, 1986), and is thought to be subserved by the dorsolateral prefrontal cortex. Working memory is described as comprising a central executive control system, and two “slave” or buffer systems: the phonologic loop and the visuospatial scratchpad (Baddeley & Hitch, 1974). In Baddeley’s model, the central executive system functions to integrate sensory input, coordinate and allocate processing resources, and plan and control actions. The phonologic loop and the visuospatial scratchpad are buffers for acoustic and visual information, respectively. Working memory not only integrates sensory information from the environment, but also is involved in processing of information retrieved from long-term memory.

Long-term memory can be conceptualized as being declarative or nondeclarative (Squire, 1994). Declarative memory is memory for factual information, and comprises semantic, lexical, and episodic subsystems. Semantic memory refers to general conceptual knowledge, whereas lexical memory comprises knowledge for words. Tulving (1983) defines episodic memory as an individual’s autobiographical memory, encoded in a temporal/spatial context. Declarative memory is assessed routinely using explicit memory tasks that require recall or recognition of past episodes or specific facts (Schacter & Tulving, 1994). Declarative memory is dependent upon the hippocampus and adjacent structures and connections of the medial temporal lobe (Broadbent, Clark, Zola, & Squire, 2002) as well as areas of prefrontal cortex that are active during encoding and retrieval (Schacter, 1996). Patients with damage to these neuroanatomic areas have difficulty with explicit memory. However, implicit memory expression may be preserved.

Implicit memory is the “unintentional or nonconscious use of previously acquired information” (Schacter & Tulving, 1994, p. 12). For example, patients with dementia may be unable to recall consciously a previous learning episode in which several words were practiced. However, if given the first few letters or stem of the practiced word, the practiced word may come to mind. This exemplifies how knowledge gained in the training sessions is expressed through improved performance rather than conscious recollection (Squire, 1994). This facilitated performance, following exposure to a related stimulus, is referred to as positive

“priming” and is inferred from decreased response time and/or increased response accuracy. The occurrence of priming in individuals with deficits in explicit memory suggests that priming depends on different neuroanatomic and functional systems than those that support explicit, declarative memory (Butters, Heindel, & Salmon, 1990; Schacter & Tulving, 1994).

Nondeclarative memory consists of verbal and motor procedural memory subsystems, reflexes, and habit memory (Squire, 1994). Procedural motor memory refers to knowledge for motor procedures, such as playing tennis or shoveling snow. Importantly, learning of procedures may not require conscious recollection of previous study episodes. Rather, motor learning can be implicit, and is demonstrated by behavioral change rather than explicit recall (Squire, 1994). The anatomic systems underlying procedural memory include the basal ganglia, cerebellum, and other neuro-motor regions and connections (Daselaar, Rombouts, Veltman, Raaijmakers, & Jonker, 2003; Doyon & Ungerleider, 2002).

The vulnerability of declarative and nondeclarative memory systems varies by disease. Those diseases that primarily affect cortical structures are more likely to produce declarative memory deficits. Diseases that primarily affect subcortical structures, such as the basal ganglia, produce nondeclarative memory impairments. The memory and language profiles of four common diseases associated with progressive dementia will be presented in the following section (Table 35–1).

ALZHEIMER’S DISEASE

The most common cause of irreversible dementia is Alzheimer’s disease (Katzman & Bick, 2000). Diagnosis of AD can only be made upon postmortem examination of the brain; however, while an individual is alive, the diagnosis of probable AD can be made by exclusion. The criteria for diagnosis are specified in the DSM-IV-TR (APA, 2000) and include gradual onset of cognitive deficits that progressively worsen and are not due to other central nervous system etiologies, systemic conditions, or substance-induced conditions; neither do they result from a psychiatric disorder such as schizophrenia or depression.

Neuropathologic and neurochemical changes play a role in the development of AD (Fig. 35–1). Neuropathologic changes are characterized by neurofibrillary tangles and neuritic plaques that are distributed initially in the entorhinal cortex (adjacent to the hippocampus), spreading in stages to the hippocampus, inferior and lateral temporal lobes, and eventually other neocortical association areas (temporoparietal and frontal regions) (Braak & Braak, 1991, 1997). Changes are less apparent in primary sensorimotor (Braak & Braak, 1997) and occipital (Tomlinson, 1982) areas.

TABLE 35-1	
Common Etiologies of Irreversible Dementia and Associated Cognitive Profiles	
Alzheimer's disease	• Early stage: deficits in episodic and working memory • Later stage: impairments in semantic memory • Relatively spared procedural memory in early to middle stages of disease
Cerebrovascular disease	• Cognitive signs and symptoms are heterogeneous depending on lesion distribution • Cortical lesions are associated with amnesia, visuospatial deficits, and aphasia • Subcortical lesions (common in the periventricular white matter and basal ganglia) are associated with impairments of memory, executive functions, attention, and motor function
Lewy body disease	• Fluctuating presentation of cognitive symptoms • Procedural memory and learning deficits may occur with subcortical pathology • Declarative memory systems may be impaired with cortical pathology
Parkinson's disease	• Procedural memory impairment • Declarative memory deficits when cortical lesions exist

Neurofibrillary tangles are intracellular deposits that occur when fibers within the neuron become twisted in a helical fashion. Scientists have provided evidence to suggest that these paired helical filaments are composed of the protein tau in an abnormally phosphorylated state (Goedert, 1993). Neuritic plaques are extracellular deposits best described as aggregations of neurons with an amyloid core surrounded by a ring of granular material. It is not clear how amyloid deposition is related to AD; it may be an inert by-product of neuronal death, or a causative agent in neuronal degeneration (Goldman & Côté, 1991; Uylings & de Brabander, 2002).

General overall neuronal atrophy also is present in the brains of individuals with AD, and is seen in areas that have plaque and tangle pathology (Goldman & Côté, 1991). Neuronal degeneration in AD is marked by a loss of synapses and “presynaptic marker proteins” in the neocortex

Figure 35-1. Neuropathological changes associated with Alzheimer's disease. Nerve cells (neurons) in several regions of the brain are affected. Illustration by Lydia Kibiuk. (Reprinted with permission from Alzheimer's disease: Unraveling the mystery. NIH Publication #96-3782. National Institutes of Health, 1995.)

and hippocampus (Goldman & Côté, 1991). Taken together, these neuropathologic changes interfere with axonal transport and cause synaptic dysfunction. It is important to note that researchers have discovered the presence of neurofibrillary tangles and neuritic plaques in sufficient numbers to warrant a definite neuropathologic diagnosis of AD in individuals who did not meet the criteria for a diagnosis of probable AD while alive (Davis, Schmitt, Wekstein & Markesbery, 1999).

Neurochemical deficiencies, specifically in the cholinergic system, also contribute to the disruption of nerve transmission at the cellular level. The cholinergic system is a neuronal network that transmits nerve impulses through acetylcholine. Enzymes necessary for the manufacture of acetylcholine, choline acetyltransferase, and acetylcholinesterase

have been found to be reduced by 80% in individuals with AD (Bowen, Davison, & Sims, 1981; Davies, 1983). Of interest to scientists is the connection between cortical changes and subcortical nuclei containing cholinergic neurons, particularly the nucleus basalis of Meynert (Coyle, Price, & DeLong, 1983). This nucleus is a major component of the substantia innominata located beneath the globus pallidus. In individuals with AD, extensive reduction of cholinergic neurons has occurred within the nucleus basalis, a finding that has led researchers to theorize a relation between lack of cortical cholinergic input and the development of neuritic plaques and neurofibrillary tangles. Consistent with the cholinergic hypothesis is the observation that drugs that interfere with acetylcholine can produce memory impairment and confusion in normal individuals (Drachman & Leavitt, 1974; Goldman & Côté, 1991). In addition to the loss of acetylcholine, reductions are apparent in other neurochemicals, among them dopamine and serotonin.

Although specific causative factors of AD have not been determined, certain risk factors have been identified (Salmon & Bondi, 1997). Besides age, which is the most important risk factor, a genetic contribution to the development of late-onset AD is now recognized. Apolipoprotein E (ApoE), a protein involved in cholesterol transport, is associated with an increased risk of AD. The gene for ApoE is found on chromosome 19 and exists in three common allelic forms in humans: ApoE-2, ApoE-3, and ApoE-4 (National Institute on Aging/Alzheimer's Association Working Group, 1996). Individuals having one or two alleles for the e4 form are at a greater risk for developing AD than those who do not have the e4 allele (Honig, 1997), and the e4 form has been found to exist about three times more frequently in individuals with AD than among age-matched controls (National Institute on Aging/Alzheimer's Association Working Group, 1996). Despite the genetic risk factor of ApoE-4 presence, late-onset AD is not characterized as an "inherited" disorder. Only a small proportion of AD cases (approximately 5%) are transmitted by autosomal dominant inheritance (van der Flier & Scheltens, 2005).

Memory Deficits of Individuals with AD

The neuropathology of AD begins and is distributed most densely in areas of the brain important to episodic memory. Not surprisingly, therefore, the most commonly reported initial symptom is difficulty remembering recent events. Individuals with early AD consistently perform poorly on tests of episodic memory, such as verbal recall tasks, which are useful for early differential diagnosis. Working memory also is impaired in AD. Deficits in verbal and visuospatial span tasks have been reported (Spinnler, Della Sala, Bandera, & Baddeley, 1988), and individuals with AD have

demonstrated diminished performance on tasks of central executive function (e.g., dual task performance) compared to control subjects (Baddeley, Bressi, Della Sala, Logie, & Spinnler, 1991).

Semantic memory, on the other hand, is not always impaired in early AD. Hodges and Patterson (1995) reported that individuals with early-stage AD exhibited variability in their performance on semantic memory tasks, with some participants even demonstrating intact abilities as compared to healthy control participants. Other evidence for relative preservation of semantic memory comes from the literature on priming. As mentioned earlier, priming occurs when a response is facilitated by previous exposure to a related stimulus. Some researchers have found that individuals with AD demonstrate intact priming (Lustig & Buckner, 2004; Nebes, 1994; Nebes, Boller, & Holland, 1986; Nebes, Martin, & Horn, 1984), although others report negative effects (Salmon, Shimamura, Butters, & Smith, 1988). Nevertheless, the presence of positive priming supports the notion of gross preservation of semantic memory at least in the early stages of AD.

Of course, as dementia severity increases semantic memory is affected. Individuals with AD have particular difficulty on tasks that require the use of conceptual information, such as naming, category knowledge, attribute knowledge, and verbal fluency (Bayles & Kaszniak, 1987). However, the exact nature of the breakdown in semantic memory is debatable. Some researchers have argued that it occurs from the "bottom up," with knowledge of attributes of objects being lost before generic categorical knowledge (Martin & Fedio, 1983; Warrington, 1975). Evidence from this hypothesis comes from the misnamings of individuals with AD who often give the name of another item in the same category, such as "orange" for "lemon." The argument is that individuals with AD lose knowledge of the attributes that distinguish "orange" from "lemon," but retain the categorical knowledge that they are "fruit." Several investigators have challenged the "bottom-up" deterioration theory (Cox, Bayles, & Trosset, 1996; Nebes & Brady, 1988), showing that individuals with AD are as likely to give attributes as category information when asked to define words.

Other types of memory that may be spared in AD include nondeclarative types of memory such as motor procedural memory. On implicit memory tasks of motor learning, individuals with AD in the mild to moderate stages have been shown to improve task performance over time (Heindel, Salmon, Shults, Walicke, & Butters, 1989), or demonstrate the ability to acquire and retain a skill (Dick, Nielson, Beth, Shankle, & Cotman, 1995). These types of memory are preserved relative to declarative memory because the basal ganglia, cerebellum, and other neuromotor areas are relatively spared throughout much of the course of the disease.

CEREBROVASCULAR DISEASE

Cerebrovascular disease (CVD) is increasingly common and may be the second most common cause of dementia (Dubois & Hébert, 2001). When CVD causes dementia, it is referred to as vascular dementia (VaD). In addition to the basic criteria for dementia, the DSM-IV-TR (2000) specifies that a diagnosis of VaD be based upon presence of the following: focal neurologic signs and symptoms (e.g., weakness of an extremity), or laboratory evidence (i.e., neuroimaging results of multiple infarctions involving cortex and underlying white matter). However, the diagnosis of VaD remains controversial owing to its various causes and differing clinical manifestations.

VaD can be caused by ischemia (and less frequently by hemorrhage) in large arteries and in smaller, penetrating arteries (McPherson & Cummings, 1997). In the case of large-vessel disease, patients often have thrombosis or embolism in cerebral arteries that causes a single “strategic” infarct in cortical areas important for cognition and language or multiple, recurrent infarcts in these same areas (Román, 2005). In small-vessel disease, deep, penetrating arteries or arterioles are most affected, causing infarcts in subcortical structures and pathways (e.g., periventricular white matter, basal ganglia) (Mungas, 2005).

Cognitive signs and symptoms associated with VaD are heterogeneous and depend on the distribution and type of lesions involved. Small-vessel disease is considered the most common cause of VaD and is marked by multiple cognitive deficits in attention, executive functions, memory, language, and motor skills (see Jefferson, Brickman, Aloia, & Paul, 2005 for a review; McPherson & Cummings, 1997). The prominence of dysexecutive syndrome in individuals with subcortical VaD (Kramer, Reed, Mungas, Weiner, & Chui, 2002) has prompted researchers to call for revised diagnostic criteria that include dysexecutive syndrome as a cardinal feature of VaD (Jefferson, Brickman, Aloia, & Paul, 2005). The clinical course of subcortical VaD also resembles AD in that it is chronic and progressive; however, deterioration can occur in a stepwise fashion, with marked fluctuations in cognitive and functional abilities (Hachinski et al., 1975).

Individuals who suffer from acute strokes, as in large-vessel disease, may not always present with prominent memory problems and may have a stable or improving progression of symptoms (Román, 2005). In these cases, patients may not meet the DSM-IV-TR (2000) criteria for dementia, despite the demonstration of other cognitive deficits and evidence of cerebrovascular disease.

One of the most important developments in research on VaD is the recognition that VaD may actually moderate the expression of AD when the diseases co-occur (“mixed dementia”). Specifically, the presence of cerebrovascular lesions may actually promote clinical expression of AD

symptomatology (Snowdon, Grenier, Mortimer, Riley, & Markesbery, 1997; Román, 2003, 2005).

LEWY BODY DISEASE

Dementia with Lewy bodies (DLB) rivals VaD as the second most common type of dementia. Although DLB commonly co-occurs with AD, and is considered by some researchers to occur most often as a variant of AD (LBV of AD), others report that it is neuropathologically distinct from AD (Cercy & Bylsma, 1997) and can occur in isolation (“pure” DLB).

The neuropathology of DLB is marked by protein deposits (Lewy bodies) in neuronal-cell bodies. The pathologic distribution of Lewy bodies can be classified as brainstem predominant, limbic, and neocortical (McKeith et al., 1996; McKeith & O’Brien, 1999). According to McKeith and colleagues (2005), certain features, called “central features,” are essential for a diagnosis of possible or probable DLB. These include presence of dementia with a progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function; prominent or persistent memory impairment that may not necessarily occur in the early stages but is usually evident with progression; and prominent deficits on tests of attention, executive function, and visuospatial ability. Other features (classified as core, suggestive, and supportive) can help contribute to the certainty of a possible or probable diagnosis. Core features of fluctuating cognition with pronounced variations in attention and alertness, recurrent visual hallucinations that are typically well-formed and detailed, and spontaneous features of parkinsonism are considered sufficient for a probable (in the case of two or more) or possible (if one feature is present) DLB.

Continued research with larger samples is needed to further elucidate the cognitive and linguistic characteristics of DLB. Researchers have noted, however, that patients with DLB have marked deficits in visuospatial and construction abilities that are not typically present in individuals with early AD (Calderon, Perry, Erzinclioglu, Berrios, Denning, & Hodges, 2001; Connor, Salmon, Sandy, Galasko, Hansen, & Thal, 1998; McKeith & O’Brien, 1999; Salmon et al., 1996; Tiraboschi, Salmon, Hansen, Hofstetter, Thal, & Corey-Bloom, 2006).

PARKINSON’S DISEASE

Idiopathic Parkinson’s disease (PD) accounts for most cases of parkinsonism. The classic signs of rigidity, resting tremor, and bradykinesia are consequent with deterioration of dopaminergic neurons in the basal ganglia. The basal ganglia are important in the control of movement, and dopamine is a neurotransmitter involved in the initiation of movement. As a result of decreased levels of dopamine, patients with PD have difficulty initiating movement and

commonly exhibit a slow, shuffling gait, flexed posture, and an inexpressive, mask-like face.

Increasingly, the term “Parkinson’s disease with dementia” (PDD) is being used to describe those individuals with PD who develop dementia over the course of the disease process. The prevalence of dementia among individuals with PD has been reported to range from 10% to 20% (Tison, Dartigues, Auriacombe, Letenneur, Boller, & Alperovitch, 1995) up to 70% (Aarsland, Andersen, Larsen, Lolk, & Kragh-Sorensen, 2003).

Lewy bodies are present in all patients with PD (both with and without dementia) and are a prerequisite for post-mortem diagnosis of PD (Braak, Del Tredici, Rüb, de Vos, Jansen Steur, & Braak, 2003). However, in PD without dementia the distribution of the Lewy bodies tends to be confined to subcortical areas, in particular the substantia nigra, whereas in PDD the distribution of Lewy bodies is more diffuse (Emre, 2003). Unsurprisingly, then, both groups of individuals with PD demonstrate difficulties with procedural memory and learning (Saint-Cyr, Taylor, & Lang, 1988). The neuropsychological profiles of individuals with PDD greatly resemble those of individuals with DLB (Noe, Marder, Bell, Jacobs, Manly, & Stern, 2004) and are sometimes clinically indistinguishable. These similarities between PDD and DLB have led some researchers to conclude that PDD is a subtype of DLB (Press, 2004). However, researchers have also found AD-type pathology in the brains of individuals with PDD; thus, AD cannot be ruled out as the cause of dementia among patients with PD (Braak et al., 2003; SantaCruz et al., 1999).

EFFECTS OF MEMORY DEFICITS ON COMMUNICATION ABILITY OF INDIVIDUALS WITH ALZHEIMER-TYPE DEMENTIA

Intact cognition is necessary for normal communication abilities. As a result of memory and other cognitive impairments, individuals with dementia have considerable difficulty communicating. Most of the research on communication in dementia has been conducted with individuals with AD. Early in the disease, individuals with AD become repetitious and forget what they have heard or read. Over time, the discourse of individuals with AD becomes impoverished and fragmented (Tomoeda & Bayles, 1993), and is characterized by a lack of coherence (Ripich & Terrill, 1988), tangentiality (Obler, 1983), and perseverations (Hier, Hagenlocker, & Shindler, 1985). The ability to formulate ideas and express them orally and in writing diminishes (Bayles & Kaszniak, 1987). Auditory comprehension of language also is impaired because memory for what was recently seen or heard fades rapidly. Nonetheless, phonology and syntax are relatively preserved into the advanced stages of the disease. The following discourse samples are

from a patient with AD who was followed for several years. His responses to the same stimulus picture reveal the disease effects on linguistic communication. The devastation of semantic content and verbal output is apparent. Note, however, the relative preservation of grammar.

Sample 1—Year 1

Examiner (E): Now I’d like you to look at that picture there.

Subject (S): Too many children.

E: Yes, I’d like you to tell me everything you can about that. Describe what’s happening in the picture.

S: Well, here’s a man reading something. It’s happening, but he’s not looking at the reading. See he’s looking someplace else, and he’s he’s talking to these beautiful ladies here, and also reading his own paper beside. And here’s his little boy. Isn’t he cute?

E: Describe what’s happening there.

S: Well the father’s gotten a little tired of reading all this, see, so he’s just getting rid of that, one at a time as they march past him going to their own reading or whatever else they do. (laugh) That’s real good. And he has his own great big, great great big newspaper. And then he has a few down here like this. Two feet for all that. That’s a cute thing right there. (laughing)

E: Okay, do you want to say anything else about that?

S: No, I don’t think anything needs to be seen on it.

E: Okay, great.

S: There’s a man that thinks maybe something else might be, but he’s left everything alone except his newspaper. So everything is all right with him. Don’t you think?

E: Yeah.

S: He’s he’s keeping some of the papers with his teeth. (laughs)

E: All right, thanks.

Sample 2—Year 2

E: Describe what’s going on in this picture, and say what you would like to about that.

S: Well, they look like the pictures that uh don’t want to be pick-picketed or or made made up into an odd creature in in the meantime.

E: Is there anything else that you want to say about that?

S: Yes, they do. They they they they they actually look so actable that it makes you want to run away for some reason or other. But um they have their their special aqualgelge over. The way people take uh take uh an (actoba) that they don’t even know anything about. But they just don’t try to bother with these other people who have their.

E: Okay, great, thank you.

Sample 3—Year 3

E: Tell me about this picture. What can you tell me about that picture?

S: Yes. Mhm. It must be a ah, ah, somebody that really thought themselves really gone and close way.

E: What’s happening in this picture?

S: No.

E: What’s happening in this picture?

S: Well, there’s that’s something that we’d be supplied with it, but usually goes away with a

E: Okay. good.

ASSESSMENT

Clinicians need to evaluate for the presence of dementia and its effect on communication skills. To detect dementia, the clinician will benefit from case history information about any neuropsychological changes. Interviewing the primary caregiver, usually the spouse, is advantageous. As part of a longitudinal study of the effects of AD on language, the primary caregivers of 99 individuals with AD were interviewed about early linguistic and nonlinguistic symptomatology (Bayles, 1991). Caregivers commonly reported memory deficits, word-finding problems, difficulty with finances, and trouble writing letters as antedating the medical diagnosis of the disease.

Identifying the presence of dementia demands consideration of whether current behavior is congruent with the individual's premorbid intellectual ability. For example, an individual whose clinical performance on intellectual tasks was average, but who was a Phi Beta Kappa in college, would be suspect. Such an individual would be expected to perform above average. Premorbid intelligence can be estimated using demographic information (Barona, Reynolds, & Chastain, 1984; Wilson, Rosenbaum, & Brown, 1979). Because individuals with dementia are older, hearing and visual problems may exist and can confound the dementia diagnosis. Polypharmacy also can confound the diagnosis because many drugs affect mental status.

Another condition that can cause the performance of the individual to mimic dementia is depression, often referred to as pseudodementia. Consider screening for depression using one of the many depression scales, such as the Hamilton Rating Scale (Hamilton, 1960), and the Beck Depression Inventory (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961). The Hamilton Rating Scale is an interview-based rating scale composed of a 17-item inventory of symptoms, both physical and psychological, that are rated for severity by one or two clinicians. The Beck Depression Inventory is a self-report instrument comprising 21 items, and has been used extensively in research and screening applications with elderly adults (Gallagher, Breckenridge, Steinmetz, & Thompson, 1983; Miller & Seligman, 1973).

As mentioned previously, AD and VaD commonly co-occur in individuals with dementia, making it important to consider the possibility of cerebrovascular disease in patients suspected of having dementia. The Hachinski Ischemic Scale (Hachinski et al., 1975) is widely used to identify individuals with symptoms typically associated with vascular disease and stroke. The scale comprises 13 features associated with vascular disease and stroke, such as history of hypertension, focal neurologic signs, and abrupt onset. Each feature is evaluated and points are accumulated for those present. Individuals who have seven or more points are considered at risk for VaD.

Neuropsychological Tests Sensitive to Dementia

The neuropsychological test most sensitive to early dementia is the episodic memory test. However, because dementia is by definition the loss of multiple cognitive abilities, neuropsychologists typically evaluate attention, problem-solving, reasoning, and other intellectual functions in addition to memory. It is beyond the scope of this chapter to review all of the neuropsychological tests used with individuals with dementia. Instead, the focus will be on measures of cognitive-linguistic function that can be used to screen for dementia, stage dementia severity, and comprehensively evaluate the communicative abilities of individuals with dementia (Table 35–2).

Screening Tests

Tasks most sensitive to the dementia syndrome are those that are active, nonautomatic, or generative, and ones that depend on logical reasoning. Active nonautomatic tasks require the patient's mental and linguistic involvement in a creative way, such as in retelling a story or generating names of items in a category.

The Story Retelling subtest of the Arizona Battery for Communication Disorders of Dementia (ABCD; Bayles & Tomoeda, 1993) is an effective screening tool. In this test, subjects are asked to tell a short story immediately after hearing it and again after an imposed delay. The subtest takes about 5 minutes to administer, and has high sensitivity (i.e., correctly classifies adults who have dementia as having dementia) and specificity (i.e., correctly classifies adults who are not demented as being nondemented) (Bayles & Tomoeda, 1993). The scores of individuals with mild and moderate AD and the scores of individuals with PD (with

Story Retelling, Immediate	14.0 (2.3)	7.3 (4.1)	2.6 (3.0)	13.8 (2.5)	7.3 (4.1)
Story Retelling, Delayed	12.4 (4.5)	1.0 (2.6)	0.0 (0.0)	12.9 (3.9)	4.1 (6.3)

*NPD = nondemented Parkinson's disease; DPD = demented Parkinson's disease (Reprinted with permission from Bayles, K. A., & Tomoeda, C. K. (1997). *Improving function in dementia and other cognitive-linguistic disorders*. Austin, TX: Pro-Ed.

and without dementia) are shown in Table 35-3. Note that individuals with moderate AD remember nothing about the story in the delayed condition.

Generative naming or verbal fluency tests also are sensitive to the presence of dementia (Chertkow & Bub, 1990; Ober, Dronkers, Koss, Delis, & Friedland, 1986). When individuals have to conceive of and produce, either in writing or orally, a series of related ideas or examples of objects in a category, they are performing a generative task. The two most common types of fluency tasks are semantic and letter tests.

Semantic verbal fluency requires that individuals produce words in a specific category, such as animals. The Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983), and the Arizona Battery for Communication Disorders of Dementia (Bayles & Tomoeda, 1993) both contain semantic verbal fluency tests. Letter-fluency tasks involve the production of words that begin with a target letter. An example of a letter task is the FAS Verbal Fluency Test or the Controlled Oral Word Association Test (Borkowski, Benton, & Spreen, 1967), in which an individual must think of as many words as possible beginning with the letters F, A, and S in 1 minute. Individuals with AD have been reported to be deficient in performing both types of verbal fluency tests, likely because of frontal-lobe damage. Patients with PD and those with DLB also are reported to be deficient on generative naming tasks (Salmon et al., 1996; Bayles, Trosset, Tomoeda, Montgomery, & Wilson, 1993). Because verbal-fluency performance involves recruitment of multiple cognitive systems, it is an extremely sensitive indicator of the cognitive impairments of individuals with dementia (Azuma & Bayles, 1997).

The Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975) is a widely used screening instrument. The MMSE comprises 11 items related to orientation, attention, calculation, language, memory, and visuospatial construction, and takes 5 to 10 minutes to administer. Although education may influence examinee performance, reliability and validity of the measure for

assessing mental status have been reported to be high (Farber, Schmitt, & Logue, 1988; Foreman, 1987), and age- and education-adjusted norms have been reported (Crum, Anthony, Bassett, & Folstein, 1993).

Staging Severity

One of the most commonly used scales to stage dementia severity is the Global Deterioration Scale (GDS; Reisberg, Ferris, deLeon, & Crook, 1982). An observation scale, it is composed of seven stages that include detailed descriptions of functional deficits typical of individuals at each stage of disease severity. An extension of the GDS, the Functional Assessment Staging Scale (FAST; Reisberg, Ferris, & Franssen, 1985), was developed to better characterize the functional abilities (e.g., dressing, communication) of individuals in the more severe stages of cognitive decline.

Comprehensive Evaluation of Cognitive-Communicative Functioning

Although individual tests are appropriate for domain-specific assessment, a comprehensive evaluation of language and communication abilities is best accomplished with a battery of tests. A battery for testing the communicative functions of individuals with dementia must contain measures of the effects of cognitive deterioration, particularly memory deficits, on communication.

Pragmatic and semantic skills are more vulnerable to deficits in higher cognitive functions than phonologic and syntactic skills. This is understandable because the content of language and the purpose for which it is used require conscious thought, memory, and planning. The rules of phonology and syntax are finite, predictable, and typically do not require conscious attention. For this reason, measures of semantic and pragmatic reasoning should be included in a test battery for patients with dementia.

A relatively short test that is being increasingly used in clinical settings to assess the cognitive and language abilities

of individuals with AD is the Cognitive Subscale of the Alzheimer's Disease Assessment Scale (ADAS-Cog; Rosen, Mohs, & Davis, 1984). This test includes items related to attention, memory, reasoning, praxis, language production (naming), and comprehension (following commands). Although not considered a comprehensive evaluation measure, administration of the ADAS-Cog may yield information on cognition and language useful in structuring further in-depth assessment.

Bayles and Tomoeda (1993) designed the Arizona Battery of Communication Disorders of Dementia (ABCD) for the purpose of quantifying the communication disorders associated with mild to moderate dementia. The battery contains 14 subtests that yield information about five cognitive constructs: linguistic expression, linguistic comprehension, verbal episodic memory, mental status, and visuospatial construction. Raw scores are obtained from individual subtests and are converted to summary scores to allow comparisons between subtests. Summary scores can be converted to construct scores, for interconstruct comparisons, and construct scores can be summed to obtain a total score for the complete test (Bayles & Tomoeda, 1997). The validity and reliability have been reported to be high, and the test has been standardized on individuals with AD, PD, and healthy young and elderly control subjects in the United States, Great Britain (Armstrong, Bayles, Borthwick, & Tomoeda, 1996) and Australia (Moorhouse, Douglas, Panaccio, & Steel, 1999).

For the patient with more severe dementia, a second test battery was developed, the Functional Linguistic Communication Inventory (FLCI; Bayles and Tomoeda, 1994). The FLCI has 10 components that allow quantification of linguistic communication. Subtests include tasks such as greeting and naming, writing, reminiscing, comprehending signs, and gesturing. The test battery is sensitive to differences in patients with moderate, moderately severe, severe, and very severe dementia (Bayles & Tomoeda, 1994), and has established reliability and validity. Additionally, patterns of responses to test questions can be profiled to determine intra-individual communication strengths and weaknesses. These profiles are extremely useful for completing the Minimum Data Set (MDS; Morris et al., 1990) and developing care plans, as well as for designing individualized stimulation and activity programs for individuals with moderate and severe dementia.

BEHAVIORAL TREATMENT FOR INDIVIDUALS WITH AD

The functional deficits that individuals with dementia experience in communication, activities of daily living, and quality of life result directly from the cognitive impairments that define dementia. As mentioned previously, the pattern of

these impairments depends upon the distribution of the neuropathology associated with different diseases that cause dementia. In AD, certain aspects of cognitive processing remain relatively preserved, despite severe impairments in other cognitive areas. Recognition of residual capacities in addition to diminished abilities will provide the basis for successful interventions for individuals with dementia.

Principles for Successful Intervention

Bayles and Tomoeda (1997) propose several principles for improving function in individuals with AD. Clinicians should first reduce demands on episodic and working memory systems. Second, increase reliance on nondeclarative memory systems. Third, provide activities that strengthen lexical and conceptual associations, and fourth, provide sensory cues that will evoke positive fact memory, action, and emotion.

Application of these principles to treatment can help to improve or maintain cognitive-linguistic abilities of individuals with AD. In the following section, several recent studies are reviewed in which one or more of these principles has been utilized to improve functioning of individuals with AD or related dementias.

Spaced-Retrieval Training

Spaced-retrieval training (SRT) is a technique used to teach new and forgotten information and behaviors to patients with dementia. In SRT, a patient is told a piece of information and then is asked to recall that information repeatedly and systematically over time. Intervals are manipulated to facilitate production of a high number of correct responses to the stimulus question and retention of information over increasingly longer periods of time. SRT is considered to require little cognitive effort (Schacter, Rich, & Stamp, 1985), and can occur without the patient having explicit recall of the training situation. Also, because strength of association between concepts in semantic memory depends on how often they are activated, repeatedly bringing into consciousness these associations will result in their increased accessibility (Bayles & Tomoeda, 1997). Therefore, SRT involves strengthening of associations, increasing reliance on implicit memory expression (Camp, Foss, O'Hanlon, & Stevens, 1996), and reducing demands on episodic and working memory.

Clinicians may use SRT to teach individuals with dementia new information and helpful behaviors. Camp and colleagues (1996) assessed the effectiveness of SRT to teach calendar use for improving prospective memory performance. Also of interest to these investigators was whether the effects of the calendar intervention would be maintained at least 6 months after training. Treatment sessions lasted approximately 30 minutes and continued for 10 weeks. Each session

started with the prompt question “How are you going to remember what to do each day?” The participant had to answer “Look at my calendar” to be correct. If the response was correct, a delay was followed by another recall trial. Intervals were increased if the participant continued with correct responses. If a response was incorrect on any trial, the experimenter provided the correct answer and then immediately repeated the prompt question. When the participant could recall the strategy after a 1-week interval, SRT was terminated.

Once calendar training was successful, up to 5 weeks of additional therapy, one session per week, was provided to teach each patient to complete two tasks on each page of the daily calendar. In this way, the investigators were able to teach the implementation of the skill and evaluate its usefulness in aiding performance of prospective memory tasks in daily life (e.g., walk the dog, write a letter).

Results indicated that the individuals with mild, moderate, and moderately severe dementia were able to recall the calendar strategy over a 1-week period, and some participants used the calendar to remember to perform daily tasks. Although participants did not consistently perform tasks on each day, they showed improvement in using the calendar to carry out the majority of the noted tasks. Six-month follow-up visits showed that calendar use continued well after completion of the study.

McKittrick, Camp, and Black (1992) also conducted a study in which prospective memory was targeted. Four individuals with mild to moderate dementia participated. Sessions were conducted once weekly, and involved teaching subjects verbal and motor responses necessary to redeem a coupon for money. SRT was used to first teach participants a verbal response to the prompt question “What are you going to do when I come back next week?” (“Give you the [pink] coupon”). The motor response consisted of having the subject select the correct coupon and hand it to the examiner. To be successful, the participant had to hand the coupon to the experimenter at the start of the following week’s session. In return, the participant was given a dollar. Different colored coupons were trained to criterion successively.

The results again showed that individuals with AD could learn to perform a task following intensive training. Three of the participants required only one session of therapy, whereas one subject required five training sessions. Two of the participants, who had the lowest cognitive functioning scores, actually performed better on the task than the two with higher scores. This finding suggests that level of cognitive function may not be the only predictor of performance on the SRT task and that more severe memory dysfunction does not prevent the learning of some types of factual and procedural information.

Other functional information also has been taught to individuals with dementia using SRT. Vanhelle, Van der

Linden, Belleville, and Gilbert (1998) used SRT to teach face–name associations to a dementia patient. Although they found that the patient was affected by proactive interference (i.e., learning of previous items interfered with the learning of subsequent items), the SRT technique was successful in teaching the patient to recall new names.

SRT can be implemented in the context of other activities, such as speech-language therapy sessions. To demonstrate the utility of SRT in this context, Brush and Camp (1998) conducted a study with nine participants: seven with memory deficits resulting from dementia, and two patients with memory disorders resulting from stroke. The goal was to assess the effect of SRT with memory disordered patients of different etiologies, and to examine the application of SRT within the speech-language therapy session.

Three pieces of information were taught to each participant: the therapist’s name, a personal fact that was considered important to the person (e.g., wife’s birthday, room number), and a compensatory technique that was being practiced in speech-language therapy sessions (e.g., using a louder voice, describing an item when unable to name it). Successful recall of the information at the beginning of two consecutive sessions was criterion for completion of the SRT for each piece of information. The three pieces of information were taught sequentially.

Five of the participants with dementia completed the study. All learned the three pieces of information but had varying levels of recall of the information at 4 weeks post-therapy. The two patients who had suffered strokes also successfully completed the study and demonstrated consistent recall of the information at the 4-week follow-up probe.

The aforementioned studies were included in a systematic review of the literature on SRT conducted by Hopper and colleagues (2005). The researchers reviewed 15 studies that were judged to provide Class II and III research evidence (Miller et al., 1999) for SRT with people who have AD or a related dementia. In conclusion, using SRT to teach compensatory strategies that enhance communication is a promising technique for speech-language pathologists. Although patients may not remember the specific episodes of learning, they may show an increase in the number of correct responses produced and exhibit a change in the trained behavior.

Capitalizing on Spared-Memory Processes

Treatment approaches that draw on spared abilities, specifically procedural memory skills, have been shown to be effective when used with individuals with AD. Zanetti, Binetti, Magni, Rozzini, Bianchetti, and Trabucchi (1997) assessed the effects of procedural-memory stimulation on performance of activities of daily living (ADLs) of individuals with mild to moderate AD. Ten individuals with AD were trained to perform different basic and instrumental ADLs, such as

washing the face and using the telephone. Twenty activities were chosen for treatment and divided into two sets. Over 3 weeks, five patients were trained on the first set of 10 activities, and the other five patients were trained on activities in the second set. Training sessions were structured such that performance would be more dependent on procedural rather than episodic memory processes (Zanetti et al., 1997). Specifically, verbal cues and prompts were provided during tasks, and patients were not asked to remember how to perform any task. The time taken for patients in both groups to perform the trained and untrained activities was recorded. Other outcome measures included performance on neuropsychological batteries, including tests of skill-learning, word-stem completion (a measure of lexical priming), and paired-associate learning (a test of episodic memory). These measures were given at the beginning and end of the treatment program.

After 3 weeks of training, patients performed the trained tasks in significantly less time than they did at baseline testing. They also showed a significant improvement in the time taken to perform untrained tasks. No significant differences between scores on neuropsychological tests administered before and after treatment were obtained, although a statistical trend for improvement by patients on the lexical priming tests was reported. Although limited by the absence of a control group, these preliminary results provide evidence that ADL training that is focused on the motor or procedural aspects of tasks may be an effective technique for improving performance of individuals with AD. The improvement on the untrained tasks may have resulted from generalization from trained activities, although practice effects may have contributed to improved performance.

Another technique that capitalizes on spared memory systems and that may be beneficial for promoting new learning by individuals with AD is errorless learning. Errorless learning involves minimization of the number of errors that are allowed to occur during learning trials. This approach differs from usual protocols for rehabilitation of memory and language deficits in that it does not involve “trial and error” techniques to promote learning. Baddeley and Wilson (1994) suggest that individuals with episodic memory impairment have difficulty eliminating errors made during learning trials because they cannot explicitly recall the learning experience. Therefore, these individuals continue to make the same errors on subsequent trials, rather than learning from the errors and making corrections.

The errorless learning technique has been used successfully with amnesic patients (Baddeley & Wilson, 1994; Wilson, Baddeley, Evans, & Shiel, 1994), and recently the technique has been applied to memory rehabilitation with individuals who have AD. Clare, Wilson, Breen, and Hodges (1999) used errorless learning principles, in conjunction with several other techniques, to teach a 72-year-old man with early AD to learn the names and faces of mem-

bers of his social club. The subject learned the name-face associations, demonstrated some generalization from the pictures to real faces in the environment, and retained the information for 9 months. Although the design of the study makes it difficult to attribute the improved performance solely to reduced errors during learning trials, errorless learning principles were the core component of the instruction and clearly contributed to learning and retention of new information. Subsequent studies have been conducted and positive results of errorless learning paradigms reported by the authors (Clare, Wilson, Carter, Breen, Gosses, & Hodges, 2000; Winter & Hunkin, 1999).

The term “errorless learning” does not connote a standardized treatment program but a practice achieved through manipulation of stimulus characteristics and response contingencies. For example, spaced-retrieval training may constrain errors through practice of correct responding over several trials. Also, memory books for individuals with dementia contain printed and pictorial materials to reduce effort and errors associated with free recall of personally relevant information.

Reducing Demands on Episodic and Working Memory Systems: Using Recognition Memory

Bourgeois (1990, 1992) has improved the functioning of individuals with dementia by capitalizing on spared recognition memory and decreasing demands on impaired episodic and working memory systems. In 1990, she studied the effect on conversational ability of providing stimulus materials in the form of wallets with photographs. Three subjects and their spouses participated in the study. An individualized memory wallet was assembled for each AD subject, consisting of pictures of events and persons the patient could not remember. Caregivers were trained to use the memory wallets in conversation with the subjects, and data were collected on communicative behaviors that occurred when the wallets were used in conversation. When caregivers used the memory wallets in conversation, subjects made significantly more statements of fact and fewer ambiguous utterances.

In a second study, Bourgeois (1992) sought to replicate the treatment effects of the first study, and to investigate whether training the use of the wallets was necessary for patients to use them effectively. Initially, six patients with AD and their caregivers were trained to use the memory wallets in conversation. Positive treatment effects were obtained, with patients making more novel, on-topic statements and fewer ambiguous statements when wallets were used in conversation. Next, three additional participants with AD were given memory wallets without any specific training. The experimenter served as the communication partner during this phase of the study. Two of the participants generated more novel, on-topic utterances when the wallets were used in conversation, although the third

participant's behavior was more variable. Generally, the results were positive, suggesting that the use of memory wallets improved communication even when participants were not trained in their use.

Positive results have been reported in subsequent studies by Bourgeois and other researchers (Hoerster, Hickey, & Bourgeois, 2001; Holmes, 2000). The memory wallets used by individuals with AD and communication partners acted as tangible stimuli that remained visible in a conversation, alleviating the demands that conversation typically places on working memory. Additionally, the photographs stimulated recognition of episodes and people in the patients' lives, reducing the reliance on free recall that usually occurs during conversations about remote and recent events (episodic memory). The use of pictures and sentences about familiar people and places in patients' lives capitalizes on often spared reading ability and may promote positive reminiscence and emotion.

Using Sensory Stimulation to Evoke Positive-Fact Memory, Action, and Emotion

Providing sensory stimulation to evoke positive-fact memory, action, and emotion is an important principle in the management of individuals with dementia. Frequently, people with AD in the more moderate to advanced stages are given stuffed animals as companions or decorations in their rooms. Results of several case studies and anecdotal reports support the use of such stimuli to improve communicative function of individuals with AD. Bailey, Gilbert, and Herweyer (1992) observed improved levels of alertness, increased smiling and nodding, and decreased agitation when four patients with AD were given dolls and stuffed animals. Other researchers have noted similar outcomes (Francis & Baly, 1986; Milton & MacPhail, 1985).

In a single-subject experiment, Hopper, Bayles, and Tomoeda (1998) showed that using toy stimuli improved the amount and quality of language produced by four females with moderate to moderately severe dementia. In response to questions, the subjects produced more information units when toy stimuli were present than when they were absent. The results lend support to the use of tangible stimuli, individualized according to patient preferences, when attempting to improve conversation and social interaction.

Multicomponent Treatment Programs

A program that is based on several of the aforementioned treatment principles and that capitalizes on the life experience of individuals with AD is the Montessori-based intervention developed and described by Camp and colleagues (1997). Montessori activities were originally developed for children and include materials and tasks that require active participation. The use of Montessori programming promotes learning through procedural memory processes,

utilizes concrete everyday stimuli to facilitate action and memory, and reduces demands on episodic and working memory by using structured tasks and repetition.

Camp and colleagues (1997) describe intergenerational Montessori programming between individuals with dementia and children, and the positive results from a pilot study. In the study, adults and children were matched according to cognitive level, with the adult being more advanced cognitively than the child. This pairing allowed the adult to act as a mentor and teacher to the child during the Montessori activities (e.g., matching, sorting, reading aloud). The primary measure of interest was "disengagement." Disengagement was defined as time spent staring into space for at least 10 seconds or sleeping (Camp & Brush, 1998). Five-minute observation intervals were used to record data on the amount of time individuals with AD were disengaged. Results showed that when the adults were working with the children, no instances of disengagement were observed, in contrast to the times when adults were not working with the children and episodes of disengagement were common.

Camp and Brush (1998) also reported on the use of Montessori-type tasks in group activities for individuals with dementia in skilled-nursing facilities. In these group activities, engagement was a primary treatment outcome measure (see Orsulic-Jeras, Judge, & Camp, 2000). Investigators collected data on the amount of time individuals spent in active engagement (defined as verbal or motor activity focused on the environment) and passive engagement (defined as passively observing what is going on in the environment) during Montessori activities, and compared those instances to the time spent actively and passively engaged during regular adult day-care activities. Results showed that individuals participating in the Montessori group activities were more actively engaged than those who participated in the regular programming.

Mahendra, Hopper, Bayles, Azuma, Cleary, and Kim (2006) conducted a systematic review of Montessori techniques conducted individually and in groups for individuals with dementia. Five studies met criteria for inclusion in the review and were judged to provide Class II and III evidence for the use of Montessori programming for individuals with AD or a related dementia.

In another type of multicomponent treatment program, Santo Pietro and Boczeko (1998) compared the effectiveness of different group therapies for individuals with AD. Outcomes of a group communication therapy called the "Breakfast Club" were compared to those of "standard" conversational group therapy. Four groups of five mid-stage individuals with AD participated in the Breakfast Club, five days per week for 12 weeks, and four matched control groups participated in conversation groups at the same frequency and duration.

Activities in the Breakfast Club were based on facilitation of procedural memory, stimulation of positive emotions, and

strengthening of associations, and included a 10-step protocol to facilitate communication. Topics related to breakfast were introduced and the group members engaged in the familiar task of choosing and preparing a breakfast. Throughout, language was elicited by the clinician who “facilitated” conversation using visual cues, semantic associations, and paired-choice questions during meal preparation, eating, and clean-up.

Individuals in the control conversation group sat at a table with a clinician who facilitated conversation by introducing a topic for discussion. Language was elicited using open-ended questions, paired choices, and key-word visual prompts. Social conversation was encouraged during greeting and leave-taking.

Group differences were compared using pre- and post-treatment scores on the Arizona Battery for Communication Disorders of Dementia (Bayles & Tomoeda, 1993), and the Communication Outcomes of Communicative and Functional Independence Scale (COMFI; Santo Pietro & Boczek, 1997), a caregiver rating scale with 20 items related to cognition, psychosocial behavior, communication and conversation, and meal-time independence. Also, the number of incidents of “cross-conversation” between members within a group was compared. Cross-conversation was defined as any utterance between one group member and another, and was used as a measure of social awareness and communicative ability. Results showed that individuals in the Breakfast Club exhibited significantly improved language skills, improved functional independence, and increased use of cross-conversation as compared to members in the standard conversation groups who showed no improvement on any measure. Several other within-group improvements for Breakfast Club participants were noted, including increased interest and involvement in meal-time activities.

The multifaceted approaches underlying the Montessori group activities and the Breakfast Club were effective in promoting meaningful change in the cognitive and communicative abilities of individuals with mild to moderate AD. Most investigators have favored procedures and programs that focus on relatively preserved skills and have not attempted to directly stimulate the cognitive processes impaired in dementing diseases. However, some recent research provides encouragement for cognitive-stimulation programs.

Strengthening Associations through Cognitive Stimulation

Quayhagen, Quayhagen, Corbeil, Roth, and Rodgers (1995) produced preliminary evidence that intensive cognitive therapy may slow the general cognitive and behavioral decline associated with dementia. These researchers sought to determine the impact on individuals with AD of a home-

based intervention program of active cognitive stimulation provided by family caregivers. Pairs of individuals with AD and their primary caregivers were assigned to experimental, placebo, and control groups. Families in the experimental group were trained to provide 60 minutes of “active” cognitive stimulation. The cognitive-stimulation program consisted of memory, problem-solving, and conversation activities in which the patient had to participate actively. Memory techniques were characterized by the recall and recognition of verbal and visual information. The placebo group engaged in more “passive” interventions that were designed to match experimental interventions, and yet not require active participation by the subject. For example, patients might watch “Wheel of Fortune” in the placebo group instead of playing the game “Hangman” in the experimental group. The control-group families were placed on a wait list for therapy sessions after the study was completed. Multiple behavioral and cognitive measures were used to assess intervention effects on memory, verbal fluency, problem-solving, and attention. Patients in all three groups were tested at three points in time: on entrance into the study, after 12 weeks of treatment, and 6 months after completion (Quayhagen et al., 1995).

The individuals with AD who received the active cognitive stimulation showed no decline from pre to post-testing on the measures of global cognitive functioning, whereas the control group declined on all measures. The placebo group declined on some measures and remained stable on others. Interestingly, the experimental group improved on some measures throughout treatment and for a period after treatment, and maintained their pre-treatment level of cognitive function on others, although their performance returned to baseline levels at the 9-month probe.

Bach, Bach, Bohmer, Fruhwald, and Grilc (1995) also compared the effects of two treatments on the function of 44 individuals with mild to moderate dementia. The subjects were randomly assigned to a control group or a treatment group. The control group received 24 weeks of “functional” rehabilitation, including tasks from occupational, physical, and speech therapists. The treatment group received the same functional treatment, in addition to twice-weekly small-group treatment consisting of memory training, manual/creative activities, and self-management tasks. Several measures were used to assess change as a result of treatment, including cognitive tests, measures of psychosocial function, and measures of depression. The results showed that both groups had significantly higher levels of cognitive performance and a decrease in depressive symptoms after 24 weeks of treatment. However, the patients in the treatment group had significantly better scores than the people in the functional group on measures of cognition, psychosocial functioning, subjective well-being, and depression (Bach et al., 1995).

The recognition that cognitive-stimulation programs have beneficial effects for individuals with AD has led

researchers to investigate the combined effects of these programs in conjunction with commonly prescribed medications to treat AD. Chapman, Weiner, Rackley, Hynan, and Zientz (2004) recruited 54 patients with mild to moderate AD to participate in a study to assess the effects of combining cognitive-communication stimulation with donepezil, an acetylcholinesterase inhibitor prescribed for people with AD. The participants were randomly assigned to a control group (donepezil only; $n = 28$) and a treatment group (donepezil plus stimulation group; $n = 26$). The cognitive-communication stimulation program consisted of activities implemented in a group format for 12 hours over a 2-month period. The tasks included discussions about current events, information related to AD, life stories (i.e., personal narratives with pictures), and life-interest topics (e.g., hobbies or work).

The investigators followed the participants for 1 year and measured aspects of cognition, communication, emotional symptoms, and quality of life at baseline, 4 months (1 month after the end of the 2-month stimulation program), 8 months, and 12 months. Participants in the treatment group demonstrated a slower rate of decline than did participants in the control group on caregiver interview and standardized measures of discourse abilities, ADLs, and overall functioning.

Promoting Generalization

A primary goal of any cognitive-communication intervention is the generalization of treatment effects and their continuance after the intervention is discontinued. Little research has been conducted to determine the factors that promote generalization and maintenance of behaviors in individuals with dementia. Further, the progressive nature of dementia leads clinicians to think that generalization over time is unrealistic. However, the duration of dementia can be quite long, sometimes more than 10 years, and change in cognitive status occurs gradually. A treatment that improves function for several months can improve quality of life and reduce demands on caregivers, and therefore is worth investigating. To assess generalization and maintenance of treatment effects, consider evaluating behaviors that reflect stimulus generalization rather than response generalization.

Stimulus generalization is the occurrence of trained behaviors in nontraining conditions that include different people, situations, or materials than those used in treatment sessions (Olswang & Bain, 1994; Thompson, 1989). The trained response, or treatment behavior, generalizes to different stimulus conditions. For example, stimulus generalization is exhibited by the patient with dementia who is taught a strategy for requesting help in a treatment session with the clinician, who later asks for help outside of the treatment session, showing transfer of the trained response to an untrained context.

Response generalization is the occurrence of untrained responses or behaviors as a result of training other, related

responses or behaviors (Thompson, 1989). For example, Lowell, Beeson, and Holland (1995) taught patients with aphasia to use a semantic-features diagram to aid in self-cueing and naming. Two of the three subjects used the schema to improve naming of trained items as well as to “generate semantic information regarding any word they wished to retrieve” (p. 110), thus demonstrating response generalization.

Stimulus generalization may be the more appropriate measure for documenting the effects of treatment of individuals with dementia, as the multiple cognitive deficits associated with dementia may prevent robust response generalization. Treatment and measurement of generalization should be focused on trained responses, such as names of family members, that can be used in different stimulus situations.

Clinicians need to program for generalization. The “train and hope” (Stokes & Baer, 1977) method, in which clinicians conduct treatment and hope for functional effects, is a commonly used, yet frequently ineffective, procedure for facilitating generalization. Stokes and Baer (1977) recommend several techniques for facilitating generalization, among them the introduction of natural contingencies and the use of common stimuli during treatment. Introducing natural maintaining contingencies involves teaching the patient behaviors that will be reinforced in the natural environment. Choosing treatment behaviors that are functional and important to patients and caregivers increases the likelihood that these behaviors will be maintained outside of the treatment situation (Bourgeois, 1991). Similarly, the use of common stimuli increases the probability that the individual with dementia will exhibit trained behaviors in other contexts.

Given the importance of generalization, it is highly desirable to include caregivers in the treatment program. They can learn to promote generalization and provide patients with opportunities to strengthen their communication skills.

Caregiver Training Programs

Nash, Koury, and Lubinski (1991) have evaluated different methods of training nursing staff to communicate effectively with individuals with dementia. These researchers investigated the effect of two training programs on nursing assistants’ interactions with patients, their knowledge of geriatric communication disorders, and their problem-solving skills. Program A was traditional in-service training (i.e., 1-hour lecture format) and Program B involved in-service role-playing (i.e., 1-hour training with the focus on enacting situations and problem solving). One group of nursing assistants received no training.

Outcome scores on a test of knowledge of geriatric communication disorders and strategies for improving communication were compared before and after treatment. Results revealed that role-playing was more effective than lecture for promoting a change in employee behavior, although

nursing assistants in the lecture group also showed improved test performance. These findings underscore the importance of staff training in creating a supportive communication environment and improved quality of care for institutionalized individuals with dementia.

Ripich (1994) developed a functional communication program for training caregivers of individuals with AD. The seven-step program is called "FOCUSED." Each letter in the word FOCUSED refers to a strategy for improving communication: (F) functional and face-to-face; (O) orient to topic; (C) continuity of topic and concrete topics; (U) unstick any communication blocks; (S) structure with yes/no and multiple-choice questions; (E) exchange conversation and encourage interaction; and (D) direct, short, simple sentences. The FOCUSED training program is divided into six, 2-hour modules designed for family and "formal" caregivers. To test its effectiveness, a pilot study was conducted. Seventeen nursing assistants completed the FOCUSED training program. Knowledge of communication strategies was measured before and after completion of the training. The participants demonstrated increased knowledge of communicative strategies following training, and anecdotally reported increased satisfaction during interactions with individuals with AD (Ripich, 1994). Further positive treatment effects associated with FOCUSED were noted by Ripich, Wykle, and Niles (1995) and Ripich and Zioli (1999). For a review of caregiver education and training programs and the evidence for their use with caregivers of individuals with AD and related dementias, see Zientz and colleagues (2006).

Functional Maintenance Therapy

The primary avenue of service delivery for speech-language pathologists who work with individuals with dementia in skilled-nursing facilities under Medicare reimbursement policies is through functional maintenance therapy (FMT). Glickstein and Neustadt (1995) define FMT as a program for individuals with chronic conditions who need intervention by skilled professionals. FMT typically consists of an evaluation by the rehabilitation professional, followed by the development, establishment, and short-term implementation of a treatment program. As speech-language pathologists and other rehabilitation professionals increasingly provide services to individuals with dementia in a consultant role, caregivers must be trained to carry out treatment prescribed by clinicians. Functional maintenance therapy and other short-term treatment programs necessitate early planning and inclusion of caregivers for carry-over of treatment behaviors to the natural environment. Such an approach is preferable to one in which the planning takes place only when the patient is discharged from therapy.

An example of a functional maintenance program for an individual (BW) with moderately severe dementia (Mini-Mental State Examination score of 9/30) (Folstein et al.,

1975) was reported by Bayles, Hopper, Gillespie, Mahendra, Cleary, and Tomoeda (1998). BW was living at home with 24-hour care, until he fractured his hip while transferring from his chair to the bed. BW was admitted to the hospital for 3 days, and then discharged to a skilled-nursing facility for short-term rehabilitation. The speech-language pathologist evaluated BW and spoke with caregivers about techniques to improve communication during transfers. Caregivers were concerned that his dementia, coupled with a moderate hearing loss, would make it impossible for them to teach him transfer strategies. The speech-language pathologist worked with the physical therapist and the family caregivers, using the spaced-retrieval training (SRT) technique, to teach a "safe transfer" maneuver. The patient was prompted with the stimulus question, "You are standing up. You go to sit down. What do you do with your hands?" which was used consistently during training. Initially, the patient responded with statements such as "put them in my pockets" or "put them on my lap." However, after only eight sessions of SRT, and correct responding in the therapy sessions, he learned to reach back with his hands and generalized this strategy to everyday situations when cued by caregivers. This case illustrates the benefit of collaborating with caregivers to promote improved functioning after discharge from treatment.

Use of Volunteers in Treatment with Dementia

Collaborations with activities personnel and recruitment of volunteers are two other ways to extend services to individuals with AD following skilled treatment. Arkin (1995) provided a model for the use of volunteers with her Volunteers in Partnership (VIP) program. Individuals with mild to moderate dementia are paired with university students who assist them in performing weekly volunteer services and who provide memory and language stimulation. Volunteer activities are tailored to each patient's preferences, and include helping at day-care centers, working at animal shelters, and assisting other residents in nursing homes. Memory and language tasks are designed by the clinician and students are trained in their implementation. Audio-taped quiz tasks (Arkin, 1992) are used to teach factual information, and language is stimulated through activities such as association, picture description, solicitation by the student of opinions or advice about how to solve real-life problems, and reading short passages of text. In a pilot program, seven of eleven patients produced more on-topic utterances in response to questions about specific topics, such as President Kennedy's assassination. Eight patients produced more information units during picture description, and three of four patients, who used memory tapes, substantially increased their recall of biographical facts (Arkin, 1995). Doing volunteer work in partnership with university students not only stimulates individuals with dementia, it provides respite for family caregivers.

Measurement Issues

Measuring the effects of treatment for individuals with dementia is especially challenging because intellectual deterioration is progressive. However, as Camp and colleagues (1996) have noted, individuals with AD can demonstrate improvement on specific treatment tasks, despite exhibiting an overall decline in cognitive function. Assessment of change as a result of treatment should include consideration of activities and participation levels of functioning (World Health Organization, 2001). Evaluating change in one dimension of function, such as degree of memory impairment, will be insufficient. Specifically, assessing change with only pre- and post-standardized tests of memory and language will not capture the improvement that individuals with dementia may exhibit in conversational ability, affect and level of engagement, and skills or behaviors taught in treatment sessions. However, measures of quality of life, quality and quantity of communicative interactions, level of engagement and activity participation, and change in behavior may reveal the positive impact of treatment. Focusing solely on improvement in the amount or degree of deficit as a means of demonstrating improvement in therapy is inadequate with patients whose impairments are progressive. Inclusion of multiple measures allows the clinician to determine treatment effects by providing converging evidence of behavioral change.

FUTURE TRENDS IN TREATMENT RESEARCH

In 1991, Bourgeois reviewed the meager literature on behavioral treatments for individuals with dementia. Since 1991, however, interest in treating the cognitive-communication problems of individuals with dementia has increased and results of studies to date suggest that many older adults with dementia can improve function and maintain abilities longer when they participate in cognitive-communication treatment. In fact, enough literature exists to support the development of practice guidelines for speech-language pathologists working with individuals with dementia (see Bayles et al., 2005), and ASHA has published a position statement and technical report (ASHA, 2005 a, b) regarding the roles of SLPs working with individuals who have dementia and the theory and evidence for clinical work with this population. Future researchers should continue to focus on factors that influence patient performance in behavioral therapy, including stage of cognitive decline, type of dementing illness, profile of cognitive deficits, degree of caregiver support, and type of living situation.

Data are needed from large numbers of individuals with dementia to support treatment for individuals at different stages of decline. Generally, most of the treatment studies reported in this chapter involved participants with mild to moderate dementia. Future research should examine treat-

ment of individuals with moderate and moderately severe dementia. Also, differences exist between institutionalized and non-institutionalized individuals, making it difficult to extend results from working with individuals who reside at home to patients living in long-term-care centers. Characteristics of the learning environment, particularly frequency, intensity, and type of therapy, as well as the educational background and expertise of the person providing the therapy still require systematic investigation.

Speech-language pathologists can make important contributions to the well-being of individuals with dementia. With knowledge of preserved abilities and effective intervention principles, the cognitive-communication deficits of individuals with dementia can be minimized. Positive outcomes of behavioral treatment are promising and provide the foundation for continued investigation of effective therapeutic interventions.

KEY POINTS

1. Dementia is a syndrome associated with several different causes, the most common of which is Alzheimer's disease.
2. Individuals with dementia are the profession's fastest growing clinical population.
3. Individuals with dementia develop multiple cognitive deficits and therefore problems in communicating.
4. The distribution of neuropathology of the various dementing diseases explains the patterns of spared and impaired cognitive abilities.
5. Knowledge of these patterns is necessary to provide appropriate assessment and treatment services.
6. The functioning of individuals with dementia can be improved by capitalizing on spared memory systems and reducing demands on impaired memory systems.
7. Individuals with dementia can learn new information and behaviors with appropriate therapeutic techniques.
8. To measure change as a result of therapy, clinicians must evaluate patient function in personal activities and participation in daily life, rather than focusing solely on level of cognitive impairment.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. Explain the difference between dementia and AD. What are other diseases that cause dementia?
2. What kind of memory is used when a person (a) explains the steps in changing a tire; (b) tells when and where he

- or she graduated from high school; and (c) explains what he or she did last Friday night?
3. Discuss the relation between cognition and communication. What effect would a deficit in the following have on communication: episodic memory, lexical memory, procedural memory?
 4. Should the communication disorder associated with AD be called aphasia? Why? Why not? Should the communication disorder associated with multiple stroke and vascular disease be called aphasia? Why? Why not?
 5. Describe cognitive-communication function of individuals with mild, moderate, and severe AD.
 6. What aspects of communication and cognition are important to assess in individuals with AD? What standardized tests might you use to assess these abilities?
 7. Explain the principles of successful intervention for individuals with dementia. How is intervention for individuals with irreversible dementia different than intervention for individuals with nonprogressive neurologic conditions?
 8. Discuss several behavioral interventions for individuals with dementia and the research evidence associated with these interventions. Think about how you would measure change in a treatment program using one or more of these interventions.

Chapter 36

The Nature and Management of Neuromotor Speech Disorders Accompanying Aphasia

Julie Wambaugh and Linda Shuster

OBJECTIVES

The primary objective of this chapter is to provide the clinician with the information needed to understand the neuromotor speech disorders that co-occur with aphasia and to make appropriate management decisions based upon the current available evidence. To achieve this overarching goal, the following objectives were specified:

1. To provide readers with an understanding of the role of the left cerebral cortex in the control of movement, specifically speech movement.
 2. To demonstrate, based upon functional neuroanatomy, that neuromotor speech impairments are probable in many patients with acquired brain damage that produces aphasia, most probably because of the overlap of several of the neural substrates mediating linguistic and motor behaviors.
 3. To provide evidence from the literature that argues for the hypothesis that motor speech deficits resulting from damage to the dominant hemisphere are likely to be heterogeneous because of the varied roles that different brain networks play in speech production.
 4. To provide suggestions for assessment of apraxia of speech (AOS) for the purposes of developing treatment programs and measuring treatment effects.
 5. To provide a summary of the techniques and treatments available for AOS along with a description of the rationale underlying those treatments.
-

Damage to the language-dominant hemisphere may result not only in aphasia but also in neuromotor speech disorders. Previous editions of this text have provided summaries of early reports of neuromotor speech disorders associated with dominant-hemisphere damage (Square & Martin,

1994; Square, Martin, & Bose, 2001), and the reader is referred to those sources for historical accounts of these disorders. Whereas it is well accepted that the dominant hemisphere is crucial for both language and motor-speech functioning (Square et al., 2001), our knowledge concerning the structural and functional neuroanatomy associated with speech and language is rapidly expanding and changing. In keeping with previous editions of this text, this chapter will provide the reader with current information concerning developments in our understanding of the underlying neurologic bases of motor-speech production. Progress has also been made relative to the management of neuromotor speech disorders in aphasia, and this chapter will serve to inform the reader about treatment advances.

MOTOR-SPEECH DISORDERS ACCOMPANYING APHASIA: STRUCTURAL AND FUNCTIONAL NEUROANATOMY

In the past few years, there has been an explosion of studies using a variety of (mainly noninvasive) technologies to investigate the structural and functional neuroanatomy underlying speech and language. These technologies include positron emission tomography (PET; e.g., Schulz, Varga, Jeffires, Ludlow, & Braun, 2005), functional magnetic resonance imaging (fMRI; e.g., Bohland & Guenther, 2006; Shuster & Lemieux, 2005), transcranial magnetic stimulation (TMS; Watkins & Paus, 2004), diffusion tensor imaging (DTI; Catani, Jones, & ffytche, 2005), and magnetoencephalography (MEG; Gunji, Hoshiyama, & Kakigi, 2001). Each of these technologies has its drawbacks; however, they are powerful tools for studying speech behavior in humans in vivo.

These new studies, as well as scores of earlier lesion, animal, and post-mortem studies on humans, have revealed a speech production network that includes the primary motor (M1) cortex, the left posterior inferior frontal gyrus, lateral premotor areas (PM), medial premotor areas, the left insula, the left parietal cortex, the left superior temporal gyrus (STG), the basal ganglia, the cerebellum, and the thalamus.

Moreover, evidence continues to accumulate in support of the view, proposed by investigators such as Liberman and Mattingly (1985), that there is a tight coupling between the networks involved in speech perception and speech production (Watkins & Paus, 2004). While there is still much to be learned, we do have some idea of the role that each of these areas plays in speech production, as well as how lesions to these areas affect speech production. We describe the cortical areas of the network and their functions below.

Primary Motor Area (M1)

The primary motor area (M1) is located in the anterior bank of the precentral sulcus in area 4 of Brodmann's cytoarchitectonic map of the human cortex (Fig. 36-1). M1 receives direct inputs from somatosensory regions in the parietal lobe,

including Brodmann's area (BA) 1, 2, 3a, and 3b, as well as from BA 5 in the posterior parietal lobe (Ghez & Krakauer, 2000; Purves, Augustine, & Fitzpatrick, 2001). In primates, it also receives direct inputs from four premotor regions: the dorsal and ventral premotor areas on the lateral surface of the hemisphere and the supplementary and cingulate motor areas on the medial surface of the hemisphere. M1 receives indirect inputs from the basal ganglia and cerebellum via the ventrolateral thalamus. In a recent study using cortical stimulation in patients with epilepsy who were undergoing surgery, Greenlee and colleagues (2004) provided evidence of a connection between the orofacial region of M1 and the inferior frontal gyrus (Broca's area). M1 provides direct outputs to cranial-nerve nuclei in the brain stem via the corticobulbar tract and to spinal motor neurons in the spinal cord via the corticospinal tract. The pyramidal cells (also called Betz cells)

Figure 36-1. Brodmann's areas of the human cerebral cortex. A. Lateral view. B. Medial view. Cortical motor fields are also indicated. MI = primary motor cortex; SMA = supplementary motor area; PM = premotor cortex; Area 44 = Broca's area. (Adapted from Brodmann 1909, 2006, with permission.)

in cortical layer V of M1 that give rise to these tracts are referred to as upper motor neurons. Importantly, these cells also have extensive horizontal connections within M1 (Ghosh & Porter, 1988; Huntley & Jones, 1991).

Our conceptualization of M1 as an area that simply initiates voluntary movements has undergone considerable revision in recent years. Evidence suggests that it participates in motor-learning and cognitive behaviors (Sanes & Donoghue, 2000), and that it can undergo rapid plastic changes, which may underlie both motor learning and recovery of function after a lesion (Classen, Liepert, Wise, Hallett, & Cohen, 1998). Much of our knowledge regarding the functional organization of M1 comes from studies of limb (particularly upper limb) movement (Sanes & Donoghue, 2000). To a large extent, this is because animals can be studied more easily using invasive techniques, such as single-unit recording. However, so far, the general principles underlying movement in primates appear to be universal across body divisions (arm, leg, etc.; Sanes & Donoghue, 2000).

We have known, since John Hughlings Jackson's observations of patients during seizures in the late 19th century, that M1 is organized somatotopically (Jackson, 1931). That is, there are different, separable regions of M1 that represent the body's musculature from head to feet, with the head being represented more laterally and the feet being represented on the medial surface of the hemispheres (Asanuma & Rosen, 1972; Penfield & Roberts, 1959). However, there is considerable evidence to show that, although there are separable motor regions in M1 for the major body divisions (i.e., arm, leg, face, etc.), there is considerable overlap in the representation within these divisions (Barinaga, 1995; Graziano, Taylor, & Moore, 2002; Huang, Sirisko, Hiraba, Murray, & Sessle, 1988, 1989; Sanes, Donoghue, Thangaraj, Edelman, & Warach, 1995). M1 is not organized as a one-to-one mapping of cortical neurons to individual muscles. Rather, cortical neurons act on multiple muscles that behave together in a synergistic way to allow the performance of complex movements (Cheney & Fetz, 1985; Graziano et al., 2002), and to inhibit muscles that perform the opposite movements. Graziano and colleagues (2002) found that electrical microstimulation to the face area of M1 in monkeys evoked complex mouth movements, and the final position of the mouth at the end of the movement was the same for a given site, regardless of the starting position of the mouth. These data show that M1 is organized to allow us to achieve particular movement goals and that the nature of this organization permits us to achieve the same goal in a variety of different ways. Thus, humans adjust their speech movements remarkably well in response to perturbations, such as having a bite block clenched between their teeth while speaking (Warren, Allen, & King, 1984).

Another aspect of the organization of M1 is that, similar to auditory neurons, which are tuned to specific frequencies, and visual neurons, which are tuned to particular visuospatial orientations, motor neurons that are involved in reaching are

tuned to particular higher level movement parameters, such as direction (Naselaris, Merchant, Amirikian, & Georgopoulos, 2006), distance (Paninski, Fellows, Hatsopoulos, & Donoghue, 2004), and target position (Paninski et al., 2004).

M1 demonstrates plasticity, and this is thought to be driven by synaptic changes in the horizontal connections within M1 (Sanes & Donoghue, 2000). This plasticity is believed to contribute to both motor learning and recovery of function after a brain lesion, and the plastic changes can occur quite rapidly. For example, Classen and colleagues (1991) used TMS to elicit thumb movements that were consistently in a particular direction. They then asked subjects to practice movements in the opposite direction for 30 minutes. After the practice, the TMS evoked the same thumb movement, but in the opposite direction from the original movement that was elicited, illustrating the rapid use-dependent plasticity of M1. Finally, M1 is thought to be involved in higher cognitive functions. For example, in a study using MEG, Saarinen, Laaksonen, Parviainen, and Salmelin (2006) found that face motor cortex participates in processes such as visuomotor mapping (e.g., learning to make a particular movement in response to a visual symbol) and movement sequencing.

At least since the time of Broca and Wernicke, we have parceled speech production and speech perception into two separate processes. Recent studies, however, suggest that these processes are not so easily separable. Watkins and Paus (2004) found that listening to but not watching speech resulted in larger motor evoked potentials recorded from the orbicularis oris muscle. In an fMRI study, Wilson, Saygin, Sereno, and Iacoboni (2004) found that listening to speech activated motor areas, including M1.

Lesions to M1 result in a variety of symptoms, including spasticity, hyporeflexia, and the loss of the ability to produce fine movements (Purves et al., 2001). Individuals with a unilateral lesion to the face region demonstrate an inability to move their lower faces voluntarily or in response to command, while maintaining the ability to move involuntarily, under conditions such as laughing or crying. In the Mayo nomenclature of dysarthria, lesions to speech areas of M1 produce spastic dysarthria (Darley, Aronson, & Brown, 1975; Duffy, 2005).

Premotor Areas

There are six premotor areas on the lateral and medial surfaces of the hemispheres that have been well defined in monkeys (Picard & Strick, 1996, 2001). In human beings, we have learned about these areas mainly through imaging studies (Schubotz & von Cramon, 2003), and our knowledge is continuing to evolve. The medial areas include the supplementary motor area (SMA, BA 6), the pre-SMA, and three areas in the cingulate sulcus (the cingulate motor area [CMA]): the rostral cingulate motor area (CMAr), the dorsal cingulate motor area (CMA_d), and the ventral cingulate motor area (CMA_v) (Picard & Strick, 2001). The lateral areas in humans

include dorsal (PMd) and ventral (PMv) premotor areas (also BA 6), which lie immediately anterior to the precentral gyrus (Picard & Strick, 2001; Schubotz & von Cramon, 2003).

Medial Premotor Areas

The supplementary motor area (SMA) has been subdivided into two areas (possibly three, see Vorobiev, Govoni, Rizzolatti, Matelli, & Luppino, 1998) based on functional and anatomical differences. They are the SMA proper and the pre-SMA (Picard & Strick, 1996, 2001). The boundary between the SMA and the pre-SMA is the verticofrontal (VCA) line, which is an imaginary vertical line passing through the anterior commissure, perpendicular to the anterior-posterior commissure line (Picard & Strick, 1996, 2001; Talairach & Tournoux, 1988). The SMA projects directly to M1 and to the spinal cord, while the pre-SMA does not. Conversely, the pre-SMA, but not the SMA, is interconnected with the prefrontal cortex. In a recent study using DTI in humans (which permits visualization of the white-matter pathways), Lehericy and colleagues (2004) found that the SMA and the pre-SMA also project to different areas of the striatum. The pre-SMA projects to the middle portion of the putamen, while the SMA (and M1) project to the posterior portion of the putamen. Like M1, SMA is organized somatotopically, while the pre-SMA is not (Picard & Strick, 2001). Finally, there is little interconnection between the pre-SMA and the SMA.

The role of the pre-SMA was originally thought to be in learning sequential movements; however, it has been shown that it is active during cognitive tasks, such as those involving attention and working memory. In light of these findings, Picard and Strick (2001) suggested that it might be functionally considered to be a part of the prefrontal cortex, rather than being a motor area. Alario, Chainay, Lehericy, and Cohen (2006) suggested, based on an fMRI study of speech production, that the pre-SMA could be subdivided. They found that the anterior pre-SMA was active during effortful word selection. Activation in the posterior pre-SMA revealed an interaction between factors of word familiarity and word length, which they suggested revealed “a marker of the post-selection encoding processes that precede articulatory execution” (p. 135).

The role of the SMA is related to movement. Intracortical stimulation to the SMA produces movements of the head, forelimbs, and hindlimbs in somatopic order (Picard & Strick, 1996). Alario and colleagues (2006), in the fMRI study described above, found that the SMA was active during word articulation. Lesions to either the left or right SMA from surgical resection lead to a cluster of deficits called the “SMA syndrome” (Krainik et al., 2003, 2004). The resulting speech impairments range in severity from complete mutism to reduced spontaneous speech output. However, complete or nearly complete recovery occurs within a few weeks or months (Krainik et al., 2003, 2004). The basis for this recovery seems

to be in the recruitment of the SMA in the contralesional hemisphere (Krainik et al., 2004).

Three cingulate motor areas within the cingulate sulcus have been identified in primates: the rostral cingulate motor area (CMAr), the ventral cingulate motor area (CMAv), and the dorsal cingulate motor area (CMA_d). Picard and Strick (2001) proposed that humans have corresponding areas and refer to these as the rostral cingulate zone (RCZ), which is further subdivided into anterior (RCZ_a) and posterior (RCZ_p) zones, and the caudal cingulate zone (CCZ). However, there is considerable variability in the configuration of the human cingulate sulcus (Paus et al., 1996). Paus and colleagues found that, although the cingulate sulcus (CS) was continuous in the majority of subjects they studied, a “significant number” had a CS that was divided into two or three segments. Moreover, they observed two secondary sulci, the paracingulate sulcus (PCS), which was present in most subjects, and the intra-limbic sulcus, which was rare. Paus and colleagues also found left-right asymmetries. The CS was more likely to be divided and the PCS to be present in the left hemisphere than in the right hemisphere. These anatomical variations suggest that we need to be cautious in interpreting group data from functional imaging studies of the CS. With regard to function, the CCZ appears to be involved in motor execution, while the RCZ_a and the RCZ_p appear to be involved in conflict monitoring and response selection, respectively.

In an fMRI study of word generation by category, Crosson and colleagues (2001) found that the pattern of brain activation (which was analyzed individually for each subject) was dependent on whether a subject did or did not have a prominent PCS. In the majority of subjects who had a PCS, there was activation in the PCS during the word-generation task that did not extend into the CS. However, in subjects who did not have a prominent PCS, the activation did extend into the CS. Kremer, Chassagnon, Hoffman, Benabid, and Kahane (2001) used electrical stimulation to stimulate the ventral bank of the CS in a patient undergoing surgery for epilepsy. The stimulation produced an urge to grasp an object (although there was no object present). The patient was able to describe both her urge to grasp and her inability to resist the urge.

Lateral Premotor Areas

The lateral premotor area (BA 6) lies immediately anterior to the precentral gyrus. BA 44 is sometimes included as part of this area; however, we will discuss BA 44 along with BA 45 in the section on the inferior frontal cortex. The lateral premotor areas are divided, based on both anatomical and functional differences, into dorsal (PMd) and ventral (PMv) regions. However, the precise locations and boundaries of human PMd and PMv are not certain (Picard & Strick, 2001; Schubotz & Yves von Cramon, 2003). The PMd can be further subdivided, also based on anatomical and functional differences, into a rostral and a caudal division. The differences between rostral and caudal PMd are similar to those that

underlie the pre-SMA/SMA distinction (Picard & Strick, 1996, 2001). Like the SMA, caudal PMd projects directly to M1 and the spinal cord, while rostral PMd does not. Like the pre-SMA, rostral PMd has connections with the prefrontal cortex, suggesting that it may be involved in cognitive rather than motor functions (Picard & Strick, 1996, 2001; Schubotz & von Cramon, 2003). Schubotz and von Cramon (2003), in their summary of functional imaging studies of the PM, described three functional trends related to the rostral-caudal anatomical gradient in the PMd: one from complex to simple execution, one from the intention to move to the execution of movement, and one from early to late sensorimotor learning stages. In a recent study using MRI, Amiez, Kostopoulos, Champod, and Petrides (2006) found considerable variability in the morphology of human PMd. In the same study, using fMRI, they found activation in the PMd when subjects performed a conditional motor-response task in which they had to push a particular computer mouse button, depending on what color they saw on the computer screen.

In monkeys, the ventral premotor area (PMv) consists of two fields, F4 and F5. It is currently not clear whether there is a human equivalent of F4. It has been proposed that BA 44 (often considered to be part of Broca's area) is the equivalent of monkey F5 (Rizzolatti & Arbib, 1998). This is discussed in further detail below. The PMv appears to be particularly involved during manipulation of objects by the hands. For example, it is active when subjects alter the force of their grip on an object (Ehrsson, Fagergren, & Forssberg, 2001).

Lesions to the PMd in monkeys and man affect the ability to perform conditional motor learning tasks, that is, to select a movement based on a (typically visual) cue (Halsband & Freund, 1990; Purves, Augustine, & Fitzpatrick, 2001). Transcranial magnetic stimulation (TMS, which produces a temporary lesion effect) of the PMd in human subjects disrupted movement selection at an early stage of performance (Schluter, Rushworth, Passingham, & Mills, 1998).

Left Posterior Inferior Frontal Gyrus (IFG)

The posterior inferior frontal gyrus consists of the pars opercularis and the pars triangularis. This region is also known as Broca's area, since Broca originally proposed that this region was the seat of "articulate language" (Broca, 1861). In Brodmann's map, opercularis and triangularis are BA 44 and 45, respectively. Studies have shown that the borders of human BA 44 and 45 vary greatly (Amunts et al., 1999, 2004; Amunts, Schleicher, Ditterich, & Zilles, 2003; Tomaiuolo et al., 1999; Uylings, Jacobsen, Zilles, & Amunts, 2006). BA 44 generally occupies the pars opercularis, but it may encroach on pars triangularis. Similarly, while BA 45 occupies pars triangularis, it may encroach on pars opercularis. There are asymmetries in the size of right and left IFG, and these differences are obvious in children as young as 1 year of age (Amunts et al., 2003). Moreover, the asymmetry in cytoarchitecture continues to change throughout life, suggesting that

this region demonstrates plasticity. In a recent postmortem study of 10 brains (five male and five female), Uylings and colleagues (2006) measured the number of neurons and the volume of BA 44 and 45. They found that the volume in left BA 44 was greater than that of right BA 44 in all 10 cases. In addition, all five females and one male showed greater volume of BA 45 in the left hemisphere than in the right, although this asymmetry reached statistical significance only in the females. The total number of neurons was significantly greater in left than in right male BA 44. The number was greater in the left than in the right in female subjects, but the difference did not reach statistical significance. Although the study had a limited number of subjects, these data suggest that investigators who are using neuroimaging to study speech may want to analyze the data of male and female subjects individually, in addition to analyzing the data from the whole group.

Anwander, Tittgemeyer, von Cramon, Friederici, and Knösche (2006) used DTI to study connectivity in Broca's area. They found evidence for three separate anatomical regions, based on white-matter connections, that corresponded to the deep frontal operculum, BA 44, and BA 45. The deep frontal operculum projected through the anterior subinsular white matter and the external capsule to the temporal isthmus and continued to the anterior temporal lobe, into the inferior occipitofrontal fascicle and the inferior longitudinal fascicle. In five of the six subjects, the deep frontal operculum was also connected to the anterior temporal lobe via the uncinate fasciculus. Both BA 44 and 45 displayed the same connections through the inferior external capsule as the deep frontal operculum did. Moreover, they projected to the parietal lobe and the perisylvian region via the arcuate fasciculus in four subjects and to the dorsomedial prefrontal cortex and the ventral portion of the precentral gyrus in all six subjects. Anwander and colleagues also found that the arcuate fasciculus was more dominant in BA 44, while dorsomedial and external capsule connections were more dominant in BA 45. They suggested that their structural data support the conclusions of functional-imaging investigations that have proposed that Broca's area can be parceled into functional subdivisions (e.g., Devlin, Matthews, & Rushworth, 2003; Friederici, 2002).

Imaging studies have shown that IFG is active during a variety of different speech and language tasks, including syntactic tasks such as asking subjects to compare more or less syntactically complex sentences (Friederici, 2002); semantic tasks, such as asking subjects to determine whether a word represented a man-made object (Devlin et al., 2003); phonologic tasks, such as asking subjects to segment words into phonemes (LoCasto, Krebs-Noble, Gullapalli, & Burton, 2004); and speech articulation (Binkofski & Buccino, 2004).

In 1992, Giacomo Rizzolatti and colleagues (de Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992) reported that neurons in F5 in the premotor cortex of monkeys fired both when the monkey performed an action and when the monkey observed a similar action performed by the experimenter. They called these neurons "mirror" neurons and proposed

that these neurons “represent” the observed action. Rizzolatti and colleagues argued that the function of mirror neurons is in movement preparation. In particular, they suggested that observation of a movement elicits automatic preparation to perform the same movement, which, in turn, allows the monkey to become faster at executing the movement and to prevail on possible competitors (Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). Based on a subsequent study of humans using TMS, they concluded that humans also possessed a mirror neuron system in BA 44, which they argued is the equivalent of monkey F5 (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995). Moreover, they suggested that the mirror neuron system provides evidence that modern language abilities arose from a more primitive gestural communication system mediated by F5 in primates. One piece of evidence that is often offered for this claim is human beings’ ubiquitous use of gestures while speaking (Rizzolatti & Arbib, 1998).

Since the initial work by Rizzolatti and colleagues, there have been numerous imaging studies of the mirror neuron system that are designed to explore the role in human behavior, particularly speech and language (e.g., Binkofski & Buccino, 2004; see Nishitani, Schürmann, Amunts, & Hari, 2005, for a review). However, contrary to the claims of mirror neuron mechanism supporters, some investigators have argued that Broca’s area is not crucial for imitation (Makuuchi, 2005). Moreover, Schütz-Bosbach, Mancini, Aglioti, and Haggard (2006) noted that an important aspect of the putative mirror neuron mechanism is its implication that humans (and other primates) represent their own actions in the same way that they represent the actions of others. However, their study suggested that this is not the case. Finally, the suggestion that the mirror neuron system is important for human speech and language discounts the fact that much of speech articulation is hidden in the mouth and invisible to the listener, and that individuals who are congenitally blind acquire speech and language with little difficulty. Binkofsky and Buccino (2004) suggested that, rather than being specific to speech and language functions, posterior BA 44 is “a high level sensorimotor interface integrating sensory stimuli and cognitive tasks with the related motor representation of hand- and face-related actions” (p. 366). If there is a mirror neuron system that is critical for speech and language, it is more likely to be an auditory mirror neuron system, something that will be discussed below.

As mentioned above, it has been suggested that the IFG plays a role in syntax, semantics, phonology, and articulation. In some studies, these functions have been localized to particular subdivisions of the IFG, while in others, investigators have reported activation simply in Broca’s area of the IFG. For example, Friederici (2002) proposed a neurocognitive model of auditory sentence processing in which specific areas of the IFG play particular roles in auditory comprehension. According to the model, the superior-posterior region of BA 44 is involved in phonologic memory, and the superior-anterior and inferior BA 44 are involved in memory of syntactic structure, while BA 45/47 and BA 44/45

work to assign thematic structure based on semantic and morphosyntactic features. Burton, Small, and Blumstein (2000) observed activation in the left IFG when subjects had to separate an initial consonant from a consonant-vowel-consonant (CVC) word stimulus; however, they did not localize the activation to a specific region with the IFG.

The IFG has also been shown to play a role in speech articulation. Based on a meta-analysis of functional imaging studies of speech and language, Indefrey and Levelt (2004) argued that the posterior IFG is involved in syllabification, or the process of clustering segments into syllables. Levelt has also suggested that this area houses a repository of the motor patterns for all of the syllables that a speaker knows, or what he calls the “mental syllabary” (Levelt, 2001). Guenther and colleagues (Bohland & Guenther, 2006; Guenther, Ghosh, & Tourville, 2006) proposed the DIVA (Directions Into Velocities of Articulators) model of speech acquisition and production. In the model’s most recent incarnation, each cell in its speech sound map is hypothesized to correspond to neurons in the left PMv and/or posterior Broca’s area (Guenther et al., 2006). The cells in the speech map represent different speech sounds. According to Guenther and colleagues, PMv was chosen for the location of the speech sound map cells because of the cells’ functional correspondence with mirror neurons. Moreover, Guenther and colleagues have proposed that the speech sound map cells form the mental syllabary of Levelt.

Lesions to the IFG can produce apraxia of speech (Duffy, 2005; Hillis, Work, Barker, Jacobs, Breese, & Maurer, 2004; Mohr et al., 1978). They can also produce aphasia; however, it is the case that lesions that produce persistent aphasia usually involve a large region of the IFG and often encompass the underlying white matter, insula, and basal ganglia (Alexander, Naeser, & Palumbo, 1990; Naeser & Hayward, 1978).

Parietal Lobe

The anterior parietal lobe contains the primary somatosensory cortex, BA 1, 2, 3a, and 3b, or S1. BA 1 lies in the crown of the central sulcus, while BA 3a and 3b lie in the fundus and the rostral bank, respectively. BA 2 lies in the caudal bank of the postcentral gyrus (Geyer, Schleicher, & Zilles, 1999). Studies that have investigated the cytoarchitecture of human S1 have shown that, while there is similarity regarding the location of these areas across brains, there is inter-subject variability in their extent (Geyer, Schormann, Mohlberg, & Zilles, 2000). Like M1, S1 is organized somatotopically. The subdivisions of S1 generally respond to different stimuli. BA 1 and 3b neurons respond to cutaneous stimulation, while BA 3a neurons respond to proprioceptive stimulation, and BA 2 responds to both tactile and proprioceptive stimulation (Purves et al., 2001). S1 receives direct input from the thalamus. It projects to more posterior areas in the parietal lobe. In a recent study in monkeys, Simonyan and Jürgens (2005) found that all four subdivisions of S1

projected to the larynx representation in M1. Electrical stimulation to S1 in humans usually produces a tingling or numbness sensation in the representative body part on the contralateral side, rather than the kinds of feeling natural stimuli produce (Nolte, 1993).

There is a secondary somatosensory area (S2) in the parietal operculum, including BA 43 and a small portion of BA 40. S2 is also somatotopically organized (Eickhoff, Amunts, Mohlberg, & Zilles, 2006; Eickhoff, Schleicher, Zilles, & Amunts, 2006). This region has been shown to be responsive to light touch, pain perception, and visceral sensation.

The area of the parietal lobe posterior to the postcentral gyrus is divided into two regions: the superior parietal lobule and the inferior parietal lobule (IPL). The boundary between these areas is the intraparietal sulcus (IPS). The IPL is further subdivided into the supramarginal gyrus (BA 40) and the angular gyrus (BA 39). These areas are connected with the pulvinar and the lateral posterior nuclei of the thalamus (Nolte, 1993). Catani, Jones, and ffytche (2006) used DTI to study the white-matter connections of perisylvian language areas. They discovered a previously undescribed indirect pathway passing through the inferior parietal cortex parallel to the arcuate fasciculus. There was an anterior segment that connected IPL to “Broca’s territory” and a posterior segment that connected IPL to “Wernicke’s territory.” In another recent study using DTI, Rushworth, Behrens, and Johansen-Berg (2006) found that BA 40 and the IPS were connected to the PMv via the arcuate fasciculus, while posterior BA 39 was connected with the parahippocampal gyrus.

Since the seminal work of Liepmann (1913), limb apraxias have been attributed to lesions of the left IPL. Liepmann proposed that space–time plans underlie the performance of skilled movement and that apraxias are a disruption of these plans (Assmus, Marshall, Ritzl, Noth, Zilles, & Fink, 2003). Neuroimaging studies in humans have supported this notion. The right parietal cortex also appears to play a role in these plans. It is involved in processing spatial aspects of movement, while the IPL is involved in processing temporal aspects, such as rhythm (Assmus et al., 2003; Schubotz & von Cramon, 2003). Rushworth, Johansen-Berg, Göbel, and Develin (2003) suggested that the role of the IPL is in motor attention, which they describe as movement preparation or redirection. Assmus and colleagues (2003) proposed that the IPL is involved not only in the computation and storage of space–time plans, but also in processing aspects of movements, so that the plans can, if necessary, be modified.

In the literature on vision, multiple, parallel neural pathways have been identified for processing visual objects. These include a “what” pathway (for identifying an object) and a “where” pathway (for identifying the location of an object in space). Similar pathways have been proposed for speech and language (Guenther et al., 2006; Hickok & Poeppel, 2004; Poeppel & Hickok, 2004; Scott & Wise, 2004). These investigators have suggested that there is an auditory “how” pathway that involves the IPL, in particular the temporoparietal junction.

The role of this pathway (which projects to frontal-lobe regions) is to map “speech sounds on to motor representations of articulation” (Scott & Wise, 2004, p. 15). This pathway would be particularly important for behaviors such as imitation. In the DIVA model (Guenther et al., 2006) a component of the model, the somatosensory error map, lies within the IPL. The role of this component is to compare speech-motor and somatosensory information for the purposes of speech learning and feedback-based motor control.

Kimura and Watson (1989) suggested that the left parietal cortex is involved in selecting movements for movement sequences. In a recent study using fMRI, Shuster and Lemieux (2005) found greater activation in the left parietal cortex when subjects produced longer words (something individuals with AOS putatively have more difficulty with), as compared to when they produced shorter words. Bohland and Guenther (2006) found activation in posterior parietal regions when subjects produced more complex syllable sequences, as opposed to simpler sequences. Longer words and more complex syllable sequences would require more sequencing, so the data from these studies are compatible with Kimura and Watson’s view. Like limb apraxias, speech apraxias have been attributed to parietal-lobe lesions (Buckingham, 1979; Duffy, 2005; Kimura & Watson, 1989; Square, Roy, & Martin, 1997; Square-Storer & Apeldoorn, 1991).

Insula

The insula lies hidden beneath the frontal, temporal, and parietal opercula. In Brodmann’s map, it is areas 13 to 16 (Augustine, 1996; Dupont, Bouilleret, Hasboun, Semah, & Baulac, 2003). In monkeys, the insula is divided into three cytoarchitectonic areas. The cytoarchitectonic regions are related to different functions, including olfactory, gustatory, somatosensory, auditory, and visual functions. The insula projects to the cerebral cortex (including the SMA, pre-SMA, S2, and the anterior cingulate gyrus), the basal ganglia, and limbic areas (Augustine, 1996). It receives inputs from a variety of areas, including S1, the superior temporal sulcus, the basal ganglia, and the thalamus.

The insula has been implicated in language function for many years (e.g., Freud, 1891). Functional imaging studies of speech have confirmed this. In an fMRI study of the overt and covert (silent) repetition of mono- and multisyllabic words, Shuster and Lemieux (2005) found that there was greater activation in the left insula during overt production than during covert production. In a study of bilingual individuals, Chee, Soon, Lee, and Pallier (2004) found that the left insula appeared to be involved in phonologic working memory, and that better phonologic working memory correlated with better second-language development.

Although lesions to the left insula were thought to produce AOS (Dronkers, Redfern, & Shapiro, 1993), the insula received considerably more attention in this regard after the publication of a study by Dronkers in 1996. In this study, she

found that 25 patients who had been diagnosed with AOS all had lesions encompassing the left anterior insular cortex, while 19 patients who had been diagnosed with aphasia, but not AOS, did not have left insula lesions. This paper has had a significant influence on many investigators' views of AOS and of normal speech production, both because of the double dissociation that she observed, and also because some investigators believe that lesion studies, unlike neuroimaging investigations, reveal brain areas that are *necessary* for the normal performance of a behavior, rather than the areas that are involved in the performance of a behavior but might not be *critical* for that behavior (although cf. Hillis et al., 2004; Marshall & Fink, 2003).

Superior Temporal Gyrus

The superior temporal gyrus (STG) is the location of the primary auditory cortex (A1), as well as Wernicke's area (in the posterior left STG), which has long been associated with the comprehension of spoken language (Wernicke, 1874, 1885). In Brodmann's map, A1 is BA 41 and Wernicke's area is posterior BA 22. The STG is connected to the frontal lobe via the arcuate, uncinate, and inferior occipitofrontal fasciculi, the parietal lobe via the arcuate fasciculus, and the occipital lobe via the inferior occipitofrontal fasciculus (Nolte, 1993). Functional imaging data are changing our view that the STG is only involved in speech reception (Wise, Scott, Blank, Mummery, Murphy, & Warburton, 2001). Wise and colleagues performed a re-analysis of four previous PET studies. They found that the most posterior part of the STG was active during speech production, rather than speech perception. They found that the posterior left superior temporal sulcus was active when subjects listened to the speech of others and during recall of lists of words during verbal fluency tasks. These data suggest that left STG, like the left IFG, is involved in a variety of different receptive and expressive speech and language behaviors.

We have not explicitly described the role of the right cerebral hemisphere (RH) in speech and language behavior. This is not because the RH does not make an important contribution to normal communicative function (Hickok & Poeppel, 2004; Pell, 2006). Such a discussion is simply beyond the scope of this chapter.

Summary and Implications for a Model of Motor-Speech Disorders Accompanying Aphasia

In summary, our views of the role of different brain regions in speech production is changing. Broca's area is not limited to speech production, and Wernicke's area is not limited to speech perception. Moreover, nearly every one of the brain regions that we reviewed has been shown to be involved in speech, language, and cognitive-linguistic functions. This is probably why it has been so difficult to find individuals who

demonstrate a pure AOS. It also may be why there has not been universal agreement on the characteristics and labels for the speech disorders that accompany aphasia. Moreover, rather than a strict separation, as some have argued, evidence suggests that the processes of speech production and speech perception are tightly coupled. Studies are finding that there is a great deal of intersubject variability in the size and location of different brain regions, and the functional consequences of these anatomical differences require further exploration.

Developing a model of motor-speech disorders presents some difficulties. As mentioned above, the brain regions involved in speech and language are multifunctional. Data from functional neuroimaging studies can be used to develop such a model, but while these data tell us which areas are involved in a behavior, they do not tell us which areas are critical for the normal performance of that behavior. One way to overcome this problem is to combine imaging technologies (e.g., fMRI and TMS), something that is occurring more and more frequently. An exciting development that will also help are new data-analysis methods, which provide information regarding the temporal characteristics of the activation patterns found with technologies such as fMRI.

The use of lesion studies to develop a model also poses problems. The assumption underlying lesion studies—that if a lesion to a particular area disrupts a function, that area must be responsible for that function—may be erroneous. As Hillis and colleagues (2004) noted, these studies typically assess the probability that a patient with a particular deficit has a lesion in a certain area, rather than assessing how many patients with a lesion to that area demonstrate that particular deficit. The consequence of this is, for example, that “. . . it is possible that all patients with apraxia of speech have insular damage, but that few patients with insular damage have apraxia of speech” (p. 1480).

Despite the difficulties described above, we can make an attempt to develop such a model. A lesion that encompasses the IFG may result in speech sound-substitution errors. These could result from problems such as the incorrect selection of syllables from the mental syllabary, or a disruption of phonologic processes. A lesion to this region might also result in difficulties with producing longer words, which would require greater syllabification. A lesion that encompasses face areas of M1 may result in speech that has a paretic quality. A lesion encompassing the left IPL may result in distortion errors, due to an impairment of motor sequencing, or to an inability to determine how well the somatosensory feedback matches the intended movement. These distortion errors could be perceived as substitution errors at times, due to what Buckingham and Yule (1987) have called “phonemic false evaluation,” or an inability to detect subphonemic features (see Shuster & Wambaugh, 2000 for a further discussion of this issue). This could also result in greater difficulties in producing longer words, since they require more motor planning/programming and sequencing.

DISORDERS OF MOTOR-SPEECH PRODUCTION ACCOMPANYING APHASIA: DEFINING FEATURES

A focal lesion in the language-dominant hemisphere that results in aphasia may also result in a neuromotor speech disorder (or disorders). The neuromotor speech disorders most likely to be associated with such a lesion are apraxia of speech (AOS) and unilateral upper motor neuron dysarthria (UUMN dysarthria; Duffy, 2005).

We consider the speech production errors observed in AOS and UUMN dysarthria to be nonaphasic in nature. Square and colleagues (2001) provided a discussion of “speech errors in aphasia” and noted that a significant amount of research has been dedicated to determining whether speech errors in aphasia are motoric (phonetic) or linguistic (phonologic) in nature. As summarized by Square and others (Blumstein, 2001; Kurowski, Hazen, & Blumstein, 2003), persons with “anterior” aphasia tend to evidence phonetic-level disruptions realized as errors in various aspects of articulation. Although sound errors in “posterior” aphasia are generally considered to be phonologic in nature and phonetically intact, some subtle temporal speech differences have been reported (see Square et al., 2001, for a review).

It is not the purpose of this chapter to engage in a discussion of the nosology of speech errors associated with aphasia. Whereas some authors consider phonetic-level disruptions to be symptoms of aphasia (Blumstein, 2001; Kurowski et al., 2003), we believe phonetic-level errors such as sound distortions and slow rate of production are necessarily motoric disturbances and, even when observed in persons with aphasia, are most likely the result of neuromotor speech disorders. Descriptions of the defining characteristics and symptoms of AOS and UUMN dysarthria are provided in the following sections.

Apraxia of Speech

The speech behaviors considered to define AOS have undergone considerable revision since Darley and colleagues’ early description of the disorder (Darley et al., 1975). We agree with Croot (2002) that our current understanding of AOS is a “work in progress” (p. 268), which includes our knowledge of the symptoms that define the disorder. We ascribe to the diagnostic criteria advanced by McNeil, Robin, and Schmidt (1997) and elaborated by Wambaugh, Duffy, McNeil, Robin, and Rogers (2006a). These criteria reflect a carefully considered synthesis of classic and current perceptual, acoustic, and physiologic evidence concerning behaviors observed in individuals with AOS. As described by McNeil and colleagues (1997), the speech characteristics considered to be necessary for a diagnosis of AOS include slow speech rate (lengthened segments and intersegment durations), sound distortions, distorted sound substitutions, sound errors that are relatively

consistent in type and location on repeated productions, and prosodic abnormalities. Symptoms that are consistent with a diagnosis of AOS, but do not allow a differential diagnosis in and of themselves include articulatory groping, perseverations, speech-initiation problems, awareness of errors, repeated attempts, and increasing errors with increasing length or complexity of utterances. Behaviors that are more likely attributable to a language disruption than to AOS would include transposition and anticipatory errors. Behaviors such as normal prosody or consistently normal or fast rate of speech production would contraindicate a diagnosis of AOS.

UUMN Dysarthria

Our understanding of the clinical characteristics and pathophysiology of UUMN dysarthria is also a work in progress. The reader is referred to Duffy (2005) for a concise summary of the speech characteristics observed in UUMN which reflects findings from Duffy and Folger’s (1996) retrospective study supplemented by additional confirmatory reports. As reported by Duffy (2005), the most frequently occurring speech deficit observed in UUMN dysarthria has been a disruption of articulation, primarily in the form of imprecise consonants. Disturbances in speech alternate-motion rates (AMRs) were the second most commonly occurring speech disorder seen in UUMN dysarthria, with slow rate reported most often (note: imprecise and irregular AMRs were each reported in approximately one-third of Duffy and Folger’s cases). Disorders of phonation were also reported in a relatively high percentage of cases, with harshness being the most frequently reported symptom. Mildly slowed rate and mild hypernasality and/or nasal emission were noted in 18% and 14% of cases, respectively (Duffy, 2005).

MANAGEMENT OF NEUROMOTOR SPEECH DISORDERS ACCOMPANYING APHASIA

As discussed in the previous section, AOS and UUMN dysarthria are the neuromotor speech disorders most likely to accompany aphasia. Although other dysarthrias may co-exist with aphasia, in most cases additional neurologic conditions beyond that which resulted in aphasia would probably be present.

In the remainder of this chapter, we will focus on the treatment of AOS rather than the dysarthrias. Our decision to limit discussion of the management of the dysarthrias was made for several reasons. First of all, UUMN dysarthria may often be mild and relatively transient in terms of clinical presentation (Duffy, 2005). In addition, Duffy notes that “when UUMN dysarthria is the primary communication deficit, aphasia, apraxia of speech, and nonaphasic communication deficits are frequently not present” (p. 260). Furthermore, published investigations of treatment for UUMN dysarthria are not currently available.

To reiterate, other types of dysarthria may be present with aphasia, but rarely will be the result of the same neurologic event that caused the aphasia. Treatment for the dysarthrias is a complex subject; a superficial review of the topic would be of little use to the reader, and a thorough consideration of the topic is beyond the scope of this chapter. The reader is directed to recent publications concerning the management of dysarthria and is encouraged to take note of the treatment guidelines provided by the Academy of Neurologic Communication Disorders and Sciences (ANCDS; www.ancds.org) (Duffy, 2005; Duffy & Yorkston, 2003; Hanson & Yorkston, 2004; Spencer, Yorkston, & Duffy, 2003; Yorkston, Hakel, Beukelman, & Fager, 2006; Yorkston et al., 2001; Yorkston et al., 2003).

Considerations in the Treatment of AOS

The development, testing, and reporting of treatments for AOS began in 1973 with Rosenbek, Lemme, Ahern, Harris, and Wertz's influential report of the effects of their eight-step task continuum. Since that time, considerable progress has been made and a substantial body of literature now exists documenting the benefits of AOS treatments. The Academy of Neurologic Communication Disorders and Sciences (ANCDS) Writing Committee of Treatment Guidelines for AOS recently reviewed and evaluated the existing evidence base for AOS treatments and concluded that "taken as a whole, the AOS treatment literature indicates that individuals with AOS may be expected to make improvements in speech pro-

duction as a result of treatment, even when AOS is chronic" (Wambaugh, Duffy, McNeil, Robin, & Rogers, 2006b, p. lxiii).

Despite advances in understanding the effects of various AOS treatments, a technology of AOS treatment, per se, does not exist. Limited data are available to guide the clinician in the selection of a specific treatment for a specific patient. Outcome prediction is extremely limited for most AOS approaches, particularly with respect to functional outcomes. We will provide a summary of the available AOS treatment approaches along with considerations for selecting appropriate treatments and documenting treatment effects. As noted by Wambaugh and colleagues (2006b), the treatment of individuals with AOS requires integration of objective evidence, knowledge gained through clinical experience, theoretical rationale, and consideration of patient requirements and wishes.

In the previous edition of this text, Square and colleagues noted that recommendations for selection of treatment interventions for AOS had historically been based upon AOS severity (see Table 36-1; Square et al., 2001). They questioned the appropriateness of such an approach and instead, proposed that the presumed underlying pathophysiologies should guide treatment selection. Specifically, Square and colleagues suggested that three types of deficits related directly to three types of interventions: (1) postural shaping; (2) production of functional units (coordinative structures); and (3) rhythm and pacing. Accordingly, as seen in Table 36-1, they specified levels of intervention at which various treatment techniques were considered to operate.

TABLE 36-1

Traditional Approaches for Patients with Apraxia of Speech of Different Degrees of Severity with Speculated Level of Intervention

Severity Level	Recommended Approaches	Level of Intervention
Severe	Segmental/syllabic level imitation with • Imitation • Phonetic placement • Phonetic derivation • Derivation plus placement • Key-word technique	Postural shaping (spatial targeting) and/or production of functional units of speech (coordinative structures)
	Imitation of contrasts Contrastive stress drills	Rate and melodic flow
Moderate	Intersystemic facilitators • Tapping foot • Tapping leg • Finger counting • Finger tapping	Rate and melodic flow
	Intrasystemic facilitators Pacing board	
Mild	Expanded contrastive stress drills	Rate and melodic flow

(From Square, P. A., .)

We would argue that the choice of a treatment approach should take into consideration both the theorized pathophysiology and the level of severity. For example, an individual with AOS may present with difficulties in transitioning between sounds/syllables only in the context of multisyllabic words containing consonant clusters. Another individual may evidence difficulty in transitioning between sounds in monosyllabic words. Although both individuals demonstrate difficulties in coordination of movements, the level of disruption in terms of severity obviously differs and so should the treatment approach. A disruption of coordinated production at the syllabic level would likely require significant direction from the clinician and necessitate techniques such as phonetic placement, modeling, and practice with integral stimulation. A disruption of coordinated production at the multisyllabic level may require minimal clinician instruction and may benefit from reducing the rate of production.

The reader may have noted a “mismatch” in suggested technique and presumed pathophysiology for the less severe patient in the preceding paragraph. That is, a rate and melodic flow technique (i.e., rate control) was suggested for a problem of coordination. This suggestion was made to illustrate the point that at present, the impact of most treatments for AOS on the underlying speech disruption is not well understood. Rate and melodic flow treatments (to be termed “rate/rhythm treatments” in subsequent discussions) have been shown to improve articulation (i.e., spatial targeting and/or production of functional units of speech) (Wambaugh & Martinez, 2000). It is not unlikely that articulation-oriented treatments will eventually be shown to have a positive influence on rate and melodic flow. For example, Croot, van Heyst, Deacon, and Law (2006) provided preliminary findings suggesting that an articulatory-kinematic treatment was associated with a reduction in multiple attempts in a speaker with AOS. Therefore, the reader should recognize that presently it is not possible to establish empirically a clear correspondence between pathophysiology and purported level of intervention for a given AOS treatment. Until treatment outcomes are demonstrated across a range of behaviors for a specific AOS treatment, the clinician should understand the theoretical mechanisms by which a treatment operates (i.e., treatment rationale) and determine whether those mechanisms are compatible with the patient’s pathophysiology. The AOS Treatment Guidelines Technical Report: Evidence Table (ANCDs, 2006) is a comprehensive resource for reviewing the rationales for the AOS treatments included in the development of the guidelines.

The selection of a treatment should entail more than a determination of severity and probable pathophysiology. A thorough assessment should not only assist in making the preceding determinations, but should also lead to the identification of appropriate treatment targets, outcome measures, and viable treatment techniques. As noted by Square and colleagues (2001), neuromotor speech disorders associated with

aphasia are not homogeneous. Consequently, assessment and treatment should be tailored to the individual.

Assessment for Treatment Planning

Errors in sound production are a defining feature of AOS and articulatory precision is often the focus of AOS treatments (Wambaugh et al., 2006a). As such, the clinician should have thorough knowledge of the patient’s strengths and weaknesses in terms of sound production. In our experience, only rarely in cases of severe AOS or extremely mild AOS are all sounds produced with equal difficulty or ease. It is strongly suggested that an inventory of sound production be conducted, with multiple exemplars of all sounds elicited at levels that are appropriate for the patient. The level at which sound production becomes problematic for the individual should be apparent from initial contacts and assessments. For example, some patients may produce few sound errors with individual mono- and bi-syllabic words, but produce increasing numbers of errors with three- or four-syllable words or with phrases containing mono- and bi-syllabic words. To be able to structure therapy to include opportunities for success as well as for challenges, the clinician should have data available for production contexts that are easy for the patient as well as for those that are difficult. An example of items used to elicit production of most consonants in the initial and final syllables of monosyllabic words is shown in Appendix 36.1. A useful Internet resource for selecting words on the basis of factors such as phonemes, syllable structure, length, stress patterns, word type, and word frequency is the MRC Psycholinguistic Database (2006). Phoneme frequency may also be of interest in assessing and selecting sounds for treatment, and the reader is referred to Mines, Hanson, and Shoup (1978). An example of multisyllabic words that were selected to be balanced in terms of syllable shape and phoneme type and position, and that reflect a range of phoneme frequency, is provided by Mauszycki (2006) (Appendix 36.2).

The way in which items are presented to elicit productions can affect performance (Wambaugh, Nessler, Bennett, Mauszycki, 2004). Therefore, consideration should be given to the structuring of the stimuli used in elicitation of sound productions. Randomized presentations, wherein exemplars of target sounds are not presented sequentially, are likely to be more challenging than blocked presentations, in which all exemplars of a sound are presented in order.

Productions may be elicited through various modes, such as immediate repetition, delayed repetition, oral reading, sentence completion, confrontation naming, and discourse. Because most individuals with AOS will also have aphasia, elicitation modes may be constrained by language factors such as limited reading ability and significant word-retrieval deficits. Unfortunately, there are no data indicating how well different elicitation modes approximate spontaneous productions in AOS. Intuitively, it would seem that modes that are highly constrained and have maximal clinician input, such as repetition and modeling, may not be the most

desirable. However, this notion may not be correct, and the patient's language disturbances may necessitate constrained elicitation conditions. Although analysis of sound production in discourse may have appeal in terms of ecologic validity, reliable methods for eliciting adequate numbers of productions of significant sounds have not yet been developed.

Examples of sentence-completion items used to elicit words containing specific sounds of interest are provided in Appendix 36.3. Sentence-completion elicitation does not entail provision of a clinician model, which may serve to make it a more valid indicator of the patient's true production abilities. Difficulties in word retrieval may be minimized if sentences are constructed for maximal cueing (i.e., if sentences are heavily semantically loaded). However, it may be difficult to construct sentences that are appropriate for less frequently occurring words, and such words may be necessary when targeting sound production at a multisyllabic level of production. Furthermore, word-retrieval problems may be severe enough to prohibit sentence completion. Utilizing sentence completion in a delayed-repetition format may allow the clinician to work around the preceding problems. That is, by providing the desired response prior to the sentence-completion request, it is more likely that the factors of low frequency of occurrence and word-retrieval deficits will not prohibit production of the desired word. To use this elicitation mode, the clinician first provides an explanation of the task, then models the desired response, and finally provides the incomplete sentence for the patient to complete. Several practice trials may be necessary to establish the correct pattern of responding.

Example 1

Clinician: "I'm going to say a sentence and I'd like you to focus on the word at the end of the sentence. I'm going to repeat the sentence leaving off the last word. I would like you to finish the sentence for me, using that word."

Clinician: "My dog is very sick, so I'm going to take him to the VET. Now you finish the sentence for me. My dog is very sick, so I'm going to take him to the _____."

Example 2

Clinician: "I'm going to say a sentence and ask you to finish it for me. But first, I'll say the whole sentence so you know what to say when it's your turn."

Clinician: "To get the news, I like to read a newspaper or a MAGAZINE. Now you finish the sentence that I'm going to start. To get the news, I like to read a newspaper or a _____."

After obtaining adequate samples of sound production at appropriate levels of complexity, performance should be summarized by sound, sound class, word position, complexity level, and patterns of errors. Any error patterns are likely to be unique to the individual; consequently, error analysis should be individualized.

Beyond sound production, AOS treatments may also target and/or impact durational aspects of speech (Wambaugh et al., 2006a). The clinician may wish to measure various durations that may be germane to treatment. For example, rate of speech in syllables per second may be of interest. Whole-word durations as well as relative durations of syllables within words may be useful measures for planning and measuring the effects of rate/rhythm control treatments. Durational measures of individual sound segments and interword intervals may reveal information pertinent to treatment. The preceding types of measures are easily conducted using relatively inexpensive speech-analysis software (e.g., Multi-Speech™, Model 3700 [Kayelemetrics, 2006]).

Other behaviors that are frequently observed with AOS, such as false starts, silent or audible groping, filled or silent pauses, starters, and motor perseverations may serve as treatment targets and/or outcomes. Difficulty with speech production may affect an individual's willingness to initiate speech. As such, quantification of speech initiations may also be considered for inclusion during assessment. Reliable measurement contexts and procedures have not been developed for the preceding behaviors associated with AOS. However, as noted by Wambaugh, "the current unavailability of such measures should not prohibit . . . (one) . . . from attempting to estimate the effects of treatment at such levels; however, caveats regarding reliability should be provided when interpreting findings" (Wambaugh, 2006, pp. 320–321).

Measures of intelligibility and comprehensibility should always be considered for inclusion in pretreatment assessment. Tests designed to assess intelligibility in dysarthria, such as the Word Intelligibility Test (Kent, Weismer, Kent, & Rosenbek, 1989) and the Assessment of Intelligibility of Dysarthric Speech (Yorkston & Beukelman, 1989) are appropriate for assessing intelligibility in AOS. Qualitative ratings, such as those described by Duffy (2005) are also appropriate, as are ratings of comprehensibility (Duffy, 2005).

Variability in speech production across different sampling occasions may or may not affect assessment for treatment planning. The extent to which productions vary from day to day is likely to be a factor that differs for each individual with AOS. To ensure that appropriate treatment goals and stimuli are selected, the clinician may wish to conduct repeated measures of sound production. Of course, upon selection of treatment targets and outcome measures, the clinician would be well advised to establish a baseline of performance that can be used to estimate the effects of treatment. This would necessitate repeated measurement of the outcomes of interest prior to the initiation of treatment.

As noted in the AOS treatment guidelines report (Wambaugh et al., 2006a), there are virtually no data to guide the clinician in the selection of one treatment approach over another. We, like other authors (Square et al., 2001; Wertz et al., 1984) advocate a period of trial therapy to assist in selecting a treatment approach.

Therapeutic Approaches for the Treatment of AOS

The extant AOS treatment literature provides examples of many different treatment techniques. The AOS Treatment Guidelines Committee reported that existing AOS treatments generally fell into one of the following categories of general approaches: (1) articulatory-kinematic treatments, (2) rate/rhythm control treatments, (3) intersystemic facilitation/reorganization treatments, and (4) alternative augmentative communication (AAC) approaches (Wambaugh et al., 2006a).

The AOS guidelines report provided effectiveness determinations for each of the preceding treatment categories on the basis of the quality of the evidence available through December, 2003. The AOS committee concluded that “articulatory kinematic approaches were determined to be ‘probably effective’; rate/rhythm control approaches and intersystemic approaches were considered to be ‘possibly effective’; and AAC approaches could not be rated in terms of likelihood of benefit” (Wambaugh et al., 2006b; p. lxii). The report also provided recommendations concerning the clinical utilization of the different AOS approaches. The strength of the recommendation is an important component of the recommendation. Effectiveness determinations coincide with recommendation strength in that the extent and quality of the evidence supporting treatment approaches serves as the basis for the designation of both.

The AOS guidelines report used the recommendation scheme employed by the American Academy of Pediatrics (Marcuse et al., 2004) with potential recommendations being *strong recommendations*, *recommendations*, *options*, and *no recommendation*. Recommendation-strength designations are intended as translational aids for clinicians (Marcuse et al., 2004). That is, the strength of the recommendation serves as a guide for the clinician in terms of importance of adherence to the recommendation. A strong recommendation reflects the guidelines committee’s belief that the evidence supporting a treatment approach is of high quality. Strong recommendations should be followed unless there are strong contraindications for a particular patient. None of the AOS treatment approaches had enough empirical support to warrant a strong recommendation.

Recommendations are assigned when the committee considers the evidence to be less strong, but still substantial, and benefits clearly exceed risks (Marcuse et al., 2004). Clinicians should typically follow recommendations, but should consider patient preferences and be alert to new evidence concerning the approach. Articulatory-kinematic approaches were recommended for use “with individuals with moderate

to severe AOS who demonstrate disrupted communication due to disturbances in the spatial and temporal aspects of speech production” (Wambaugh et al., 2006b; p. lxii).

Options are used as the designation for treatments when the evidence base is relatively weak or when benefits do not clearly outweigh risks (Marcuse et al., 2004). Clinicians should be aware of such treatments as having potential utility, but clinician judgment and patient preference should play important roles in selecting treatment. Clinicians should be watchful for new evidence relevant to the treatment option. AOS rate/rhythm control approaches, intersystemic treatments, and AAC approaches were designated as treatment options in the AOS guidelines report.

The following sections describe treatment techniques for AOS that have been reported in the literature. The general treatment approaches identified in the AOS treatment guidelines will be used as the organizing framework (Wambaugh et al., 2006a). The presumed mechanisms for treatment effects will be discussed for each general approach so that the reader may relate the information to presumed pathophysiology. Treatment targets and candidacy issues will also be discussed so that the issue of severity may be taken into account.

Articulatory-Kinematic Approaches

Approximately half of the treatment investigations that were included as the evidence base for the AOS treatment guidelines report were characterized as articulatory-kinematic in nature (Wambaugh et al., 2006a). That is, articulatory-kinematic treatments “were those in which the therapy techniques were used to facilitate improved movement and/or positioning of the articulators in an attempt to promote better speech production” (Wambaugh et al., 2006a; p. xix). The terminology utilized in Square and colleagues’ (2001) previous version of this chapter to describe the foci of these types of techniques in terms of presumed pathophysiology was “enhancing postural shaping and re-establishing functional units of speech” (p. 864).

Numerous techniques have been used to promote improved spatial or temporal aspects of speech production. Many of the articulatory-kinematic techniques have been extensively written about in the speech literature since the 1930s (Van Riper, 1939). Explanations of these facilitative techniques used with AOS and aphasia are presented in detail by Wertz and colleagues (1984) and Square-Storer (1989).

An underlying theme crossing virtually all articulatory-kinematic approaches is that repeated, motoric practice of speech targets is a necessary component of treatment. Furthermore, most of the articulatory-kinematic treatment approaches included in the AOS guidelines utilized modeling/repetition to elicit desired productions. A potentially powerful variant of modeling/repetition, originally described by Rosenbek, Lemme, Ahern, Harris, and Wertz (1973), which has been incorporated into several treatment hierarchies, is integral stimulation, in which the patient is instructed to

“watch me, listen to me, and say it with me” (Deal & Florance, 1978; Florance & Deal, 1977; LaPointe, 1984; Rosenbek et al., 1973; Wambaugh, Kalinyak-Fliszar, West, & Doyle, 1998a; Wambaugh, Martinez, McNeil, & Rogers, 1999; Wambaugh, West, & Doyle, 1998b; Wertz et al., 1984). Integral stimulation attempts to bring to a conscious level of awareness the “look” and “sound” of the movement pattern, while combining this awareness with simultaneous practice.

Other techniques used to stimulate awareness of articulatory postures and movements are phonetic placement and phonetic derivation. Phonetic-placement techniques involve the use of descriptions of where (place) and how (manner, voice) sounds are made, with descriptions provided as verbal explanations, with or without visual modeling (Wambaugh et al., 1998a, 1998b, 1999), drawings (Raymer, Haley, & Kendall, 2002), videotaped models (Aten, 1986), and/or manipulation of the orofacial musculature by the clinician (Square et al., 2001). Phonetic derivation and shaping techniques (Wertz et al., 1984; Knock, Ballard, Robin, & Schmidt, 2000) are those that build upon an articulatory or orofacial skill already in the patient’s repertoire. That is, instructions or models are provided regarding how to modify existing productions to obtain different or improved productions. For instance, if the patient can produce nonspeech lip popping, this action may serve as the basis for providing both place and manner of production for /p/ and /b/. Or, using speech, a patient may be able to produce /s/ but not /ʃ/; /ʃ/ may be derived from /s/ by having the patient slowly draw his or her tongue posteriorly along the palate.

The key-word technique is related to phonetic derivation. In this approach, a word that the patient can produce acceptably and that contains the target sound being worked upon is produced by the patient while the clinician calls to his or her attention the feel (tactile and kinesthetic) of the sound. For instance, if the goal is volitional control over the production of /s/, and the patient can produce her husband’s name, ‘Sam,’ the name would be used to enhance the feel of /s/ so that this movement can be produced volitionally in other words.

Another method of improving speech production in AOS is to provide “enhanced sensory feedback through the pairing of dynamic tactile-kinesthetic input with auditory and visual stimulation” (Square et al., 2001; p. 866). Prompts for Restructuring Oral and Muscular Phonetic Targets (PROMPT; Chumpelik, 1984; Hayden, 1999; Square et al., 2001) is a highly developed system for providing instruction for articulatory movements and speech production in the treatment of AOS. PROMPT utilizes combinations of auditory, visual, tactile, and kinesthetic cues that are “dynamic in nature and are designed to provide sensory input regarding the place of articulatory contact, extent of mandibular opening, presence and manner of articulation, and/or coarticulation” (Bose, Square, Schlosser, & van Lieshout, 2001; p. 769). PROMPT is described more thoroughly in Square et al. (2001) and is discussed further in the subsequent section “Formalized Treatment Programs with Supporting Evidence.”

Enhanced feedback and cueing in the form of visual displays of tongue-to-palate contacts are treatment techniques made available through electropalatography (EPG). With EPG, the patient (and usually the clinician as well) wears a pseudopalate embedded with electrodes that detect contact of the tongue. A pseudopalate is custom-made from an impression of the individual’s hard palate (typically obtained through a dental service) and bears similarities to the palatal portion of a dental retainer. Electrodes embedded in the plastic pseudopalate feed information about tongue contact to computer-based software. Thus, a computerized, visual display is provided in real time, depicting tongue-to-palate contacts. The clinician may provide visual and acoustic models for the patient, who then receives visual feedback concerning the accuracy of his or her tongue placement in target productions. Little research exists to support the use of EPG in the treatment of AOS. Howard and Varley (1995) reported improvements in articulation in a case study with an individual with AOS. It is expected that the decreasing costs and increasing availability of EPG (e.g., EPG3 – Articulate Instruments, 2007; LogoMetrix, 2005) will lead to additional information concerning the potential benefits of EPG for AOS. Electromagnetic articulography (EMA) is another method by which visual biofeedback of tongue movement may be provided. Articulator movements are tracked through the use of magnetic fields and receiver coils that are attached to the articulators. Katz, Bharadwaj, and Carstens (1999) demonstrated the utility of EMA in improving /ʃ/ - /tʃ/ contrasts in an individual with AOS. Unfortunately, EMA is prohibitively costly for most clinical use. As with EPG, additional research is required to document the benefits of EMA for the treatment of AOS.

In a recent investigation, Rose (2006) compared three methods of providing information concerning articulation in a speaker with chronic, moderate AOS and aphasia. The three treatments all involved contrasting target and error productions, providing information about manner and place of production, imitation, and reinforcement. The treatments differed in terms of how the articulatory information was delivered, with “verbal” treatment utilizing verbal and graphic information, “gestural” treatment employing gesturally cued articulation, and “combined” treatment involving all techniques used in the other two treatments. Results revealed that all treatments resulted in significant improvements in production, with no difference in performance noted between treatments. Although the findings of this investigation require replication, they suggest that for this speaker, the nature of the information provided in treatment was more important than the modality of delivery. This study highlights the critical need for comparative investigations of treatment techniques.

All of the preceding techniques, with the exception of repeated practice, are designed to provide additional stimulation in various forms to the speaker to facilitate accuracy of articulation. This is consistent with the concept of AOS reflecting a disruption in the process of translation of cor-

rectly selected sounds to previously learned articulatory-kinematic parameters (McNeil et al., 1997). That is, there is an assumption that speakers with AOS are lacking information concerning either the general or specific aspects of sensorimotor specifications necessary for carrying out intended speech movements. Whether the lack of information stems from difficulty in accessing such information or from a loss of the information is debatable. Regardless, these types of articulatory-kinematic treatment techniques seek to provide movement information that is presumed to be lacking or incorrect. The treatments may be considered a form of meta-speech in that they require conscious processing of various cues associated with speech production.

The techniques described thus far have been applied at various levels of production, including individual movements and sounds (Holtzapple & Marshall, 1977; Square et al., 1985); syllables (Knock et al., 2000); monosyllabic words (Kahn, Stannard, & Skinner, 1998; Raymer et al., 2002; Wambaugh & Nessler, 2004); and multisyllabic words, phrases, and sentences (Bose et al., 2001; Wambaugh et al., 1998b).

Whereas techniques such as phonetic placement, phonetic derivation, PROMPT, and EPG provide relatively direct information about production of specific speech targets, indirect information concerning production is provided in the form of imitation of contrasts (Wertz, Rosenbek, & LaPointe, 1984). Wertz and colleagues (1984) suggested beginning with imitation of syllables in which the target sound is paired with different vowels (e.g., /se/-/si/-/su/). Following mastery at this elementary level, they recommended practice in contrasting the target sound with dissimilar sounds (e.g., /se/ - /pe/; /si/ - /fi/). Wertz and colleagues suggested further increasing the difficulty of the contrasts by utilizing sounds that are more similar to the target (e.g., /shu/ - /chu/) or utilizing a more difficult production environment for the target sound (e.g., “tight - tyke”). Wambaugh and colleagues have also used contrastive practice in the form of minimal pair words, with the target sound paired with the patient’s typically replacing sound (Wambaugh et al., 1998a, 1999, 2004). Minimal pair words have also been used with electropalatographic feedback to practice contrasting tongue contacts (Howard & Varley, 1995). Additionally, Square and colleagues (1986, 1989) employed minimal pairs during PROMPT treatment and have reported that PROMPT should be utilized to contrast articulatory movements (Square et al., 2001). Contrastive practice may allow the speaker to experience the difference in the sensorimotor specifications related to the contrasting productions.

The use of contrastive practice relates to the motor-learning concepts of variable practice and the scheduling of variable practice (e.g., random practice versus blocked practice) (Schmidt & Lee, 1999). According to Schmidt and Lee, an important aspect of learning a task is being capable of coping with novel situations. Of course, every new speech event is presumably a novel situation. Wertz and colleagues’

notion of varying the phonetic environment of a target sound is consistent with the principle of variable practice. How the variable practice is scheduled has been shown to be important for limb learning in terms of retention and transfer of behaviors (see Schmidt & Lee, 1999 and Knock et al., 2000 for discussions and reviews). When all practice trials with one target behavior occur together (i.e., sequentially), the practice is termed “blocked.” When trials of all targeted behaviors are randomly interspersed, the practice is termed “random.” For instance, if two sounds have been targeted for treatment, blocked practice would require that one sound be practiced first for *X* number of trials, followed by practice of the remaining sound (e.g., 100 trials of /r/, followed by 100 trials of /k/). Random practice would involve practice of both sounds concurrently, with the order of the items being randomized (e.g., /r/-/k/-/r/-/r/-/k/-/r/-/k/-/k/-/r/). The literature on limb motor learning indicates that blocked practice promotes more rapid acquisition of motor behaviors, but random practice results in better retention and transfer (see Schmidt & Lee, 1999, for a review).

Although the application of principles of motor learning such as variable practice and blocked versus random practice have intuitive appeal for application to motor-speech treatment, only limited data exist concerning their utility with AOS. Knock and colleagues (2000) examined the effects of blocked and random practice on production of stops and fricatives in syllables and monosyllabic words with two participants with severe AOS. Their results were not consistent with the literature on limb motor learning in terms of acquisition of behaviors during treatment, but did suggest that for one participant, random practice resulted in superior retention.

Other issues related to articulatory-kinematic treatments, such as selection of stimuli, outcome measures, and utilization of feedback, have been discussed elsewhere (Odell, 2002; Wambaugh et al., 2006b) and will not be reiterated here. The reader is strongly encouraged to consult such resources and to take into consideration these issues when planning therapy.

As noted previously, the majority of the evidence supporting treatment for AOS has taken the form of investigations of articulatory-kinematic treatments. Wambaugh and colleagues (2006b) reported that of the 87 AOS participants studied in articulatory-kinematic investigations for whom severity ratings were available, “84% were provided a severe rating, 5% a moderate-severe rating, 9% a moderate rating, and 2% a mild-moderate rating. In comparison to the total group of 146 AOS participants studied across all investigations, the participants in the articulatory-kinematic investigations were more frequently rated as severe and none received a mild severity rating” (p. xlvii). Thus, it appears that increased severity is associated with the selection of articulatory-kinematic approaches. It may be the case that disruptions in spatial and temporal aspects of sound production occur more frequently in cases of severe AOS or are

TABLE 36-2

Rate- and Rhythm-Control Approaches for the Treatment of AOS

Treatment Type	Reference	Brief Treatment Description
Metronomic pacing	Dworkin, Abkarian, and Johns (1988)	Following tasks practiced with a metronome at slowed rates of production: nonspeech tasks with bite-block, AMRs, multisyllabic words, sentence repetition; rates were gradually increased
Metronomic pacing	Dworkin and Abkarian (1996)	Practice of vowels, vowel sequences, and vowel - /h/ sequences with metronome at slowed rate with gradual increasing of rate
Metronomic pacing plus hand tapping	Wambaugh and Martinez (2000)	Repeated production of multisyllabic words with metronome and hand tapping. Clinician modeling and unison production used initially, but faded. Rate increased and syncopation added.
Metronomic pacing plus hand tapping	Mauszycki (2006)	Repeated practice of multisyllabic words at increased rates of production in time with metronome, accompanied by hand tapping
Rhythmic control	Brendel, Ziegler, and Deger (2000)	Production of target utterances in time with computerized, rhythmic signals
Stress patterning	Tjaden (2000)	Practice of reiterant speech (e.g., DAdada) and multisyllabic words with modeling, waveform and auditory feedback, feedback of relative syllable durations, and finger tapping
Rate control	McHenry and Wilson (1994)	Rate reduction with syllable-by-syllable production. Clinician cueing used initially, then faded. Pacing board added. Feedback about rate provided. Tasks progressed from imitation of functional phrases and multisyllabic words to structured responses/conversation to unstructured conversation.
Rate control	Southwood (1987)	Prolonged speech produced in oral reading at reduced rates with rate controlled by video display.

Key: AMRs = "alternating motion rates (e.g., pataka) (e.g., puh puh puh puh)"

perceived as being more disruptive of communication in severe AOS. Unfortunately, there currently are no agreed-upon, data-based methods for documenting AOS severity and determining the contribution of underlying pathophysiology to perceived severity. Or, it may be the case that behaviors in severe AOS (versus moderate or mild AOS) are more amenable to experimental control (e.g., perhaps more likely to result in stable baselines) and, thus, the existing literature may reflect conscious or unconscious experimenter bias. Regardless of the cause for the preponderance of severe cases in the articulatory-kinematic literature, it is clear that these treatments may be expected to result in improved accuracy of speech production for individuals with significant sound errors. In only one report were negative treatment findings reported (Aten, 1986), although other investigators have reported that some sounds seem to be more resistant than others for some speakers (Raymer et al., 2002; Wambaugh et al., 1998a). More data are required to document the effects of articulatory-kinematic treatments on speech production in speakers with moderate and mild AOS.

Rate- and Rhythm-Control Approaches

Another general approach to AOS treatment identified in the AOS treatment guidelines was rate and rhythm control. Rate-

and rhythm-control approaches involve manipulations of rate and/or rhythm, with both often being impacted. To date, only a few investigations have reported the effects of such treatments. As seen in Table 36-2, the techniques included in this general approach include rate control through metronomic pacing, hand-tapping, prolonged speaking, clinician instruction, and utilization of a pacing board, and rhythmic manipulation through computerized control and feedback.

A basic assumption associated with rate- and rhythm-control approaches is that AOS reflects an underlying disruption in the timing of speech production. There are many theorized mechanisms by which rate- and rhythm-control treatments are thought to impact AOS, none of which have been confirmed or disproved. Use of rhythmic treatments with AOS have typically involved rate reduction (although see Mauszycki & Wambaugh, 2006). Slowing of speech production, even in speakers who already exhibit reduced rate, is thought to allow additional time for motor planning and/or programming and processing of feedback. It has also been suggested that the entrainment provided by rhythmic sources (e.g., metronome or hand-tapping) may serve to facilitate or restore internal oscillatory mechanisms that may be involved in speech production (Dworkin & Abkarian, 1996). Rate and rhythm controls may also provide a mediating function with respect to attention. For example, Dworkin and col-

leagues (1998) hypothesized that use of a metronome may have helped to focus the patient's attention on the need for increased precision during speech production. Brendel, Ziegler, & Deger (2000) suggested a different attentional mechanism; they proposed that their rhythmic-control treatment may have drawn attention toward the externally controlling stimulus and away from speech movements.

Of the relatively few investigations designed to examine the effects of rate- and rhythm-control treatments, half have been focused on metronomic pacing (Dworkin & Abkarian, 1996; Dworkin et al., 1988; Wambaugh & Martinez, 2000; Mauszycki & Wambaugh, 2006). With metronomic pacing, speech productions are produced to the beat of a metronome, usually at a rate of one syllable or movement per beat. Most often, the beat of the metronome has been set at a rate that is considerably slower than the habitual rate used by the speaker. Dworkin and colleagues (1988, 1996) initiated practice with the metronome set at extremely slow rates (e.g., 12, 15, or 30 beats per minute [bpm]) and gradually increased rates to 120 bpm. Wambaugh and Martinez selected a rate that reflected a 50% reduction in the participant's typical speaking rate. They also gradually increased rate and added a syncopated rhythm at the participant's request.

The behaviors that have been practiced with pacing have varied. Dworkin and Abkarian (1996) utilized stimuli designed to promote increased volitional control over phonation. Specifically, the patient practiced production of individual vowels, vowel sequences, and vowel - /h/ alternations. Dworkin, Abkarian, and Johns (1988) employed a non-speech activity (raising and lowering the tongue tip to the alveolar ridge with a bite block in place) as well as speech activities (e.g., SMRs and multisyllabic word productions). Wambaugh and Martinez (2000) trained multisyllabic word productions that were grouped according to stress pattern. Mauszycki and Wambaugh (2006) utilized multisyllabic words and phrases in their practice, which involved increasing rates of production with a speaker with mild AOS.

In the investigations by Dworkin and colleagues (1988, 1996), it appeared that little clinical instruction was involved. That is, practice was largely independent and patient controlled. In contrast, Wambaugh and Martinez (2000) and Mauszycki and Wambaugh (in press) utilized clinician modeling in early treatment phases, with clinician involvement being gradually withdrawn. The treatment protocol used by Wambaugh and Martinez is shown in Appendix 36.4. Furthermore, both investigations combined hand-tapping with the metronomic pacing. Specifically, the patients were required to tap along with the beat of the metronome while performing the speech tasks. The rationale for inclusion of the hand-tapping was that the tapping (1) could serve as a self-initiated mediating device that could be used when the metronome was not present and (2) provided additional rhythmic stimulation.

Dworkin and colleagues reported positive changes for all trained behaviors in terms of reduced presence of symptoms

of apraxia (Dworkin & Abkarian, 1988; Dworkin et al., 1996). Dworkin and colleagues (1988) reported that training effects at beginning levels of practice generalized to more complex behaviors. In contrast, Dworkin and Abkarian (1988) reported a lack of generalization of treatment effects to untrained behaviors (e.g., treatment of tongue-tip raising did not result in improved performance with AMRs). Generalization to untrained behaviors was also reported by Wambaugh and Martinez (2000) in that untrained words improved with respect to articulatory accuracy, although improvements were slightly less than those observed with trained words. It is important to note that Wambaugh and Martinez provided no training for articulation and provided no feedback relative to articulatory accuracy. Mauszycki and Wambaugh (2006) also noted increased articulatory accuracy following practice with metronomic pacing and hand-tapping.

Rate of production (Southwood, 1987) and rhythm of production (Brendel et al., 2000; Tjaden, 2000) have been controlled/trained through visual displays and/or feedback. In a facilitation study (i.e., not a true treatment investigation), Southwood (1987) encouraged use of a prolonged manner of speaking and used a video display to present words for oral reading at specified rates (30-130 words per minute). Brendel and colleagues (2000) also used a video display to have speakers match their productions to computer-generated "rhythmic cues," which were controlled for rate and metrical form. Additionally, Tjaden (2000) used a waveform display, auditory feedback, and a numerical indicator of relative syllable durations to treat stress patterning. Whereas Southwood and Brendel and colleagues reported positive outcomes, Tjaden reported negative results for a generalization measure of stress patterning.

McHenry and Wilson (1994) used a combination of techniques to reduce rate. They provided clinician cueing, which was gradually faded, along with use of a pacing board, which is a board divided horizontally into sections by raised dividers. Patients are trained to touch each consecutive section on the board for each unit of speech. Such devices have been recommended for use (Wertz et al., 1984), but little data exist concerning their utility. Although McHenry and Wilson's rate-control treatment was described only briefly, they provided descriptions of a task continuum progressing from imitation of functional phrases and multisyllabic words to structured responses in conversation to unstructured conversation.

Another technique that may act at the level of rate/rhythm modification is the application of surface prompts. Surface prompts are those that highlight tempo and stress patterns. Investigations focused on the rate and rhythmic facilitative effects of surface prompts have not yet been reported. Surface prompts are discussed further in "Formalized Treatment Programs with Supporting Evidence."

Another technique that may function at the level of rate/rhythm that has not received direct investigation is

contrastive stress drills. Such drills have been advocated for treatment of AOS (e.g., Rosenbek, 1983; Wertz et al., 1984) and use emphatic stress to facilitate speech production. An additional potential benefit is that repeated productions with varied stress provide a form of variable practice. Question-and-answer dialogues that consist of short phrases centered on one or two target words are used. Questions are manipulated to require stress to be placed on a particular word in the response. The reader is directed to Wertz, et al., (1984) or Square Martin & Bose (2001) and their colleagues for further discussion.

Additional techniques that may be considered rate and rhythm techniques include finger counting (Simmons, 1978) and vibrotactile stimulation (Rubow, Rosenbek, Collins, & Longstreth, 1982). However, these approaches will be discussed in the next section, because their developers considered their therapeutic effects to derive from intersystemic reorganization.

Intersystemic Facilitation/Reorganization Approaches

Intersystemic reorganization entails the utilization of a relatively intact system/modality to promote functioning of an impaired system/modality (Rosenbek et al., 1976). The AOS Treatment Guidelines Committee added the term “facilitation” to the description of these approaches because the intent as well as the outcome of the treatments appeared to be facilitation of speech rather than necessarily reorganization of communication. The rationales for the treatments described in this section carried no assumptions about presumed pathophysiology associated with AOS. Few theories have been advanced regarding the possible mechanisms by which intersystemic facilitators/reorganizers effect changes in speech. Rubow and colleagues (1982) suggested that additional afference provided through the engagement of additional systems may play a role. Additionally, Rubow and colleagues theorized that gestural reorganization techniques may provide an organizational framework for speech production.

Utilizing gestures to enhance speech production has been the technique most often studied in terms of AOS intersystemic facilitation/reorganization (Wambaugh et al., 2006a). Both iconic (e.g., Amer-Ind gestural code; Skelly, 1979) and nonmeaningful (e.g., finger-counting; Simmons, 1978) gestures have been studied. With gestural facilitation/reorganization, gestural production is typically paired with verbal production of targets such as words or sentences (Code & Gaunt, 1986; Raymer & Thompson, 1991; Simmons, 1978; Skelly et al., 1974; Wertz et al., 1984). Dowden, Marshall, and Tompkins (1981) trained only gestural production but measured the effects of treatment on verbal production. Improvements were reported for all of the investigations in which gestures were paired with verbalizations. Improvements were noted in terms of improved articulation (Raymer & Thompson, 1991; Rubow et al., 1982; Wertz et al., 1984) as well as increases in test scores (Simmons, 1978; Skelly et al., 1974). When gestures were trained without

being paired with verbalization (Dowden et al., 1981) no verbal changes were reported (i.e., PICA verbal scores). An added benefit of gestural plus verbal training may be improvements in gestural productions (Code & Gaunt, 1986; Raymer & Thompson, 1991).

Other techniques included in this general approach are the provision of vibrotactile stimulation (Rubow et al., 1982) and singing (Keith & Aronson, 1975). Rubow and colleagues applied a vibratory source to a participant's finger during production of polysyllabic words. Words beginning with fricatives received vibrotactile plus imitation treatment, while words beginning with plosives received imitation-only treatment. Although a superior treatment effect was found for the vibrotactile treatment, the potential inequality in difficulty of the word lists served as a confound. Keith & Aronson reported a case of singing as therapy which involved choral singing of a familiar song and production of object names and functional phrases in song. Facilitative effects of singing were reported, although quantitative data were not provided.

Alternative/Augmentative Communication Approaches

The remaining general approach to the treatment of AOS identified in the AOS guidelines report was AAC (Wambaugh et al., 2006b). As noted in the AOS guidelines, “the common motivation for the eight treatment investigations involving alternative/augmentative approaches was the perceived need to improve communication through the use of modalities other than speech. That is, verbal communication was judged to be less than optimally effective and consequently, methods for either circumventing or supplementing speech were devised” (Wambaugh et al., 2006b; p. lvi).

Reports of AAC training with persons with AOS and aphasia have included development of a comprehensive communication system (Yorkston & Waugh, 1989), development of a total communication approach (Fawcus & Fawcus, 1990), instruction in use of voice-output communication aids (Lasker & Bedrosian, 2001; Rabidoux, Florance, & McCauslin, 1980), and training in use of Blissymbols (Bailey, 1983; Lane & Samples, 1981).

Lasker and Bedrosian (2001) noted that AAC options may not be adopted by potential users or may be used ineffectively because of problems with acceptance. They described a case in which an individual with chronic aphasia and AOS demonstrated unwillingness to use an AAC device beyond the confines of the speech-and-language clinic. To work through this problem, they implemented a community-based treatment program utilizing role play and outings.

The literature concerning AAC and AOS consists primarily of cases in which AOS was accompanied by significant aphasia. It is impossible to determine the contribution of the co-occurring disorders to the need for AAC in these cases. However, in terms of selecting the specific AAC approach and designing treatment, the language disturbance may be the

primary consideration. The reader is directed to Chapter 30 in this text for information concerning AAC and aphasia.

Two reports of AAC approaches that were designed specifically to circumvent problems resulting specifically from AOS are available (Lustig & Tompkins, 2002; Marshall, Gandour, & Windsor, 1988). Marshall and colleagues reported on a case in which apraxia was considered to have selectively affected motor programming of the larynx. In this case, the patient was provided with an electro-larynx to compensate for the deficits in phonation. Lustig and Tompkins (2002) designed a treatment for an individual with AOS and aphasia who had developed an unproductive communicative pattern of persistent verbal struggle. That is, when the participant had difficulty in verbal expression, she produced excessive verbal reattempts that were disruptive of communication. Lustig and Tompkins applied treatment that required the participant to use a written response upon the occurrence of spoken production that occurred with struggle behavior. The reader is referred to Lustig and Tompkins (2002) for a complete explanation of treatment and description of comprehensive outcome measures.

Formalized Treatment Programs with Supporting Evidence

As described in the previous sections, many techniques are available for the treatment of AOS. In the following sections, three treatment programs are described. These are treatments that are relatively more developed than others available for AOS. Of importance is the fact that their effects have been replicated in two or more investigations. A weakness of the existing AOS treatment literature is a lack of replications of positive treatment findings (Wambaugh, 2002; Wambaugh et al., 2006b). It is not the case that negative findings have been reported in subsequent investigations; rather, it is that replications have not been attempted for the majority of AOS treatment reports. For the treatments that follow, repeated study of the treatments has provided a more substantial evidence base than exists for most AOS treatments. However, even the following treatments require substantial additional research to address remaining questions regarding treatment outcomes and optimal conditions of application.

Eight-Step Continuum

Appendix 36.5 shows the treatment protocol described by Rosenbek and colleagues (1973), called the eight-step task continuum. The treatment was originally described along with a report of three cases in which it was applied with individuals with severe, chronic (i.e., longer than 1 year post-onset) AOS and moderate aphasia. The treatment entails selecting a limited set of target utterances for the client; Rosenbek and colleagues chose five, functional target utterances, varying in length from one to seven words, which were individualized for each client (e.g., "My name is _____."; "home"; "It's time to go."). Target productions are entered

into the continuum one at a time, beginning at Step 1. Criterion for moving to the next step is 80% correct in 20 consecutive treatment trials. In the Rosenbek report, clinician judgment apparently served as the primary determinant of correctness, with communicative adequacy being stressed.

Rosenbek and colleagues (1973) noted that various response facilitators were necessary and were individualized according to client needs. That is, in addition to the steps of the continuum, additional therapeutic techniques were employed. Presentation facilitators such as slowed presentation, increased stress, and exaggerated articulation were reported. In addition, production facilitators such as utilization of a mirror and phonetic placement cueing were used.

The continuum begins with steps at which the clinician exerts a relatively high degree of control. Clinician cues are faded as the steps progress and ultimately, the target utterances are elicited in simulated, naturalistic communication situations. Steps of the continuum may be skipped to accommodate different types of treatment stimuli (e.g., some single words may not be appropriate for Steps 7 and 8) and rapid response to treatment (e.g., generalization may permit skipping steps).

In the original report concerning the eight-step continuum, positive results were reported for the three participants. In a follow-up investigation, Deal and Florance (1978) reported successful application of a modified version of the continuum with four participants with severe AOS, three of whom had chronic AOS. Simmons (1980) used a withdrawal design to study the effects of a modified version of the continuum with an individual with moderate AOS and aphasia. The participant, who had been blind from birth, was trained on production of 10 sentences under two training conditions: one without Braille and one with Braille. The participant improved under both conditions, but demonstrated superior performance when Braille was utilized in the continuum. In summary, data from seven cases and one experimental study indicate that individuals with AOS and aphasia may benefit from application of the eight-step continuum in terms of acquisition of limited sets of functional words/phrases/sentences. More experimental investigations of this treatment are required to further specify its effects, especially in terms of generalization to untrained items and to different stimulus conditions.

PROMPT

PROMPT was developed by Chumpelik (Hayden) (1984) as a dynamic method for delivering tactile cues concerning articulation (i.e., place of articulation, timing, transitioning, and amount and type of contraction) to children with severely impaired speech. Application of PROMPT to adult speakers with AOS and aphasia began during the 1980's through collaborative efforts of Square, Chumpelik (Hayden), and colleagues (Square, Chumpelik, & Adams, 1985; Square, Chumpelik, Morningstar, & Adams, 1986).

Since its initial description (Chumpelik, 1984), PROMPT has been developed into a comprehensive approach to the

management of speech-production disorders in children (see Hayden, 2004, for a thorough review of the history, conceptual framework, and description of PROMPT). It appears from the extant literature concerning PROMPT applied to AOS that selected techniques rather than the entire treatment approach have been utilized.

Because of the complexity of PROMPT, clinician training is recommended for its correct administration (www.promptinstitute.com). Therefore, the following brief description of its techniques is meant to provide the reader with the basic concepts associated with PROMPT, not to provide instruction in its application. PROMPT uses a combination of proprioceptive, pressure, and kinesthetic cues that are “designed to heighten sensory input regarding the place of articulatory contact, extent of mandibular opening, presence and extent of labial rounding and retraction, voicing, muscle tension, time of segments, manner of articulation, and/or coarticulation” (Bose & Square, 2001, p. 5). Treatment is individualized, and PROMPT can be applied at various levels of production ranging from movement parameters such as jaw opening to sentence productions. Different types of prompts are available for use depending upon the level of support required: parameter prompts, complex prompts, and surface prompts. For a detailed description of the different types of prompts as well as the contextual application of PROMPT see Square and colleagues (2001).

The use of PROMPT is supported by the findings of several investigations (Bose et al., 2001; Freed, Marshall, & Frazier, 1997; Square et al., 1985, 1986; Square-Storer & Hayden, 1989). Initial research concerning the application of PROMPT with speakers with AOS suggested that application of PROMPT resulted in positive changes in production of trained individual sounds, single words, minimally contrastive word pairs, and phrases with speakers with AOS (Square et al., 1985, 1986; Square-Storer & Hayden, 1989). Generalization to untrained items was not evident, but anecdotal reports indicated generalized use of trained phrases beyond the treatment setting. Freed and colleagues (1997) trained an individual with severe AOS and aphasia in the production of 30 functional words and phrases. Results were similar to those reported by Square and colleagues in that the participant successfully learned the trained items, but generalization was not evident to untrained items. Stimulus generalization in the form of use of trained productions in novel situations was reported anecdotally. Bose and colleagues (2001) examined the impact of the type of sentence construction on the effects of PROMPT. Specifically they measured the precision of production of short sentences grouped by imperatives, active declaratives, and interrogatives in an individual with moderate AOS and aphasia. Findings indicated positive results for imperatives and active declaratives, but

not for interrogatives. No generalization to untrained items was observed; maintenance effects were positive for gains made with imperatives and active declaratives. It is of importance to note that the positive results reported by Freed and colleagues and Square and colleagues represent supporting data from independent research groups, which is an important component in the demonstration of treatment efficacy (Chambless & Hollon, 1998).

Sound-Production Treatment

Sound-Production Treatment (SPT; Wambaugh, 2004; Wambaugh & Nessler, 2004) has been evaluated more extensively than other treatments for AOS. SPT was designed to facilitate improved production of specific sounds targeted for treatment. Sounds selected for treatment are those that are produced in error on a relatively consistent basis at some level of production. The level of production at which sound-production difficulty may be evidenced and at which treatment is directed includes syllables, monosyllabic words, multisyllabic words, phrases, and sentences. SPT combines modeling, repetition, minimal-pair contrast, integral stimulation, articulatory placement cueing, and feedback in a response-contingent hierarchy. The original SPT hierarchy is shown in Appendix 36.6. Modifications to the original hierarchy have been made based upon research findings and the desire to incorporate principles of motor learning. The most recent version of SPT is shown in Appendix 36.7. As seen in Appendix 36.7, the minimal-contrast item is introduced only upon incorrect production of the target item. Additional repetitions are elicited upon a correct response in order to maximize repeated practice, and a reduced-feedback schedule is used with those additional repetitions. In addition, the silent-juncture step was eliminated. As noted previously, the SPT hierarchy (both versions) is response contingent. Steps of the hierarchy are used only as needed. In addition, the steps of the hierarchy are not reversed upon a correct response.

Research with SPT has shown that when eight to 10 exemplars of the target sound are trained to criterion, response generalization to untrained exemplars of the target sound may be expected to occur at levels of accuracy that approximate trained items (Wambaugh, 2004; Wambaugh & Nessler, 2004; Wambaugh et al., 1998, 1999). Generalization to untrained sounds that are unrelated (i.e., are not cognates or closely related in manner of production) is likely to be minimal. Partial generalization has been observed for sounds that demonstrate similar manner of production with similar types of errors (Wambaugh & Cort, 1998). Stimulus generalization has not been evaluated extensively; consequently, predictions cannot be made concerning these effects with SPT. However,

positive stimulus generalization to longer and more complex production conditions has been observed for some speakers (Wambaugh, 2004; Wambaugh & Nessler, 2004; Wambaugh et al., 1998b).

SPT has been modified with successful results for application to multiple sound targets (Wambaugh & Nessler, 2004), sentences containing numerous target words/sounds (Wambaugh et al., 1998b), and words elicited through sentence completion (Wambaugh & Nessler, 2004). Although much remains to be clarified about the outcomes associated with SPT, it can be expected that SPT will result in improved production of targeted sounds for speakers with AOS.

Treatment for AOS and Aphasia

Virtually all of the participants described in the AOS treatment literature presented with some type and degree of aphasia (Wambaugh et al., 2006a). Unfortunately, the descriptions of the accompanying aphasia and its impact on verbal expression have usually not been provided in sufficient detail to allow inferences about its effect on treatment outcomes. Most treatments for AOS, with a few exceptions (such as those focused on AAC), have provided relatively superficial attention to the accompanying aphasia. The consideration of aphasia has most often been reflected in the selection of treatment stimuli. That is, in the selection of items for treatment, the following factors, which impact language production as well as speech production, have sometimes been taken into account: frequency of occurrence, length of stimuli, functionality, and patient preference. It is our impression that treatments for AOS have generally been designed to work around the constraints of the patient's language disorder in order to focus on the motor-speech deficit.

One treatment for aphasia that has been specifically modified to accommodate the presence of AOS and that has incorporated treatment techniques considered to facilitate speech production in AOS is Response Elaboration Training (RET; Kearns, 1985). RET was developed to promote increased production of content and length of utterances through the use of modeling and forward-chaining applied to patient-initiated verbalizations. Wambaugh and Martinez (2000) modified RET by incorporating additional modeling, integral stimulation, and repeated practice of utterances to make the treatment more amenable for application with persons with significant AOS. Wambaugh and Martinez reported positive changes in production of verbal content upon application of modified RET in three speakers with chronic AOS and aphasia. The effects of modified RET on speech-production accuracy have not been examined. Although it is likely that changes in speech production in AOS will necessitate significant amounts of repeated practice, modifications to existing aphasia treatments, such as RET, may allow clinicians to target both speech and language deficits simultaneously in the future.

Treatment Summary

Persons with aphasia may also have neuromotor speech disorders such as AOS and dysarthria. The presentation of such disorders will be unique for each individual, as will the communication disruption resulting from the combination of aphasia and AOS/dysarthria. Significant evidence exists indicating that persons with aphasia and neuromotor speech disorders can benefit from treatment directed toward their speech disruption.

KEY POINTS

1. Thanks to the advent of new, mainly noninvasive, technologies, we have learned a great deal about the brain regions that subserve speech production. Areas such as M1, which were thought to be purely motor, appear to play a role in higher level cognitive functions relating to movement, not simply in the execution of movement.
2. Several cortical regions, such as the left IFG, have been shown to play a role in both language and speech behaviors. This may explain why speech and language deficits frequently co-occur after damage to the left hemisphere.
3. Speech production and speech perception, once believed to be separate processes, appear to be tightly linked in the brain.
4. In light of what we have learned about the role that different brain regions play in speech production, we can understand how damage to different brain regions could produce similar deficits. For example, based on what we know about their function, we can understand why damage to the left IFG or the left IPL could result in problems in producing longer words.
5. Apraxia of speech (AOS) and unilateral upper motor neuron dysarthria may occur with aphasia and may exacerbate its effects, particularly in terms of verbal expression. Other forms of dysarthria may be present with aphasia, but rarely will they be the result of the same neurologic event that caused the aphasia.
6. Clinicians must understand the impact of both the language and motor aspects of verbal-production disorders associated with brain damage to the language-dominant hemisphere.
7. Clinicians should be aware of the treatment recommendations and options described in the AOS Treatment Guidelines (Wambaugh et al., 2006a, 2006b).
8. Clinicians should base treatment decisions on balanced consideration of the best available evidence, clinical experience, theoretical rationale, and patient needs and preferences.

ACTIVITIES FOR REFLECTION AND DISCUSSION

1. It appears that Broca's area plays a role in multiple aspects of speech and language behavior. Discuss how it might be possible for a brain region to have such diverse functions and yet still be efficient.
2. Describe how our view of the relationship between speech perception and speech production has changed. Discuss whether what we know about this relationship would change your approach to evaluation and/or treatment of motor-speech disorders.
3. Develop at least two explanations for why, after decades of study, there is still no universal agreement on the location of the lesion that produces apraxia of speech.
4. Review the characteristics that are considered *necessary* for a diagnosis of AOS and those that are *consistent with* a diagnosis of AOS, but that *should not be used* for differential diagnosis. Revisit the early descriptions of AOS (e.g., Darley et al., 1975) and discuss how the diagnostic descriptors have changed.
5. Describe the speech characteristics of a patient with AOS (real or fictitious). Discuss the possible advantages and disadvantages of an articulatory-kinematic approach versus a rate/rhythm control approach for treating this patient.
6. Review the various ways in which speech may be sampled when assessing AOS. Discuss patient-specific considerations that should be taken into account when selecting methods for sampling.

Tri-Syllabic Words by Final Phoneme

z	d	m	s	l	k	p
memorize	latitude	catacomb	nemesis	chemical	bailiwick	teletype
paralyze	renegade	maximum	paradise	topical	tomahawk	leadership
televise	marinade	synonym	Genesis	parallel	Similac	lollipop
maximize	solitude	minimum	populous	monorail	Tillamook	handicap

(From Mauszycki, S. C. (2006). Variability of sound production in apraxia of speech and aphasia: Perceptual analyses. Unpublished doctoral dissertation.)

APPENDIX 36.3

Examples of Sentence-Completion Items

/s/

- (see) Before I can read the newspaper, I need to put on my glasses because I can't _____.
- (set) A track-and-field runner always gets ready when he or she hears the phrase: "On your marks, get _____."
- (seal) In order for a passport to be legal, the immigration department has to stamp a _____.
- (Sue) My best friend's name is Susan but I call her by the nicknames of Susie or _____.
- (sigh) Everybody knows when my father is extremely tired and ready to go to sleep because he tends to yawn and _____.

/p/

- (pie) Julie usually makes desserts when she has company. Last Saturday, her parents came and she baked a delicious apple _____.
- (pail) The little boy wanted to build a sandcastle, so his mom bought him a shovel and a _____.
- (pet) We have a goldfish, a hamster, and a dog in my house. I'm responsible for the hamster because she is my _____.

- (pat) Every time I get home, my dog wants me to play with him and give him a friendly _____.
- (pier) I tied my boat up at the dock or the _____.

/v/

- (vee) The little boy learned today to write words such as violin, van, and vase, which are words that begin with the letter _____.
- (veil) A bride bought her wedding gown, shoes, and accessories. But later she realized that she did not buy a _____.
- (view) If you live on the mountain and look over the city, you have a beautiful _____.
- (vet) My dog has been very sick for the past two days. I need to take her to the _____.
- (veal) Instead of making my beef stew with beef, I prefer to use the meat of a calf, which is better known as _____.

/k/

- (key) I was frustrated because I locked myself out. Fortunately, I remembered that I was carrying an extra _____.

2. (cut) My hair is too long. I need to go to my hairdresser and get a new hair _____.
3. (cot) Grandpa came to visit. Mom said to my brother: "Grandpa can sleep in your bed and you can unfold the _____."
4. (coo) When I went to New York, I visited Central Park. I loved to feed the pigeons and hear their _____.
5. (car) I've been riding the bus for many years. I finally saved enough money to buy a good _____.

/f/

1. (shoe) The little boy is almost ready to go outside and play. He'll be ready once he ties his left _____.
2. (shot) The flu can be deadly in older people. That's why older people have been encouraged to have a flu _____.
3. (shut) The little boy was so tired that when his mom finished reading the story, his eyes were already _____.
4. (share) At the beginning of the school semester, the teacher did not have enough books for all the children so she said: "We'll have to _____."
5. (she) We saw a beautiful dog at the pet shop. We wanted to get a "he" so we asked: "Is it a he or a _____?"

/dʒ/

1. (jail) A man committed a crime and was caught. He was sentenced to 15 years in _____.
2. (Jew) My friend believes in Judaism, so everyone considers him a _____.
3. (jaw) The boxer threw a punch near his opponent's mouth and broke his _____.
4. (jar) The little boy was so hungry that he couldn't wait for his lunch and grabbed some cookies from the cookie _____.
5. (gee) The little girl learned in class today that the words girl, game, goat, and guitar begin with the letter _____.

/l/

1. (light) I was reading a book and all of the sudden the room became dark. I told my husband to turn on the _____.

2. (late) Tim is never on time. He usually gets to school ten to fifteen minutes _____.
3. (lit) Julie doesn't like to live in a dark house. When she was looking for a home, she made sure that it was well-_____.
4. (low) Ted wants to apply for medical school but he needs to retake the test because he scored too _____.
(lie) I tried to believe what they said but it was very hard for me because they always _____.

/m/

1. (mitt) Tim was ready to play baseball. He brought a ball and a bat, but then he realized that he forgot to bring his baseball _____.
2. (me) Julie's mom told her to call home as soon as possible. So when Julie was leaving, mom said: "Don't forget to call _____."
3. (mate) Ted is always dating but never seems to find the right person. He's still searching for the perfect _____.
4. (mow) The big kids share the yard work with their dad. The grass is tall and dad asked: "Who is going to _____?"
5. (moo) I would like to live on a farm. I love to hear the horses neigh, the ducks quack, the pigs oink, and the cows _____.

/n/

1. (knit) I know how to cross-stitch, sew, and crochet, but I don't know how to _____.
2. (know) The teacher asked a question about what the children were studying in class. A kid raised his hand and said "I _____."
3. (night) The mom put her son in his bed, covered him with a blanket, gave him a kiss, and said: "Good _____!"
4. (need) The Boy Scouts were knocking on every door, asking for donations for families in _____.
5. (knee) The boy was running and tripped over a rock. He was crying because he scraped his left _____.

(From Wambaugh, J. L., & Nessler, C. 2004)

APPENDIX 36.4

Metronome and Hand-tapping Treatment

Level One:- Clinician Model, Unison Production, Beginning Patient Production

- A. S/T^a
- B. Metronome setting: 93 bpm
- C. Treatment steps:
 1. CM^b - 1 production
 2. Patient taps along (no verbal production), while clinician produces word - 5 productions
 3. UPT^c - 3 productions
 4. PPT^d - 1 production
- D. Target-item presentation: Clinician presents experimental words (treatment items only) in random order. Clinician presents as many items per session as possible.
- E. Feedback: Clinician provides positive or negative feedback about tapping, production of correct number of syllables, and/or production of syllables on beat, *but not about sound accuracy*
- F. Scoring: “+” or “-” for PPT step (“+” = correct use of tapping with production of correct number of syllables on the beat)

Criterion: 95% accuracy for entire treatment session in two consecutive sessions

Level Two:- Faded Clinician Model, Repeated Patient Production

- A. S/T
- B. Metronome setting: 93 bpm
- C. Treatment steps:
 1. CM - 1 production
 2. PPT - 3 productions
 - a) If any errors in tapping to the beat or in producing the correct number of syllables: CM (1 production) plus UPT (3 productions); if errors remain: clinician presents next target word
 - b) If correct, clinician begins treatment steps with next word
- D. Target item presentation: same as Level 1
- E. Feedback: same as Level 1
- F. Scoring: “+” or “-” for first production of PPT step

Criterion: 95% accuracy for entire treatment session in two consecutive sessions

Level Three:- No Clinician Model, Repeated Patient Production

- A. S/T
- B. Metronome setting: 93 bpm
- C. Treatment steps:
 1. Clinician says word with normal rate and prosody (no metronome or tapping)

2. PPT - 3 productions
 - a) If any errors in tapping to the beat or in producing correct number of syllables: CM (1 production) plus PPT (3 productions); if errors remain: CM (1 production) plus UPT (3 productions); if errors remain: clinician presents next target word
 - b) If correct, clinician begins treatment steps with next word
- D. Target item presentation: same as Level 1
- E. Feedback: same as Level 1
- F. Scoring: “+” or “-” for first production of PPT step

Criterion: 95% accuracy for entire treatment session in two consecutive sessions

Level Four:- Increased Rate of Production

- A. Metronome setting: 100 to 110 bpm
- B. Treatment steps: same as Level 3
- C. Target item presentation: same as Level 1
- D. Feedback: same as Level 1
- E. Scoring: “+” or “-” for first production of PPT step

Criterion: 95% accuracy for entire treatment session in two consecutive sessions and no decrease in accuracy of trained items on probes

Level Five:- Syncopated Production

- A. Clinician explains concept of syncopation: The target word will be produced in two beats, with the first syllable on downbeat of hand tap, the second syllable on the upbeat, and the third syllable on the downbeat of second hand tap.
- B. S/T
- C. Metronome setting: 100 bpm
- D. Treatment steps: apply syncopation sequentially at each of preceding levels, beginning with Level 1

Abbreviations

^a**Schematic/tapping review (S/T):** Clinician explains/reviews schematic of stress pattern for words under treatment; clinician and patient practice tapping with the schematic (_ _ ↓).

^b**Clinician model (CM):** Clinician produces word with metronome (one syllable per beat), while tapping

^c**Unison production and tapping (UPT):** Clinician and patient simultaneously produce target word, while tapping

^d**Patient production and tapping (PPT):** Patient produces target word, while tapping; clinician provides no model or assistance

(From Wambaugh, J. L., & Martinez, A. L. (2000).

APPENDIX 36.5

Eight-Step Continuum

Step 1. Integral Stimulation. The target utterance is produced simultaneously by the client and clinician simultaneously with auditory and visual stimulation. “Watch me, listen to me” plus simultaneous production.

Step 2. Integral Stimulation and Delayed Production. The clinician provides a model of the utterance, then asks the client to produce the utterance while the clinician produces the utterance without sound. That is, the auditory model is eliminated during simultaneous production.

Step 3. Integral Stimulation and Delayed Production with No Visual Cue. The clinician provides a model while instructing the client to watch and listen. The client is asked to repeat the utterance. “I’ll say it first, then you say it after me.”

Step 4. Integral Stimulation and Successive Productions. The clinician provides a verbal model and the client is asked to produce the target several times without any cues.

Step 5. Written Stimuli and Simultaneous Production. The client reads the target utterance aloud with written stimulus present.

Step 6. Written Stimuli and Delayed Production. The clinician provides the written utterance, then the client is asked to produce the utterance after the written stimulus is removed.

Step 7. Appropriate Utterance Elicited by Question. The clinician asks a question that is appropriate for eliciting the target utterance.

Step 8. Appropriate Response in Role-Playing Situation. The clinician and others assume roles to elicit the target utterance in a contextually appropriate situation.

Rosenbek, J. C., Lemme, M. L., Ahern, M. B., et al. (1973). A treatment for apraxia of speech in adults. *J Speech Hear Disord*, 38, 462–472.

APPENDIX 36.6

Original Sound-Production Treatment Hierarchy

Step 1—Modeling/Imitation: The therapist produces the minimal contrast pair* and instructs the speaker to repeat the pair (e.g., “say pie ... buy”). If the speaker cannot repeat the paired words together, each member of the pair is presented separately. If the target sound and contrasting sound are correct, feedback about accuracy is provided, another production of the target word is elicited, and the next pair is presented. If either sound is incorrect, feedback about accuracy is provided and this step is reattempted. If either sound is incorrect upon second attempt, feedback is provided and Step 2 is attempted.

Step 2—Modeling plus Written Letter Cue/Imitation: The therapist points to printed letters representing the target sound and contrasting sound while modeling production of the minimal-pair items. The speaker is asked to repeat each item. If both sounds are correct, feedback is provided and the next pair is presented. If either sound is incorrect, feedback is provided and Step 3 is attempted.

Step 3—Integral Stimulation: If only the target sound or both sounds are incorrect in Step 2, then the target sound *only* is focused upon at this step. If only the contrasting sound is incorrect, then that sound is focused upon. Using the single item (i.e., nonpaired item), the therapist instructs the speaker to “watch me, listen to me, and say it with me”. If correct, then feedback is provided, another production is elicited, and the next pair is presented. If the contrasting sound is incorrect, feedback is provided and the next pair is presented. If the target sound is incorrect, the therapist provides feedback and moves to Step 4.

Step 4—Modeling with Silent Juncture/Imitation: The clinician models the target word using a silent juncture, separating the sound from the rest of the word (e.g., “Say the word like this, p . . . ie). The speaker is instructed to repeat the word. If correct, feedback is provided and the next pair is presented. If incorrect, feedback is provided and the clinician moves to Step 5.

Step 5—Articulatory Placement and Modeling: The therapist provides verbal articulatory placement instructions specific to the speaker's perceived error, models the sound in isolation, and asks the speaker to repeat the sound. If correct or incorrect, feedback is provided and the clinician moves to the next pair of contrasts at Step 1.

***Modifications to the Minimal-Pair Presentation:**

- A. 80% to 100% correct production at Step 1 in a single trial (10 items), use hierarchy exactly as above.
- B. 50% to 79% correct production at Step 1 in a single trial, use single items in alternate trials instead of contrast pairs at every trial (i.e., use only the target item without the minimal-contrast item).

- C. 0% to 49% correct production at Step 1 in a single trial, use two single-item trials alternately with one minimal-pair trial.

Notes:

- 10 exemplars of the target sound presented in random order constitute one trial
- As many productions as possible should be attempted per session (attempt to complete a minimum of seven 10-item trials)
- Continue treatment until at least 80% of trained items are produced correctly in PROBES (not during application of treatment) in two of three consecutive sessions

(From Wambaugh et al., 1998a)

APPENDIX 36.7

Modified Sound-Production Treatment

- 1) Clinician produces the target item and requests a repetition
 - a) if correct, the clinician provides positive feedback concerning accuracy, requests five additional repetitions,* and moves to the next target item
 - b) if incorrect, the clinician gives feedback and says: "Now, let's try a different word" and models the *minimal contrast word*
 - if correct, the clinician says: "Now, let's go back to the other word" & goes to Step 2 with the target word
 - if incorrect, the clinician gives feedback, and attempts production of the contrast word with integral stimulation for a maximum of 3 trials; the clinician then moves to Step 2 with the target word
- 2) The clinician shows the letter representing the target sound, models the *target item*, and requests a repetition
 - a) if correct, the clinician provides feedback, requests five additional repetitions,* and moves to the next item
 - b) if incorrect, the clinician goes to Step 3
- 3) The clinician requests production of the target item using integral stimulation: "watch me, listen to me, and say it with me," for a maximum of three trials
 - a) if correct, the clinician provides feedback, requests five additional repetitions,* and moves to the next item
 - b) if incorrect, the clinician moves to Step 4
- 4) The clinician provides articulatory placement cues appropriate to the participant's error and requests production of the target item using integral stimulation; if correct, request additional repetitions (five times*)
 - a) if correct, the clinician provides feedback, requests five additional repetitions,* and moves to the next item
 - b) if incorrect, the clinician provides feedback and moves to the next item

*Feedback is provided on approximately 60% of attempts.

(From Wambaugh, J. L., & Nessler, C. (2004). Modification of Sound Production Treatment for aphasia: Generalization effects. *Aphasiology*, 18(5/6/7), 407–427.)

APPENDIX 36.8

Modified Response Elaboration Training

Treatment Steps

Step 1. The clinician presents a picture and elicits a response (e.g., “Tell me about this picture.”, “What does this remind you of?”, “Tell me what’s happening.”)

- A. If the response is correct,* the clinician moves to Step 2.
- B. If there is no or an incorrect response, the clinician models two response options (e.g., “You could say something like . . . noun phrase [NP] or verb phrase [VP].”) If the response is correct, the clinician moves to Step 2.
- C. If there is no or an incorrect response, the clinician models a one-word response and requests a repetition (e.g., “Say noun.” or “Say verb.”) If the response is correct, the clinician moves to Step 2.
- D. If there is no or an incorrect response, the clinician uses integral stimulation, with a maximum of four attempts, to elicit the noun or verb production. If the response is correct, the clinician moves to Step 2. In the event of an incorrect or no response, the next item is presented.

Step 2. The clinician models and reinforces the participant’s production from Step 1 (e.g., “Shoe. Great. That’s a shoe.”)

Step 3. The clinician requests an elaboration of the response from Step 1 (e.g., “What’s happening with the shoe?”)

- A. If the response is correct, the clinician moves to Step 4.
- B. If there is no or an incorrect response, the clinician models two response options (e.g., “You could say something like . . . noun phrase [NP] or verb phrase [VP].”) and requests a response. If the response is correct, the clinician moves to Step 4.
- C. If there is no or an incorrect response, the clinician models a one-word response and requests a repetition (e.g., “Say noun.” or “Say verb.”) If the response is correct, the clinician moves to Step 4.
- D. If there is no or an incorrect response, the clinician uses integral stimulation, with a maximum of four attempts, to elicit

the noun or verb production. If the response is correct, the clinician moves to Step 4. In the event of an incorrect or no response, the next item is presented.

Step 4. The clinician reinforces the production from Step 3 and models a phrase/sentence that combines the participant’s productions from Steps 1 and 3 (e.g., “Right, tie. Tie shoe.”)

Step 5. The clinician models the combined production again and requests a repetition.

- A. If the response is correct, the clinician requests three more productions, using integral stimulation as needed. The clinician moves to Step 6.
- B. If there is an incorrect or no response, the clinician attempts to elicit four productions of the target, using integral stimulation. The clinician moves to Step 6.

Step 6. The clinician removes the picture, waits for at least 5 seconds, returns the picture, and requests that the participant again describe the picture.

- A. If the entire† elaborated response is produced, the clinician reinforces the production and moves to the next item.
- B. If a partial elaborated response is produced, the clinician reinforces the production, models the entire elaboration, and requests a production with integral stimulation. The clinician then moves to the next item.
- C. If no response, the clinician reinforces the production, models the entire elaboration, and requests a production with integral stimulation. The clinician then moves to the next item.
- D. If an alternate correct response is produced, the clinician reinforces the production and moves to the next item.

*Any appropriate, intelligible noun, pronoun, verb, adjective, adverb, or preposition; not perseverative, stereotypic, or reiterative.

†Omission of functors is not considered incorrect.

(From Wambaugh, J. L., & Martinez, A. L. (2000).)

Aphasia (*continued*)

- brain anatomy and, 21–24, 26
 - Broca's, 8, 20–21, 25*f*, 27*f*, 259, 309–310, 410, 419, 537, 567, 569, 570–571, 704–706, 735, 817, 827, 855
 - canonical sentence computation and, 738
 - neuroanatomy of, 26–27, 27*f*
 - sentence deficits and, 632–634
 - characteristics of, 125
 - childhood, 3–4
 - classification of, 81, 405–406, 547–548, 817
 - conceptual frameworks for
 - body structure and function, activity, and participation, 9–10
 - concrete-abstract, 6
 - information processing, 9
 - microgenetic view of, 7
 - multidimensional, 7–9
 - problem solving, 9
 - propositional language, 4, 6
 - psycholinguistic, 9
 - thought process, 6
 - unidimensional, 6–7
 - conduction, 8, 28–30, 29*f*, 570, 690–691, 697–698, 706
 - context and therapy for, 716
 - crossed, 33, 35*f*
 - culture and, 326–327
 - declarative memory and, 709–710
 - defining, 3–4, 20, 65, 403–404
 - determining presence of, 84–90
 - disability and, 349–350
 - drawing and, 108
 - environment and, 830–831
 - epidemiology of, 10–13
 - etiologies of, 10–13, 547*t*, 569–570
 - fluent, 7–8, 187–188
 - future trends in, 15
 - gender and, 206
 - gerontology and, 206–207
 - gesture and, 101–102
 - global, 8, 30–31, 30*f*, 31*f*, 32*f*, 187, 259, 840
 - affect and, 569
 - age and, 572
 - assessment and, 577
 - behavioral treatment targets and, 577–578
 - cognition and, 568
 - communication and, 568–569
 - comprehension and, 567
 - demographics of, 566
 - depression and, 569
 - etiology of, 569–570
 - evolution of, 570–572, 572*t*
 - expression and, 567–568
 - formal tests and, 578–579, 578*t*
 - goal revisions and, 576–577
 - hemiplegia and, 572–573
 - incidence of, 566
 - informal tests and, 578*t*, 579–580
 - intervention and, 575–578
 - language and, 567–568
 - lesion site and, 566–567, 575
 - Melodic Intonation Therapy and, 840
 - neuroimaging of, 573–574
 - prognosis for, 565, 572–576
 - recovery from, 570–575
 - treatment of, 565, 576, 580–588, 581*t*
 - historical overview of, 20–21, 756–757
 - incidence of, 10–11
 - information processing and, 816
 - infrequency of, 891
 - interdisciplinary approaches to, 13
 - with intermittent auditory imperception, 406
 - interpersonal relationships and, 381
 - interpreting strategies and, 648
 - irreversible, 406
 - language intervention in, rationale for, 15
 - lexical-semantic impairment in, 696–698
